The galvanised iron spiral behaved, however, just like a copper or brass spiral, because the oscillations did not penetrate through the thin layer or skin of zinc into the iron. If, however, this zinc was oxidised or broken, then the iron core exerted its effect in damping the oscillations.

Dr. Fleming then explained that when a radio-telegraphic wave passes over the earth it penetrates to some extent into it, and also loses amplitude owing to the absorption of wave energy by the soil. The depth of penetration or depth in which the forces attenuate to $\bar{e}^1$ or to 0·368 of their surface value, and the horizontal attenuation or distance in which the surface values decrease to the same fraction of their original value can be calculated as shown by Dr. Zenneck when the values of the soil conductivity, soil dielectric constant, and frequency are known. Thus taking the generally accepted values for sea water for waves 1000 ft. in wave-length, the penetration into the sea is at most about one metre. In the ordinary dry soil it may be 100 or several hundred metres. There is a certain soil conductivity and wave-length which gives the maximum attenuation of the wave over a given distance.

The calculation of the depth of penetration and attenuation of the wave with distance can be made when this soil conductivity and dielectric constant is known. Recent researches have shown, however, that the conductivity of imperfect insulators for alternating currents is much greater than for direct currents. Dr. Fleming referred to researches by himself and Mr. Dyke for proof of this fact. Lately, he said, Mr. Bairsto had continued this work in his laboratory for currents of extra high frequency of one or more million, and found their dielectrics had a maximum conductivity for a certain high frequency. The inference from this was that the earth was an incomparably better conductor for the high frequency currents used in radio-telegraphy than for ordinary low frequency or steady currents. Dr. Fleming then went on to consider the propagation of an electric wave over the earth's surface, and pointed out that Sommerfeld had shown that when a Hertzian oscillator had one half connected to the earth there would not only be space waves through the dielectrics (air and earth), but a surface wave along the surface which would consist in longitudinal electric currents propagated as a wave motion along the surface. Dr. Fleming pointed out that this surface wave might be the explanation of the well-known facts that signals from long distance wireless telegraph stations can be picked up and detected without any high receiving wire, merely by connecting one end of the receiver to the earth and the other to any insulated mass of metal in the interior, it may be, of a house.

Passing then to the consideration of the diffraction of long electric waves round the earth, Dr. Fleming gave a brief account of the state of the theories advanced by Poincaré, Nicholson, Macdonald, and Rybczynski. These agreed that the amplitude of an electric wave sent out horizontally from any point on the earth's surface diminished according to an exponential function of the distance and wave-length. The last-named analyst had shown that this function was of the form $\bar{e}^{0\cdot0018r/\sqrt[3]{\lambda}}$ where r is the distance of the sending and receiving stations, and λ is the wave length. Actual observations by Austin over distances up to 1000 miles had led to an empirical formula differing only in that $\sqrt{\lambda}$ appears instead of $\sqrt[3]{\lambda}$.

The bulk of the evidence so far collected as to long distance transmission showed, however, that true diffraction of space waves or even the surface waves could not contribute more than a moderate fraction, perhaps not 20 per cent., to the total observed result. The chief part of the effect for distances of 3000 to 4000 miles must be contributed by space waves which had reached the receiving station indirectly, that is, after reflection or refraction at the surfaces of layers of high-altitude ionised atmospheric gases in the manner explained by Heaviside and by Eccles.

The great variations in signal strength taking place from day to day in long-distance wireless intercourse proved that this must be the case.

In conclusion, Dr. Fleming exhibited a chart showing the variation in the strength of the signals received at University College, London, from the Eiffel Tower station in Paris at 11 a.m. each day during last July, prior to the outbreak of war. The sudden falling off on certain days was remarkable. Dr. Fleming said that the further examination of the cause of these variations was one of the chief objects of the British Association Radio-telegraphic Committee which was appointed at Dundee in consequence of a suggestion made by him, and that as soon as the present calamitous world-war came to an end it was hoped these researches might be resumed.

THE CANADIAN ARCTIC EXPEDITION.

THE Scottish Oceanographical Laboratory, which had much to do with the oceanographical equipment of the *Karluk,* and especially the outfit of the Scottish contingent, consisting of Mr. James Murray, Dr. Alastair Forbes Mackay, and Mr. W. L. McKinlay, is in receipt of a considerable amount of official and private information concerning the Canadian Arctic Expedition. The expedition was hurried in its preparation and late in its departure, and the plans were "still pretty fluid" on July 21, 1913. On August 5 the *Karluk* was beset in 145° W., and drifted west to Colville River by September 7, and remained there until September 20, when she was blown adrift by a gale. Stefánsson and a party were ashore hunting on September 19, and were thus stranded. The *Karluk* drove north and west past Cape Barrow until she reached 73° N., 162° E.; then she drove south-west and west until, on January 10 last, she was crushed and sank in 38 fathoms sixty miles north by east of Herald Island. She drifted eight hundred miles at a rate of seven miles an hour. A perilous escape was made to Wrangell Island, at the heavy cost of eight lives, to which were afterwards added three more deaths on Wrangell Island, *i.e.* eleven in all.

This death-roll includes all the scientific staff except Mr. W. L. McKinlay, of Glasgow, a former assistant to Dr. W. S. Bruce. The other scientific workers missing or dead are Mr. James Murray, of Glasgow, late biologist of the Scottish Loch Survey, naturalist to the first Shackleton expedition, and worker upon the *Scotia* invertebrates; Dr. A. Forbes Mackay, of Edinburgh, who had had wide experience in many spheres of active life, including the Royal Navy, the South African War, and was member of the party that first ascended Mount Erebus, as well as that which reached the south magnetic pole under the leadership of Prof. David; Mr. Beauchat, anthropologist; Mr. Bjorn Mamen, topographer; and Mr. G. Malloch, geologist. Besides these, Mate Anderson, Second Mate Barker, and four seamen have also perished. Captain Bartlett, of North Pole fame, with an Eskimo, made an escape with difficulty from Wrangell Island to the mainland of Siberia, and there, with the help of the Russian Governor, Baron

Kleist, got Captain Petersen, of the whaler *Herman*, to take him to St. Michael. A gasoline schooner, *King and Wing*, of Seattle, relieved the Wrangell Island party, which was afterwards transhipped to the *Bear*. Stefánsson and two men started north from Martin Point on March 22, 1914, and on April 16 were to have returned after fifteen days. Stefánsson and his men have not been heard of since. He believed currents might drive them towards Banks Land, but on this coast, though searched, no trace of them has been found. The drift of the *Karluk* makes it unlikely that he has reached Banks Land.

BRITISH SUPPLY OF SYNTHETIC COLOURS.

THE Board of Trade has had under consideration the question of the supply of dye stuffs and colours, the shortage of which at the present time, owing to the cessation of imports from Germany, is causing apprehension in the textile trades and in other important British industries.

After consultation with the Committee on Chemical Manufactures, appointed in August last under the chairmanship of the Lord Chancellor, it appeared to the Board advisable to take such steps as were possible to develop the immediately available sources of supply, and also to encourage the permanent manufacture of dye stuffs and colours in the United Kingdom on a large scale, so as to guard against any recurrence of the present difficulty. As regards interim steps, arrangements have been made to encourage the immediate expansion of the various existing sources of supply.

As to the permanent supply, after preliminary consultations with representatives of some of the principal bodies of consumers, a meeting was held at the offices of the Board of Trade on November 10, and was attended by the representatives of twenty-two important associations and firms engaged in the colour-using industries. There was laid before the meeting a scheme for the formation of a limited company with a large capital, of which the bulk would be subscribed by the consumers of dyestuffs and colours and others interested, the Government indicating their willingness, conditionally on this being done, to subscribe a certain proportion of the share capital and to guarantee the interest on a large debenture issue for a term of years. Precautions would be taken to preserve the British control of the enterprise and to prevent undue encroachment on other branches of the chemical trades.

The meeting was informed that preliminary arrangements had been made enabling his Majesty's Government to acquire important dye-producing works in this country for the purposes of the new company if established, and that the Government would be prepared to take all necessary steps to secure the acquisition of any other concerns in the United Kingdom, the transfer of which to the new company might be desirable.

The meeting unanimously adopted a resolution approving in principle of a national effort being made by the trade to increase the British supply of synthetic colours and welcoming the assistance of his Majesty's Government for that purpose. A small committee representing the trades concerned was appointed to confer with the Board of Trade with a view to the elaboration of a scheme on the lines discussed at the meeting. The first meeting of this committee was held later in the afternoon. A further announcement as to the proposed company will be made at an early date.

METALLURGY AT THE ROYAL MINT.

ONE of the most interesting features of the forty-fourth annual report of the Deputy-Master and Comptroller of the Mint just received is the comparison of the melting costs according as coke or coal-gas is used as the fuel. The former was used up to the year 1909, but has since been replaced by the latter. Although the gross out-turn was 1197·7 tons in 1909, as against 1957·9 tons in 1913, the records are comparable, since the proportion of bronze and nickel-bronze—which require higher temperatures for melting than gold and silver—was nearly the same, viz., 56·3 per cent. in the earlier and 55 per cent. in the later year. The comparison is remarkably in favour of coal-gas firing, since there is a gross saving of 22·44 shillings per ton of bars, or 27·3 per cent. of the total charge in 1909. Moreover there is a saving under each item of expense, viz., fuel, crucibles, and wages. It is stated that "side by side with this economy there has been a marked increase in efficiency both in regard to the output per furnace and per man, as well as many minor economies, such as the disposal of ashes, handling of fuel, and a great reduction in the weight of sweep to be dealt with."

Sir Thomas Rose's experiments on the effect of impurities on the temperature at which gold is softened by annealing have been confirmed and extended by Mr. Phelps. The presence of two parts of hydrogen per 100,000 raises this temperature from 130° C. to at least 300° C. Silver has a similar, though less, effect. It has now been found that the relative purity of two samples of "proof" gold "can be more readily determined by heating hard-rolled test-pieces at 130–150° for half an hour than by ordinary methods of assay." The degree of softening is either measured in some form of hardness tester or is judged by the extent of recrystallisation of the metal. Sir Thomas Rose's experiments on the mode of recrystallisation of gold in various stages of annealing are of great importance, and bear directly on cases of failure of metal tubes and rods which are subjected to partial annealing conditions spread over lengthened periods of time.

The three countries—Austria, France, and Turkey—use pure nickel as a coinage metal. In the first-named this metal has been coined and issued regularly since 1892. In France it was adopted for 25 centimes only in 1903, but a new law passed on August 4, 1913, provides for the withdrawal of this issue and of the present bronze currency, and their gradual replacement by 25, 10, and 5 centime pieces, all of pure metal. The new issue will be spread over a period of ten years, and will amount to 780 million pieces. The French Government has signed a contract with a French nickel company for twenty years to purchase the requisite metal at 141*l*. a ton, the present price in the London market being about 171*l*. a ton.

Thirty-four countries use a 75 per cent. copper and 25 per cent. nickel coinage alloy, while Germany and Switzerland coin both pure nickel and the above-mentioned alloy.

H. C. H. C.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

THE physiological section of the British Association began its programme for the Australian meeting in Melbourne. Considerable alterations had to be made at the last moment owing to the unavoidable absence of members who were expected to contribute to a general discussion upon climate from a physiological point of view. This is a subject to

which considerable attention has been paid in Australia, and very complete meteorological statistics from all parts of the country are available. Wet- and dry-bulb records of temperature, rainfall, and other particulars were furnished by the authorities, and the climatic conditions of Northern Australia in particular have already been analysed locally with a view to determine the possibility of the settling of these regions by a white population. Australians are determined to people their country with none but a white population, and one of the problems of the country is how to bring this about successfully under the diverse conditions which prevail in the large tropical areas of the north.

The time at the disposal of the section was reduced by alterations in the train arrangements between Melbourne and Sydney, and Sydney and Brisbane, and by the numerous interesting excursions and hospitalities so lavishly provided by the local committees. The conditions created by the war, too, naturally deprived the meetings of the interest which they would otherwise have occasioned. In spite of this the meetings were very successful, especially in Melbourne, and it was only towards the close in Sydney that interest in the business of the section slackened.

A very full programme was presented and carried out in Melbourne. Prof. B. Moore opened the proceedings of the section by an address upon the value of research in the development of national health, and put in a strong plea for the wider application of modern scientific discoveries to the promotion of the health of the race. Sir Edward Schäfer exhibited a number of lantern slides of sections of the mammary gland, and pointed out the presence around the alveoli of non-striped muscle fibres. It is to the contraction of these fibres that he ascribes the lactagogue effect of injections of pituitrin. Prof. Halliburton, in collaboration with Dr. W. E. Dixon, gave an account of their recent investigations into the physiology of the cerebro-spinal fluid. Numerous lantern slides were shown illustrative of the response to intravenous injections of various extracts by the production and pressure of the cerebro-spinal fluid. They find extracts of dried choroid plexus to be especially active in increasing its production. Certain anæsthetics, and excess of CO_2 in the blood particularly, are also powerful stimulating agents. Evidence was adduced to prove that cerebro-spinal fluid is a true secretion, and that it is largely formed by the cells of the choroid plexus. The hormone may be a product of nervous metabolism, and the cerebro-spinal fluid may be an important agent in the rapid elimination of CO_2. A number of interesting observations upon the changes of cerebro-spinal pressure relative to the arterial and venous pressures were illustrated, a full account of which is given by the authors in recent numbers of the *Journal of Physiology*.

Prof. W. A. Osborne described experiments performed by himself, and in conjunction with Mr. Basil Kilvington, in Melbourne, upon pseudo-motor action, recurrent sensibility, and central neural response. Mr. Basil Kilvington also reported an experimental method of bringing about a successful collateralisation after occlusion of the abdominal aorta, a procedure which might be useful in surgery. Dr. E. H. Embley contributed a paper upon evidence of co-ordinate action in the circulatory system.

The second day's meeting in Melbourne was begun by a general discussion upon anæsthetics. Prof. A. D. Waller demonstrated a portable apparatus for the administration of chloroform, and dwelt upon the chief dangers to be feared in anæsthesia, and upon the question as to what are the real causes of danger. Dr. E. H. Embley, whose work in Melbourne upon anæsthetics is so well known, discussed the causes and treatment of syncope, excessive intoxication, shock, and various accidental conditions. Prevention of syncope and shock he believes to be best attained by the pre-anæsthetic injection of morphine and atropine, and by the use of ether, or ether and oxygen, instead of chloroform. Dread of operation by the patient is also largely mitigated by the preliminary use of morphine. Prof. Osborne and Prof. Milroy continued the discussion, the latter describing the effect of anæsthetics upon the electro-cardiogram. Prof. R. F. C. Leith showed lantern slides of the pathological changes in a case of delayed chloroform poisoning, and Prof. Waller summed up the discussion.

Dr. J. W. Barrett then contributed an important paper upon the vision of persons engaged in navigation and railway services. He strongly advocated the thorough testing at the earliest possible time of the eyesight of all who contemplate entering either service, so that if the candidates are unsuitable rejection will take place before they have spent time and money in their training. Legislation is required for the purpose. Dr. Barrett instanced a series of accidents which were clearly due to defective vision, and which would have been avoided if a thorough examination of the sight of the men in charge had been carried out. The committee of the section passed a resolution recommending the Council of the Association to print Dr. Barrett's paper *in extenso*.

Miss Kincaid read a paper upon the biochemical significance of phosphorus, and claimed to have shown by analysis that there is a general deficiency of phosphorus in the soil and flora of Australia. Further work upon this question is to be done and reported to the Association.

Dr. S. Sewell contributed a paper upon the mechanism of micturition control in human beings.

The reports of several research committees were presented. Very little discussion of the individual contributions was possible owing to the shortness of time at disposal.

The work of the section was continued at Sydney. Sir Thomas Anderson Stewart demonstrated a number of interesting models illustrating physiological processes, *e.g.*, the functions of the corpora Arantii, the nature of sound waves in air, the action of the stapedius muscle, and the effect of simultaneous contraction of the intercostal muscles. A cyclograph, or apparatus for quickly marking microscopical slides for the identification of any part under the microscope, was also shown.

Prof. W. A. Osborne was to have opened a discussion upon climate, but as there were no other speakers on the subject he confined his observations to a consideration of the methods of taking temperature by wet-bulb thermometers. The ordinary wet-bulb thermometer is not so sensitive to changes in wind velocity as the human body, and Prof. Osborne described a method of jacketing wet-bulb thermometers so as to render them much more sensitive to changes in air currents. He also emphasised the importance of wet-bulb temperature records from a physiological point of view.

Prof. B. Moore gave the section the results of his repetition of some of the experiments of Dr. Bastian on inorganic colloids. He showed numerous slides illustrating the appearance of branching networks and hyphæ. There were no micrococci or other signs of life. Prof. Moore believes that the appearances are merely precipitation forms, the solutions are iso-electric, and give no signs of life. Considerable discussion followed, especially upon the question of infection of the solutions, and upon the methods of

determining the presence of any vital activity in them. Other communications by Prof. Moore dealt with the action of ultra-violet light upon solutions of organic substances, and with the presence of iron salts in the colourless portion of the chloroplast, and the mechanism of photo-synthesis by iron salts. Mr. Halcro Wardlaw, a science research scholar of Sydney University, described the results of a series of analyses of the deposit obtained from milk by spinning it in a centrifuge, and Dr. Burton Bradley contributed some notes on the symbiotic activities of coliform and other organisms on media containing carbohydrates.

The last day's proceedings of the section in Sydney embraced a lengthy programme, but most of the papers were taken as read, and the section thereafter joined those of chemistry and agriculture in a discussion upon metabolism. Among the subjects brought before the section, and of which abstracts were printed, were papers by Prof. T. H. Milroy on changes in the reaction of milk under different conditions as determined by the estimation of hydrogen-ion concentration by the electrometric method, and measurements of the variations of the hydrogen-ion concentration of the blood. Prof. P. T. Herring contributed papers upon the relative activity of the pars intermedia and pars nervosa of the ox pituitary, and upon the influence of the thyroid upon the activity of the suprarenals and pituitary body. In the latter communication the chief point of interest was the loss of chromaffine-substance, and corresponding diminution of activity, of the medulla of the suprarenals which rapidly follow thyroidectomy; thyroid-feeding, on the other hand, though pushed to an extreme, has no such effect. Dr. H. G. Chapman presented a paper on the freezing point of the laked red blood corpuscles of man and some domesticated animals, and Dr. C. Shellshear a paper on precipitin reactions in pathological human urines.

Several papers on psychological subjects appeared on the programme, but it was found impossible to take them. A feature of the sectional business in both Melbourne and Sydney was the large and varied contributions by local members, evincing evidence of the activity of the physiological departments in these universities.

AGRICULTURE AT THE BRITISH ASSOCIATION.

THE paramount importance of agriculture in Australia rendered the proceedings of Section M of special local interest, and the addresses and papers were arranged to deal with subjects of real significance in that country. The two addresses delivered by the president, Mr. A. D. Hall, attracted large audiences both at Adelaide and Brisbane. They were read at sessions of the whole association, and formed as valuable a contribution to Australia's needs as agricultural science and research could well have provided.

The meetings of the section at Melbourne were devoted to the subjects of irrigation, dry farming, animal breeding, and milk supply, all of which were selected in view of their importance to the Australian agriculturist. The papers on irrigation were read at a joint meeting with Section G (Engineering), and an account of the discussion has been given in the report of the proceedings of that section (November 5, p. 266).

An excellent paper by Dr. Lyman J. Briggs on dry farming investigations in the United States gave a *résumé* of the systematic work which has been carried on for many years in America on this subject. Dr. Briggs illustrated his paper with maps and diagrams, and pointed out the differences which exist between the problems in America and those in Australia. Differences in the distribution and amount of the rainfall and in the nature of the soil indicate the necessity for much investigation into the special problems of each district. A more restricted problem of special Australian interest, "The Ten-inch Line of Rainfall," was discussed by Dr. T. Cherry, who pointed out that the rainfall throughout the southern third of the continent is almost exclusively of the winter type, and that the winter temperatures are high enough to keep the ordinary cereals growing during these months. The chief problem which in this instance has now to be solved is to devise methods by which sheep and cattle can also be profitably kept on the wheat farms in the 10-in. line of rainfall, the area already having been proved very suitable for wheat.

The very high evaporation factor, which in Western Australia is four to six times greater than the rainfall, adds to the difficulty of maintaining the soil moisture. Prof. J. W. Paterson contrasted this evaporation with that in England, which is only about one-half of the annual rainfall. He also stated that the sandy soils in these dry districts are an advantage, as they are able to absorb all the rain which falls and can yield up the retained moisture more completely to the plant than more absorbent clay soils. The movement of air and water within the soil is dependent on the sizes and distribution of the free spaces between the particles, a subject dealt with by Dr. Heber Green, who spoke of the capillary power of soils and of the experiments and calculations which he had made on this subject.

Perhaps no branch of scientific research is likely to be of more direct practical value than the investigations into the laws of inheritance. In the field of animal breeding Mr. P. G. Bailey represented the Cambridge school, and reported the progress of experiments conducted on the inheritance of wool characters in a cross made between two Merino rams from Western Australia and twenty Shropshire ewes at Cambridge. He also contributed a paper on size inheritance in poultry, a subject which bids fair to yield results of practical importance to an industry which is assuming large proportions in Australia.

The improvement of the quantity and quality of milk yield has received a great impetus in late years by the keeping of milk records and the gradual elimination of the less productive cows from herds. The development of this work in England, Scotland, and Ireland was reviewed by Dr. A. Lauder. Dr. S. S. Cameron and Mr. O'Callaghan spoke of developments in this direction in Australia.

The high cost and scarcity of labour in Australia has forced the development of milking machines. Mr. Archer estimated that in Victoria alone 2000 farmers had been supplied with milking machines, and that about fourteen different makes were in use. The principal local feature is the conduit system, in which the milk is conveyed through metal pipes to a tank in the dairy, thus saving the labour of carrying the milk.

The scientific comparison of the bacteriological purity and keeping qualities of milk obtained from eleven different types of machine at trials arranged by the Royal Agricultural Society of England formed the subject of a paper by Dr. R. Stenhouse Williams, Mr. J. Golding, and Mr. J. Mackintosh. The difficulties in cleaning many of the machines, especially those fitted with long rubber tubes, is one of the chief drawbacks to their employment under existing conditions on many farms.

A visit to the State experimental farms in Australia is sufficient to show the very great importance attached to the subject of cereal breeding. Not only is a large

area of these many farms devoted to experiments on this subject; but the keen interest taken by the staffs in scientific investigation in other parts of the world and the enthusiasm in the work of William Farrer and other Australian investigators cannot fail to impress the visitor. A whole meeting at Sydney was not sufficient to exhaust the papers and discussion on cereal breeding. The papers read were as follows:—"The Migration of Reserve Material to the Seeds in Barley, considered as a Factor in Production," by Mr. E. S. Beaven; "Wheat Improvement in Australia," by Mr. F. B. Guthrie; "William Farrer's Work, Methods, and Success: a Short Sketch," by Mr. J. T. Pridham; "Wheat Breeding in Australia," by Mr. A. E. V. Richardson. Prof. Bateson, Mr. A. D. Hall, Prof. T. B. Wood and others took part in the discussion. The value of the Mendelian theory in providing a speedy and certain method for the practical man, and in directing his problems on scientific lines was illustrated by Mr. Beaven's work on barley. He showed that the ratio of the dry matter accumulated in the seed, to the total dry matter of the plant when fully ripe, frequently influences the produce of grain to a greater extent than any other factor. This "coefficient of migration" differs with different races of barley within the gross productive power which is a product of the environment.

A joint discussion with Section B (Chemistry) on metabolism, which took place at Sydney, will be reported in an article on the work of that section. Other papers contributed included "Flax as Paying Crop," by Mr. C. P. Ogilvie; "Bacterial Toxins in Soil," by Dr. Greig Smith; "The Estimation of Condition in Cattle," by Mr. J. A. Murray; "A Review of Work on Soil Inoculation," by Dr. H. B. Hutchinson, and Mr. J. Golding; and "The Effects of Caustic Lime and Chalk on Soil Fertility," by Dr. H. B. Hutchinson and Mr. K. MacLennan.

Highly satisfactory as they were, the proceedings of the section in session cannot be taken as a measure of the work achieved in 1914, for the unique advantages which members of the section gained by a visit to so rich and varied a field of agricultural endeavour cannot fail to bear fruit rich in its benefit to the science of agriculture.

It is only possible briefly to refer to the numerous and valuable agricultural excursions which were specially arranged, not only to meet the wishes of the whole section, but also to enable individual members to make independent visits to farms and districts where the branches of agriculture in which they had specialised were seen to the best advantage.

In Western Australia the latter type of excursion prevailed, and, under the personal guidance of Mr. W. Catton Grasby, Mr. J. L. Sutton, Prof. Paterson, Dr. Stoward, and Mr. A. E. Weston, visits were made to see the great developments which have recently taken place in corn growing, fruit growing, and other departments of agriculture in the great south-west area of this promising State.

From Adelaide excursions were made to Angaston, Seppeltsfield, and Tanunda. Mr. Charles Angas entertained a large party to lunch at Angaston. Vineyards and the agricultural land in the neighbourhood were afterwards visited. Roseworthy Agricultural College was the objective of a most interesting excursion from Adelaide. The instruction given to students is of a very practical nature, the buildings and laboratories are good, and the farm very well laid out in experiments on crops and stock. The introduction of Berseem (*Trifolium alexandrium*) on an irrigated plot of four acres had proved very successful, twenty-five cows having been kept on the produce of the plot for five months during the winter, the yield of green food being 36 tons per acre.

In Victoria the principal agricultural excursion was to the Central Research Farm at Werribee. Although only started in 1912, this farm of more than 1000 acres is admirably laid out in experiments on dry farming, irrigation, and live stock. The organisation was quite a model for similar institutions; a large party was conducted over it in a most thorough manner, all the experiments being ably explained by the staff and authorities from Melbourne.

From Sydney a three days' excursion was arranged which included visits to the Wagga Experiment Farm, Mr. Anthony Brunskill's 12,000 acre farm, and two days in the interesting Murrumbidgee irrigation area, including the Yanco Government Irrigation Farm and Works. Motor-cars were provided, and nights were spent in a special sleeping car.

Mr. Wade, who himself conducted the party over the irrigation area, gave a lecture and showed lantern slides and plans of this great scheme, which will provide nearly 7000 farms and support a population of 100,000 people on land which until the scheme was taken up by the Government was used as sheep runs. The famous Hawkesbury Agricultural College was also visited from Sydney, where accommodation for 200 resident students is provided; the farm comprises some 3440 acres of land. All branches of farming, especially the orchard, dairy, piggery, and poultry farm, were well worth a visit.

The cultivation of sugar cane and a sugar mill in full work was inspected at Nambour, Queensland, by a large party, and opportunities were afforded for smaller parties to see the work on the eradication of the prickly-pear, and to visit large sheep farms, etc.

The most striking feature in the visits to experimental farms in most parts of Australia was the response shown by the crops to phosphatic manures, even when, as is the practice, very small dressings were applied with the combined manure and seed drill. In one case in Western Australia 30 lb. of superphosphate added per acre had doubled the yield of wheat (9 bushels raised to 18). Sixty to 80 lb. of superphosphate per acre were commonly used in this excellent drill.

The section met with the greatest kindness and hospitality on all sides, and it is invidious to particularise amongst such a number of generous and indefatigable hosts, but special thanks are due to Mr. W. Hutchinson, Minister of Agriculture for Victoria, Dr. Cameron, Dr. Cherry, and Mr. Richardson, of Melbourne, and to Prof. R. D. Watt, of Sydney, for the part they took in carrying out the many and valuable excursions.

BUDGETS AND STUDENTS OF UNIVERSITIES AND UNIVERSITY COLLEGES IN RECEIPT OF STATE GRANTS.

THE reports for the year 1912–13 from those universities and university colleges in Great Britain which are in receipt of grant from the Board of Education have been published in two Blue-books (Cd. 7614 and Cd. 7615). The tabular matter, which precedes the separate reports from the places of higher education dealt with, contains detailed information as to the income and expenditure of the various institutions concerned. The following summaries have been compiled from the tables, and make clear the amount available for higher education and research in the universities and university colleges receiving Treasury grants, and how the income is expended.

UNIVERSITIES AND UNIVERSITY COLLEGES.

(1) ENGLAND.

(a) Income.

	Amount £	Percentage of total
Fees	183,880	27·8
Endowments	95,045	14·4
Donations and subscriptions	22,381	3·4
Annual grants from local authorities	103,650	15·7
Parliamentary grants ...	232,821	35·2
Contributions from hospitals, etc., for services rendered	2,338	0·4
Other income	20,486	3·1
	660,601	

(b) Expenditure.

Administration	68,329	10·3
Maintenance of premises	68,670	10·4
Educational expenses ...	425,515	64·3
Superannuation	22,840	3·4
Other expenditure in respect of maintenance ...	30,219	4·6
Expenditure not in respect of maintenance ...	46,288	7·0
	661,861	

(2) WALES.

(a) Income.

	Amount £	Percentage of total
Fees	17,456	27·7
Endowments	4,448	7·1
Donations and subscriptions	2,330	3·7
Annual grants from local authorities	3,441	5·5
Parliamentary grants ...	34,217	54·3
Other income	1,132	1·7
	63,024	

(b) Expenditure.

Administration	8,020	11·8
Maintenance of premises	4,597	6·8
Educational expenses ...	48,232	71·0
Superannuation	1,733	2·5
Other expenditure in respect of maintenance ...	497	0·7
Expenditure not in respect of maintenance ...	4,891	7·2
Total	£67,970	

On comparing the statistics with those of the previous year, it is noticed that in England the total income of the institutions has risen by 38,000*l.*, which is made up as follows: the fee income has risen by 3000*l.*, the income from endowment by more than 9000*l.*, that from local authority grants by nearly 8000*l.*, while Parliamentary grants supplied nearly 18,000*l.* additional assistance, though part of the income from this last-mentioned source, is derived from grants which are referable to previous years.

Certain individual figures are interesting. Manchester University has an income from endowment of rather more than 22,500*l.*, and Liverpool University one of nearly 15,000*l.* Reading University College has an endowment income of practically 9000*l.*, which represents more than 31 per cent. of its total revenue. The largest proportions of income derived from grants from local authorities are found at the University Colleges of Southampton and Nottingham, in both of which cases nearly 40 per cent. of the income is provided from this source. Similarly, 29 per cent. of the income of Sheffield University is obtained from grants from local authorities.

The total expenditure in England has risen by nearly 60,000*l.* Nearly 4000*l.* of this increase is accounted for by administration, nearly 5000*l.* by cost of maintenance of premises, rates, etc., and more than 30,000*l.* by expenditure on teaching salaries and equipment. More than 9000*l.* additional expenditure was incurred on superannuation provision, for which increased grants have recently been made. Seven per cent. of the total expenditure at all institutions was made in respect of charges of a non-maintenance character. The highest percentages for these charges are at Sheffield, 18·5 per cent.; Birmingham, 14 per cent.; King's College for Women, 12·3 per cent.; and Bedford College, 10·2 per cent.

A new table indicates the amount of grant aid given to university institutions under the provisions of the "Statements of grants available from the Board of Education in aid of technological and professional work in universities in England and Wales" in the financial years 1912–13 and 1913–14. The total amount of grant aid under these provisions rose from 41,647*l.* in the financial year 1912–13 to 44,623*l.* in 1913–14. The total amount of Exchequer grants in England in aid for universities and university colleges in the year 1912–13 was 170,000*l.*, and, in addition, 31,000*l.* was paid to university colleges in Wales.

In addition to the financial statistics, the reports contain much useful information concerning the number of students in the various colleges, their ages, the subjects they are studying, and so on; and the following tabular statements will serve to summarise them. It is necessary to point out that the numbers concern only the following institutions:—The Universities of Birmingham, Bristol, Durham (Armstrong College), Leeds, Liverpool, Manchester, Sheffield, London (including University College, King's College, Bedford College, School of Economics, and East London College), and also the University Colleges of Nottingham, Reading, and Southampton. The University of Wales includes the University Colleges of Aberystwyth, Bangor, and Cardiff.

NUMBER OF FULL-TIME STUDENTS.

	England	Wales
Degree Students:—		
Training college	1397	420
Others	3402	648
Total	4799	1068
Non-graduate (diploma) students:—		
Training college	644	8
Others	1113	98
Total	1757	106
Post-graduate students:—		
Training college	29	—
Others	479	76
Total	508	76
Other courses	602	39
Total	7666	1289

NUMBER OF PART-TIME STUDENTS.

Day.

	England	Wales
Degree	229	4
Non-graduate (diploma) ...	182	29
Other courses	3406	297
Post-graduate	1023	19
Carried forward ...	4840	349

Brought forward (*Day*)	4840	349
Evening.		
Degree	363	—
Non-graduate	764	—
Other courses	7576	—
Post-graduate	255	—
Total	13,798	349

In England the total number of full-time students at these institutions of higher education in 1912–13 was 7666, as compared with 7827, in the previous year. The total number of part-time students has, on the other hand, increased from 13,348 to 13,798. The fall in the total number of full-time students is due to a decrease of fifty-six in the number of training college students and of 105 other students, making 161 in all. The number of full-time post-graduate students has risen by fifty-four, and the number of full-time diploma students by 103. On the other hand, there has been a fall of 159 in the number of students reading for degrees, and another of 159 in the number of students of undergraduate standing who were not reading for a degree.

It would appear, the report points out, that the rate of increase in the number of full-time students has been diminishing for some years past. The position is not satisfactory from the wider national point of view. There is little doubt that the commercial prosperity of the country during recent years has had a good deal to do with this diminution in the number of students who are seeking a university education. Furthermore, the bulk of the parents of the boys and girls in the State-aided secondary schools of the country have little sense of the value of a university education. Only a minority of these schools send students to the universities unless they happen to be placed in or very near to the university towns. It is not suggested that it would benefit all boys to go to a university without regard to their means or their ability and without a careful selection of their course of study, but there are grounds for thinking that the demand for healthy and able young men with a university training is beginning to outrun the supply. The openings for administrators of various kinds and for teachers in the Indian Empire and in the Crown Colonies are increasing in number, while suitable candidates are not. Nor is the demand confined to service abroad.

The Royal Commissioners on the Civil Service are evidently of opinion that the newer universities are not contributing a due proportion of candidates for the Home Services. "We should be glad," they say, "to see the Scottish, the Irish, and the young English and Welsh universities assert more vigorously their claim to share in Civil Service appointments." That they have not done so in the past is in part due, no doubt, to the character of the examination, but it is largely explained by the younger age at which their students graduate—in itself evidence of a hurried education—and partly by the diversion of some of the brightest minds in the schools to the practical world of business before the secondary stage of their education is complete. It is doubtful whether even the commerce of the country will benefit in the long run by this impatience; it is certain that the national and Imperial Services lose the variety of training and upbringing which is to be desired in their recruits.

By comparing the figures in England for 1911–12 with those for 1912–13 the following statistics are obtained:—

STUDENTS IN VARIOUS FACULTIES.

	1911–12	1912–13
Arts	3529	3405
Science ...	1726	1704
Medicine ...	2597	2697
Engineering ...	1105	1059
Technology ...	347	361
Agriculture ...	186	206

This table shows the number of full-time students in all institutions coming within the scope of the report, arranged according to the faculties in which they are studying.

It will be noticed that the fall in students which has been previously mentioned is confined to the faculties of arts, science, and engineering. The greatest actual fall is in the arts faculty, but the relative fall is equally great in the faculty of engineering. In the faculties of medicine, agriculture, and technology there has been an increase.

AGE OF ADMISSION OF FULL-TIME STUDENTS. (1912–13.)

	England	Wales
Number admitted	3241	371
Percentage under 17	4·9	1·6
Percentage 17–18	12·7	8·9
Percentage 18–19	24·5	32·3
Percentage above 19	57·9	57·2

It should be pointed out that the number of students under England in this table includes 257 students at the nine medical schools of the University of London, and forty-two students at the College of Medicine, which is a constituent college of the University of Durham.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GLASGOW.—The University has offered academic hospitality to accredited teachers and students of Belgian universities who have taken refuge in Glasgow. The heads of the several departments will afford them such facilities for study and research as it may be found practicable to provide.

The bequest of some 12,000*l.*, left for the department of naval architecture under the will of the late Dr. Francis Elgar, has now accrued to the University. An equal amount is bequeathed to the Institution of Naval Architects.

Mr. S. Mavor, of Glasgow, has presented to the geological department a collection of more than 500 specimens, illustrative of the coal-beds of Great Britain and the continent of Europe.

Mr. A. Fleck, formerly demonstrator to Prof. Soddy, has been appointed physical chemist to the Glasgow Radium Committee, established to administer a large fund collected in the city for the purpose of acquiring and distributing radium for therapeutic purposes. A radiometric laboratory, under the auspices of the committee, has been fitted up at the University.

IT is known that there are many Belgian medical graduates refugees in this country who may find it difficult to obtain suitable accommodation. To meet this need the committee of the London School of Tropical Medicine will be pleased to hear from Belgian medical men who may desire to avail themselves of the hospitality of the school to the extent of board and residence in the hostel attached thereto. The Committee also invites any graduate so resident to attend the various classes while the school is in session.

THE first meeting of the re-constituted Agricultural (previously Rural) Education Conference was held on Tuesday, November 10, Lord Barnard being in the chair. The conference appointed a committee, composed partly of its own members and partly of women co-opted for the special purpose, to consider the following reference received from the Board of Agriculture and Fisheries: "To consider the provision made in England and Wales for the agricultural education of female students of sixteen years of age and upwards, and to report whether the existing facilities are sufficient, and if not, to what extent and in what direction these should be developed and improved."

Teachers of domestic subjects in schools and colleges who desire to give their instruction a scientific character continually find that some of the commonest observations and methods of domestic work are very difficult to explain. To assist such teachers to arrive at satisfactory explanations of the various steps in common domestic practice, the Association of Teachers of Domestic Subjects has appointed a science committee to which problems that arise may be referred for elucidation or investigation. Prof. Smithells is chairman of the committee, which includes several well-known chemists as well as practical teachers of domestic subjects. The report of this committee for 1914, which has been received, contains abundant evidence of the utility of the work of the committee, and every teacher of domestic subjects should study the answers to the questions discussed in it.

Though the University of Bristol is one of the youngest of English universities its calendar for 1914–15, a copy of which has been received, shows that it is making rapid strides in the direction of providing a very complete system of higher education for the western counties of England. There are in the University faculties of arts, science, medicine, and engineering. We observe, among other interesting arrangements, that an alternative curriculum is provided so that undergraduates pursuing the study of agriculture and forestry may take an ordinary bachelor of science degree. Regulations are included by which students may secure the degree of bachelor of science in engineering by research. Those students who are not qualified by matriculation to proceed to a degree, may in certain circumstances procure a certificate in engineering. The University also, we notice, confers testamurs in social science and journalism. Among institutions associated with the University may be mentioned the Royal Agricultural College at Cirencester, the National Fruit and Cider Institute at Long Ashton, and the Agricultural and Horticultural Station at Long Ashton.

There is a tendency among popular philosophers and supernaturalists just now to suggest that modern science is crude materialism against which a spiritual reaction is to be encouraged. Some justification might have been found for such a view a generation or two ago, but the dogmatism of those days, both of men of science and theologians, has given way to a more liberal spirit, and all who are seeking earnestly for truth are considered to be worshippers at the same shrine. We are glad, therefore, to direct attention to a series of addresses upon the mutual relations between science and religion to be delivered by scientific men of distinction at Browning Hall, Walworth Road, S.E., during the week beginning on Sunday next, November 22. The addresses are intended for working men and women, students and teachers, and they will be delivered by Sir Oliver Lodge, Prof. J. A. Fleming, Prof. W. B. Bottomley, Prof. E. Hull, Dr. J. A. Harker, Prof. Sims Woodhead, and Prof. Silvanus Thompson; all seats will be free. There is, of course, no conflict between religion and science; one is the expression of an instinct, the other is a spirit of inquiry into the character and meaning of all things, visible and invisible, in the universe. It is particularly important at the present time to show that science is an uplifting study, and not merely the handmaid of material advance. Ruskin described the difference between science and invention long ago, but it is forgotten by most writers, and we trust that the addresses to be given at Browning Hall will do something to remove mistaken popular impressions as to the aim and meaning of scientific work.

SOCIETIES AND ACADEMIES.

London.

Geological Society, November 4.—Dr. A. Smith Woodward, president, in the chair.—L. **Richardson**: The inferior oolite and contiguous deposits of the Doulting-Milborne-Port District (Somerset). This paper embraces the country around Bruton, Castle Cary, and Blackford. In the northern half of the Doulting-Milborne-Port district the bulk of the yellow Upper-Lias Sands is of *dispansi* hemera; but in the neighbourhood of Cole and Castle Cary the topmost portion is of *dumortieriae* hemera. In the south-eastern portion, under Stowell, while the main mass is probably of *moorei-dumortieriae* hemeræ, the upper 50 ft. is of *aalensis-moorei* date. Rock of *garantianae* hemera spreads over the whole district. From Doulting to Bruton the Garantiana beds rest directly on the Sands. In the neighbourhood of Cole there is a synclinal area, and beds of *blagdeni, sauzei, witchelliae, shirbuirniae, discitae,* and *murchisonae* hemeræ are seen between the Garantiana beds and the Sands. At Corton Downs are rocks of *sauzei, witchelliae, shirbuirniae, discitae, bradfordensis,* and *murchisonae* hemeræ. In this southern portion of the district it is difficult to determine the upper and lower limits of the deposits of *discitae, shirbuirniae,* and *witchelliae* hemeræ. The rock of *garantianae* hemera varies much from place to place in thickness and lithic structure. Above the Garantiana beds come the Doulting Stone, Anabacia Limestones, and Rubbly beds. The Anabacia Limestones soon lose their lithic characters; but the Doulting Stone spreads over the Oolitic tract, and is exposed in numerous quarries. In the southern portion of the district, the lower portion of the equivalent of the Hadspen Stone passes into the Sherborne Building-Stone, and the top portion, *plus* higher beds, into the Rubbly Limestone beds, such as those displayed in quarries in the eastern portion of the Sherborne district.—E. T. **Paris** and L. **Richardson**: Some Inferior-Oolite pectens. Descriptions and illustrations are given of one new species of Camptonectes, of two new varieties of *Chlamys articulata* (auctt.), and of two new species of Velopecten.

Linnean Society, November 5.—Prof. E. B. Poulton, president, in the chair.—A. D. **Cotton**: The algæ, lichens, and fungi of the West Falkland Islands, from Mrs. Rupert Vallentin's collections. A large collection was made by Mrs. Vallentin from 1909 to 1911, and was presented by her to the Royal Botanic Gardens, Kew; the present paper dealt with those Cryptogams mentioned in the title, the Mosses and Hepaticæ being reserved for later work. These collections are valuable and have yielded interesting results, including several novelties, and many additions to the flora, and by means of ample, well-dried material, enabled previous descriptions to be enlarged and revised. The author gave an historical account of the cellular Cryptogams from the earliest record (1771) to the present time, and included in his list all previous records, revised so far as practicable.

Mathematical Society, November 12.—Annual general meeting.—Prof. A. E. H. Love (retiring president) and afterwards Sir Joseph Larmor (newly-elected president) in the chair.—Prof. **Love**: Presidential address, "Mathematical Research." Prof. G. A. **Miller**: Note on an extension of Sylow's theorem.—J. **Hodgkinson**: The conformal representation of the various triangles bounded by the arcs of three intersecting circles.—G. R. **Goldsbrough**: The dynamical theory of the tides in a zonal basin.—G. H. **Hardy**: The modulus of an analytic function.—Prof. W. **Burnside**: (i) The modification of a train of waves as it advances into

shallow water. (ii) A configuration of 21 points and 21 lines which arises from the complete quadrilateral and determines the group of 168 plane collineations.—Prof. Tadahiko **Kubota**: Convex closed surfaces.—Prof. W. H. **Young**: Integrals and derivates with regard to a function.

Mineralogical Society, November 10.—Anniversary meeting.—Dr. A. E. H. Tutton, president, in the chair.—Prof. W. J. **Lewis**: Albite; its crystal elements, etc. New values of the elements were obtained based upon measurements made on well-developed twinned crystals from Alp Rischuna. Chemical analysis showed them to be very pure albite.—H. **Collingridge**: The determination of the maximum extinction angle, optic axial angle, and birefringence of monoclinic pyroxenes in thin sections. The method depends on the presence of well-defined twins about 100, and the visibility of an optic axis through one individual. From observations in this individual of the positions of the trace of the optic axial plane and the twin plane, the extinction angle, and the position of the visible optic axis, and in the other the extinction angle and the birefringence, and, if possible, the positions of an optic axis and the trace of the optic axial plane, the requisite determinations may be made.—Prof. H. L. **Bowman**: Note on calcite from the Chalk at Corfe Castle, Dorset. Good crystals, which occur in veins in the Upper Chalk, are of the pointed habit, the forms being f $(11\bar{1})$ and x $(21\bar{2})$. Interpenetrant rhombohedra twinned about the c axis, as in cinnabar, are not uncommon.—A. **Scott**: Barkevikite from Lugar, Ayrshire, and litharge from Persia. The former occurs in lugarite in prismatic crystals up to 75 mm. in length, with mean refractivity 1·690, and very intense pleochromism, c very dark brown, b reddish-brown, a light yellow; in chemical composition it is fairly close to the type mineral from Barkevik. The latter was found at Larshuran, Persia, as a red mica-like crystalline mass; it is biaxial with mean refractivity 1·735, the double refraction being very weak, and contains more than 97 per cent. of lead oxide, the remainder being copper oxide with a little antimony oxide.—Dr. G. T. **Prior**: The meteorites of Uwet, Kota Kota, and Angela; the identity of Angela and La Primitiva. The meteoric iron of Uwet, Southern Nigeria, said by natives to have fallen about ninety years ago, is a hexahedrite of the Braunau type, containing about 6 per cent. of nickel. The meteoric stone of Kota Kota, Marimba district, British Central Africa, said by natives to have been seen to fall some years ago, is a chondrite, probably belonging to the crystalline spherulitic group. The meteoritic iron of Angela, near Iquique, Chili, was found in the nitrate beds. It is an ataxite, containing about 4·5 per cent. of nickel, and enclosing large nodules of schreibersite, and is probably identical with La Primitiva.

EDINBURGH.

Royal Society, November 2.—Prof. James Geikie, president, in the chair.—Sir William **Turner**: The Baleen whales of the South Atlantic. The paper was essentially a comparison of certain anatomical characteristics of specimens of whales recently found in the South Atlantic with those of the better known whales of the North Atlantic. The conclusion was that of the Balænopteridæ, five species were common to the north and south Atlantic oceans, namely, *Megaptera boops* (*longimana*), and the four species of *Balaenoptera, sibbaldi, borealis, rostrata, musculus*. Similarly the smaller right whale, *Balaena australis*, which frequents the temperate waters of the South Atlantic, is obviously the same species as the *Balaena biscayensis* of the North Atlantic. On the other hand, *Balaena mysticetus* of the Arctic Ocean appears to have no representative in the Antarctic.—Dr. J. E. **Mackenzie** and S. **Ghosh**: The optical rotation and cryoscopic behaviour of sugars dissolved in (1) formamide, (2) water. The mutarotation of the sugars, β-*l*-arabinose, *l*-xylose, α-*d*-glucose, α-*d*-galactose, *d*-mannose, *d*-fructose, α- and β-lactose, dissolved in the solvents named, was measured and found to be of the same character. The molecular weights of the same sugars dissolved in these solvents were also determined, and each sugar was found to be in the monomolecular state. The results of the optical rotation measurements in formamide, like those obtained in pyridine solution by Grossmann and Bloch, appear to show that the presence of water is not essential to explain the phenomenon of mutarotation of sugars.

PARIS.

Academy of Sciences, November 3.—M.P. Appell in the chair.—A. **Lacroix**: The products of alteration of aluminium silicate rocks, and, in particular, the laterites of Madagascar.—G. **Lippmann**: The Hughes electromagnetic balance and its application to medical surgery (see p. 319).—D. **Eginitis**: Observation of the solar eclipse of August 21, 1914, made at the Athens Observatory with the Doridis equatorial (Gautier, 40 cm.). Particulars are given of actinometric observations, and of measurements of air temperatures, relative humidity, barometric pressure, and wind velocity.—M. **Guéritot**: An experimental method of determining the metacentric curves of an aeroplane. Details of experiments made on a model fixed to a float in water.—J. **Bougault**: The dioxytriazines. The reaction between the semicarbazides of α-ketonic acids and aqueous soda solution takes place in the cold. The yield is better than when the experiment is carried out at the boiling point, but the reaction velocity is very slow. The dioxytriazines react with sodium hypobromite, giving substituted amides of the type $R.CBr_2.CO.NH_2$.—G. A. **Le Roy**: The waterproofing of military clothes. The whole garment is impregnated with lanoline, by immersion in a solution in a volatile solvent containing from 5 per cent. to 10 per cent. of the wool fat. The cloth remains permeable to air, but is impermeable to water.—Marcel **Baudouin**: The ossification of the metacarpal and metatarsal bones in men of the polished Stone age.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 19.

ROYAL SOCIETY, at 4.30.—Note on the Circulation of the Atmosphere: A. Mallock.—The Origin of the Indo-Gangetic Trough—commonly called the Himalayan Foredeep: Sir S. Burrard.—Approximately Permanent Electronic Orbits and the Origin of Spectral Series: G. W. Walker.—Spectroscopic Investigations in connexion with the Active Modification of Nitrogen. IV. A Band Spectrum of Boron Nitride: W. Jevons.—An Additional Note on the Production of High Permeability in Iron: Prof. E. Wilson.

CHILD STUDY SOCIETY, at 7.30.—Development of the Practical Imagination in Children: Prof. T. P. Nunn.

LINNEAN SOCIETY, at 8.—*Hydrilla verticillata*, Caspary, a New British Plant: A. J. Wilmott.—The Mosses and Hepaticæ of West Falkland Islands, from the Collections of Mrs. Rupert Vallentin: C. H. Wright.—The Thysanoptera of the West Indies: R. S. Bagnall.

INSTITUTION OF MINING AND METALLURGY, at 8.—Persistence of Ore in Depth: T. A. Rickard.

FRIDAY, NOVEMBER 20.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—The Effect of Vacuum on Steam-Turbines: G. G. Stoney.

MONDAY, NOVEMBER 23.

FARADAY SOCIETY, at 8.—Discussion: The Hardening of Metals. Introductory Address: Sir Robert Hadfield.—Some Recent Papers on Hardening and Overstrain in Metals, and the Bearing on these of the Author's Amorphous Theory of the Hardened State: Dr. G. T. Beilby.—The Influence of Allotropy on the Metastability of Metals and its Bearing on Chemistry, Physics, and Technics: Prof. E. Cohen.—The Hardening of Metals by Quenching: Prof. C. A. Edwards.—The Interstrain Theory of Hardening: Andrew McCance.—The Part Played by the Amorphous Phase in the Hardening of Steels: J. C. W. Humfrey.—(1) The Hardness of Solid Solutions; (2) A Note on Twinnings and the Martensitic Structure: Dr. C. H. Desch.—Metallic Filings: Dr. T. Martin Lowry and R. G. Parker.—The Hardening of Manganese Steel: Prof. H. M. Howe and A. G. Levy.—Instruments for Testing Hardness: H. L. Heathcote.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Mental Training of a Traveller: Viscount Bryce.

ROYAL SOCIETY OF ARTS, at 8.—The History and Practice of the Art of Printing: R. A. Peddie.

TUESDAY, NOVEMBER 24.

ZOOLOGICAL SOCIETY, at 5.30.—Exhibition of Tests of Arenaceous Foraminifera to Introduce a Discussion on the Interpretation of these Structures: E. Heron-Allen and A. Earland.—(1) A New Fossil Reptile from South Africa; (2) Notes from Some Carnivorous Therapsids; (3) *Eunotosaurus africanus*, Seeley, and the Ancestry of the Chelonia: D. M. S. Watson.—Polychæta from the N.E. Pacific: The Chætopteridæ. With an Account of the Phenomenon of Asexual Reproduction in Phyllochætopterus and the Description of Two New Species of Chætopteridæ from the Atlantic: F. A. Potts.

WEDNESDAY, NOVEMBER 25.

ROYAL SOCIETY OF ARTS, at 8.—The Supply of Chemicals to Great Britain and Her Dependencies: Sir W. A. Tilden.

THURSDAY, NOVEMBER 26.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Power Plant Testing: W. M. Selvey.

PHYSICAL SOCIETY, at 5.—Note on the Conduction of Electricity at Point Contacts: A. F. Hallimond.—Thermal Conductivity of Badly Conducting Solids: T. Barratt.

THE RESPIRATORY FUNCTION OF THE BLOOD.

The Respiratory Function of the Blood. By Joseph Barcroft, F.R.S. Pp. x + 320. (Cambridge University Press, 1914.) Price 18*s*. net.

THE title of this book gives but an inadequate idea of the scope of its contents. As the author states in the Preface, it is really an account of his "physiological ventures," and consists mainly of the researches undertaken by himself and his pupils, with slighter references to cognate work by other observers. The wealth of new facts and ideas which are here presented bears striking witness to the important part played in the advance of science by the discovery of a new technique. In practically all the investigations here presented it was necessary to determine the gaseous contents of minute quantities of blood or other fluids, so that the discoveries here made may be said to be the direct outcome of Haldane's invention of a method for the gaseous analysis of small quantities of blood—a method since perfected and elaborated to such an extent by the author of this book as to be identified with him. Armed with this new technique, he was able to attack a number of capital problems connected with the behaviour of oxygen in the blood, its uptake in the lungs, and the conditions of its utilisation by the tissues, with an ease and accuracy which previously was impossible.

This book, however, is not a mere reprint of Barcroft's physiological papers. In presenting his results, he wisely abandons the chronological for a logical order. In the first part he begins with a description of the physical and chemical characters of hæmoglobin and the determination of its combining power for oxygen in relation to its iron content. The constancy of the figures obtained in his latest experiments for oxygen capacity and iron content is regarded by the author as almost convincing proof that the combination is chemical in the strict sense of the term. He then discusses the oxidation curve of oxyhæmoglobin and the influence of temperature, electrolytes and acids on the curve. An important result arrived at is that the variations which have been described in the dissociation-curves in the blood of different animals may be ascribed to differences in the salt-content of the blood-corpuscles, which determine varying degrees of the aggregation of the colloidal hæmoglobin molecule.

In part ii. he proceeds to discuss what significance these facts have for the normal life of the animal. The question of the factors which determine the supply of oxygen to the tissues during rest and activity, involves difficult physiological experimentation on the exchange of gases between tissues and blood in voluntary muscle, heart, adrenals, pancreas, kidney and liver. From these results we are led on to another series in which the oxygen intake of the tissues is used as a criterion of the activity of the tissue-cells. In this way he is able to throw a welcome light on the nature of some of the phases of renal activity—activity of the cells being assumed as responsible for urinary formation when an increased flow of urine is associated with an increased uptake of oxygen by the kidney. A chapter on the metabolism of the blood itself (which, except in abnormal circumstances, is shown to be negligible) is followed by an account of the mechanism by means of which the supply of oxygen to the tissues may be regulated according to their needs. Prominent among these mechanisms is the local production of lactic acid and possibly other metabolites, which not only have a vaso-dilator action, so increasing the blood-flow through the part, but also, by their action on the dissociation-curve of hæmoglobin, favour the transfer of oxygen from oxyhæmoglobin to the tissues.

In the next chapter he describes a bold attempt made by him in conjunction with Verzar to determine the head of pressure driving oxygen from the blood to the tissues, using as his criterion the effect of variations in the oxygen-supply on the amount of this gas taken up by the tissues.

Under normal conditions, the blood has only a certain time to take up oxygen in the lungs and to give up oxygen in the tissues, viz. the duration of its transit through the capillaries of lungs and tissues respectively. An investigation of the rates of combination and dissociation of oxygen and hæmoglobin enables the author to show that the physical conditions which determine the form of the dissociation-curve outside the body are sufficient to account for the changes taking place within the body. This investigation naturally leads on to a discussion on the much debated question as to the mechanism of the uptake of oxygen in the lungs. A very impartial account is given of the views and investigations of Bohr, Haldane, Krogh, and Hartridge. His final conclusion is in favour of the view according to which the process is determined by the physical conditions existing in the lungs, though he points out that the question cannot be regarded as finally settled until the results obtained by Haldane and others on Pike's Peak have been reinvestigated by Hartridge's methods or have received some adequate explanation.

The third part of the work deals with the dis-

sociation-curve of the hæmoglobin as an indicator of the reaction of the blood, and contains a wealth of interesting observations on the effects of diet, exercise, residence at high altitudes, and finally, certain pathological conditions associated with acidosis. The author is to be congratulated on the production of a book interesting not to physiologists only. The lively personal note of the narrative is a happy novelty in a physiological monograph, and will enable those of his readers who have not worked with him to appreciate and, in a measure, to partake of the genial optimism of the author. E. H. S.

GYROSCOPIC MOTION.

An Elementary Treatment of the Theory of Spinning Tops and Gyroscopic Motion. Second edition. By H. Crabtree. Pp. xv+193. (London: Longmans, Green and Co., 1914.) Price 7*s.* 6*d.* net.

IN this, the second edition of Crabtree's admirable book, the text and paging of the first edition have been followed, but additions have been made where necessary, so that more recent developments may be dealt with. The first edition was noticed in NATURE (August 12, 1909, p. 182), so that it is not necessary to do more now than refer to the additional matter. The two monorail systems of Brennan and Schilowsky are illustrated and described. It may be mentioned that each of these derive their stability from a gyrostatic system, the action of which is independent of the forward motion of the car, so that the stability exists whether the car is moving forwards or backwards or is at rest, and in this respect differs entirely from the systems more recently invented by Dr. Gray.

There is a full discussion of the Anschütz gyro compass, but this is the same as that which is given in the manual published by Messrs. Elliot Bros., having been translated for them by the author and his colleagues. The writer of this notice hoped to have found also a description of the Sperry gyro compass, which differs in certain respects very materially from its forerunner, the Anschütz. A discussion by the author of the relative merits of the two systems where they differ would have been very illuminating. Unfortunately, this instrument is not mentioned. Other matters ably dealt with in the appendices are the swerving of golf-balls and the drifting of rifled projectiles, both subjects on which amazing nonsense is often written.

There is a statement in the earlier part of the book on the skidding of motor-bicycles, with which the present writer does not agree. Seeing that the back tyre is being constantly impelled to slip longitudinally on the ground by successive explosions in the cylinder, more especially where a rigid chain drive is employed, or where the flywheel of the engine is insufficient, and that a longitudinal slip will start a side slip, there is abundant cause for the side-slipping capacity of these machines, without looking to more subtle causes. Briefly, the author explains that in consequence of the gyrostatic action of the flywheel a transverse couple must be applied in order to make the flywheel's plane of rotation change when the machine is describing a curve. In order to apply this, the rider and machine must lean over to a very small extent more than would be necessary otherwise. So far so good; the transverse couple is caused by the weight of the whole combination of machine and rider acting vertically downwards, and a corresponding reaction at the road acting vertically upwards, and the arm of the couple is the excess of the horizontal distance between the centre of gravity and the wheel base due to the extra leaning. The transverse force on the road, which alone gives rise to side slip, is unchanged.

It is satisfactory to find that there is a sufficient demand for a book of such thoroughness as this to have called for a second edition in a comparatively short time. C. V. BOYS.

BRITISH FLOWERING PLANTS.

British Flowering Plants. Illustrated by Three Hundred Full-page Plates, reproduced from Drawings by Mrs. Henry Perrin. With Detailed Descriptive Notes and an Introduction by Prof. G. S. Boulger. Vol. i. Pp. xlv+plates. (London: Bernard Quaritch, 1914.)

MRS. PERRIN'S book, of which the first volume is before us, is essentially a book for the use of ladies and those who take a dilettante interest in botany and flowers. It is unfortunate, therefore, that it is of such a weight that its presumed readers may scarcely have the strength or energy to handle the bulky tomes.

Not only are the plates heavily loaded with plaster of Paris, but the large quarto pages of text are of almost equal solidity. If the contents of the book were of any scientific interest or formed a real addition to knowledge, the great bulk of the volume would be a matter of sincere regret; we cannot, however, foresee any particular use for the book, except that its handsome back may adorn the shelves of an expensive library, and can only deplore that the money expended on this production could not have been put to some object of definite botanical value.

The paintings, which afford the *raison d'être* of the book, are on the whole good, though in

many cases a more artistic arrangement of the material might have been achieved. Some pictures, as that of the snowdrop, for instance, are unworthy of the book. To the botanist the pictures are of little value, owing to the absence of an analysis of the parts of the flower and fruit, and this defect is especially noticeable in the case of the plates of the bulrush and Luzula, which give no indication of the structure of the flowers. It may be urged that such details are relegated to special plates, but even then they are so poorly executed and often on so small a scale as to be of little assistance. It is unfortunate that the artist, who undoubtedly possesses considerable skill and has bestowed so much labour on her drawings, had not sought the best advice as to the way in which she might have made her pictures of value.

The notes supplied by Prof. Boulger are full of useful information and make pleasant, if not very strenuous, reading. We doubt, however, owing to the bulk of the book, if they will receive very serious attention. He has collected together a good deal of curious and out-of-the-way information under the different plants which it is well to bring to the notice of students and those interested in flowers. In addition to the ancient lore the correct naming of the plants is fully treated, and a considerable amount of recent work of interest is incorporated as occasion demands.

Information about the habitats and general condition of life of the different plants figured is also given. In the introduction a useful outline of general floral morphology and classification is to be found, and the plates with their pages of text follow. The plants figured in the volume include the British conifers, certain monocotyledons, the willows, oak, beech, and allied trees, the nettles, Polygonaceæ, Caryophyllaceæ, and a few others.

PHYSICAL CHEMISTRY.

(1) *The Theory of the Solid State.* Based on Four Lectures delivered at University College, London, in March, 1913. By Prof. W. Nernst. Pp. viii+104. (London: Hodder and Stoughton, 1914.) Price 2*s.* 6*d.* net.

(2) *Lehrbuch der physikalischen Chemie.* By Dr. K. Jellinek. Band i. Die Lehre von den Aggregatzuständen, Teil I. Pp. xxxvi+732. (Stuttgart: F. Ende, 1914.) Price 24 marks.

(3) *Complex Ions in Aqueous Solutions.* By Dr. A. Jaques. Pp. vi+151. (London: Longmans, Green and Co., 1914.) Price 4*s.* 6*d.* net.

(1) THOSE who had the opportunity of hearing Prof. Nernst deliver his short course of lectures at University College, London, on the Quantum Theory as applied to the solid state of matter will welcome this somewhat belated publication. The book is a masterpiece of lucid condensation, covering as it does in a small number of pages the whole range of modern work on the thermal properties of solids. The limitations of the Dulong-Petit generalisation are briefly discussed. The necessity for the introduction of some new hypothesis in place of equipartition is made clear, and the fortunate application of Einstein of the Planck quantum concept to the heat capacity of vibrating atoms is shown to point the way to a new understanding of the baffling problem of the solid state. The Nernst-Lindemann empirical modification of the Einstein formula is touched upon, and later the more theoretically significant expression of Debye.

Whilst fully realising the great progress which has been made by the introduction of the quantum theory to the thermal properties of solids (and gases and liquids for that matter), it would be idle to pretend that everything is at present on a sure and certain basis. As a matter of fact nearly every stage bristles with assumptions, and although the general trend is certainly in the right direction, not a few of the assumptions are mutually conflicting. A science in this state is, however, just at its most attractive stage, and the number of investigations cited as references in the book are ample evidence of the interest which the subject has awakened, especially in Germany.

An important feature of the book is the good account of the experimental methods employed in the Berlin laboratory for the determination of specific heats, especially at very low temperatures. Perhaps the most interesting section is that entitled "General law respecting the behaviour of solid bodies at very low temperatures," in which a most suggestive account of present and future problems is given on such subjects as thermal expansion, compressibility, conduction of heat and electricity, thermal e.m.f's, and magnetic susceptibility. It would seem that before long the subject of thermal and electrical conductivity of solids will be a region of controversy between the electron view and the quantum view—which, it is to be hoped, will result in a clearer physical conception of what the quantum really is. It is noteworthy that no mention is made of Sommerfeld's views.

There is no question that during the next decade at least, the most active investigation in theoretical physics and chemistry will consist in the further extension and application of the quantum theory, hence the significance of the present publication which is a most excellent epitome of the subject (so far as it refers to solids), by

one who is himself one of the pioneers in its development.

(2) The bulky volume before us represents vol. i. of a Text-book of Physical Chemistry to be completed in four volumes. The author, Dr. Karl Jellinek, has indeed no light task before him in thus undertaking a work which is intended to be an Ostwald Lehrbuch brought up to date, and written in even greater detail than its prototype. Dr. Jellinek's repute, however, as an investigator and a writer—it seems only the other day that a large and very valuable work on a branch of physical chemistry appeared from his pen—entitles us to expect that the present book when completed will succeed in fulfilling the author's expectations. As is stated in the preface, stress is laid (though not unduly) upon the physical aspect of the subject, and the fact that two large volumes are to be devoted to the consideration of states of matter (in the widest sense) is evidence of this.

Vol. i commences with a very full account of literature sources (text-books of all kinds and journals) this being followed by an introductory chapter dealing with the principles of the kinetic theory and thermodynamics. Next comes the subject matter proper, beginning first with an account of the gaseous state (pp. 160–431), transition from gaseous to liquid (pp. 432–468), and the liquid state itself (pp. 469–711). In vol. ii., which is promised shortly, the liquid state will be still further considered, and after that the solid state and dilute solutions. As illustrating the extent of detail one may quote the table of contents of the principal chapter included in the first subsection (dilute gases) of the section dealing with the gaseous state in general, viz., the Maxwell distribution law, rigid deduction of the gas law, degrees of freedom, rotation of gas molecules, vibration of atoms in gas molecules, law of equipartition of energy between degrees of freedom inside a molecule, theory of the specific heat of dilute gases. The liquid state is considered in equal detail. A book written authoritatively as this undoubtedly is, and on this scale of minuteness, is bound to become an indispensable work of reference for all physical chemists.

(3) Dr. Jacques's monograph on complex ions in aqueous solution is an eminently useful publication. Five chapters are devoted to the principal methods of detecting and determining complexes, viz., the chemical method, distribution method, ionic migration method, solubility method, and e.m.f. method. The remaining chapters deal with applications of these methods to various cases, notably the complex mercury salts, ammoniacal solutions of metallic salts, salts of cobalt and copper (including Fehling's solution), equilibrium between metallic ions at different degrees of oxidation, polyiodides and sulphides (the latter being particularly well treated). The appendix contains a brief account of the hydrate theory and a general scheme for treating complexes theoretically. Great stress is laid upon the significance of equilibrium constants and their numerical evaluation. The book can be warmly recommended.

W. C. McC. L.

OUR BOOKSHELF.

Agriculture in the Tropics. An Elementary Treatise. By Dr. J. C. Willis. Second edition, revised. Pp. xvi+223. (Cambridge University Press, 1914.) Price 9*s*. net.

AGRICULTURE resolves itself mainly into a combination of the four factors, crops, soil, labour, and climate. Of these, in tropical countries crops are quite the most interesting on account of their diversity and high economic importance. There is therefore ample justification for the large amount of space—nearly half the volume—devoted to descriptions of the principal agricultural products; even then it is only possible to present general outlines of cultivation and preparation. The author draws largely upon his long and varied experience in Ceylon, also upon his personal knowledge of agriculture in Malaya and India. Soil problems do not receive much discussion; there is, for instance, little or no reference to modern soil science and we should have expected a fuller account of the practice and details of green manuring. The labour factor, on the other hand, especially peasant agriculture, is discussed very fully in the last seventy pages, with the object of describing native methods and considering how their efficiency may be increased. There is much soundness in the general opinions enunciated that before improvements are attempted, due regard must be had to the peasants' environment and scruples. Co-operative seed stores and education by school-gardens are advocated as the most hopeful remedial measures.

The value of the book lies largely in the original source and nature of the information supplied, based as it is upon intimate knowledge gained by many years' administration as director of the Botanic Gardens in Ceylon. The first edition of the book was published nearly five years ago.

Chemical Technology and Analysis of Oils, Fats, and Waxes. By Dr. J. Lewkowitsch. Fifth edition, entirely re-written and enlarged. Vol. ii. Pp. xiv+944. (London: Macmillan and Co., Ltd., 1914.) Price 25*s*. net.

THE second volume of this well-known work deals with the commercial preparation of the raw materials used in the oil, fat, and wax industries, and with the methods of preparing and examining the individual oils, fats, and waxes. For the fifth edition a competent editor appears to have been found in Mr. G. H. Warburton, who was associated with the late Dr. Lewkowitsch's ana-

lytical practice for a number of years. The work as a whole was reviewed in these columns on the occasion of the previous issue, and its general plan remains unchanged, though the matter has been re-written and many additions made. These include, in the volume under notice, a number of hitherto unpublished results obtained in the author's laboratory, and also data respecting certain oils such as those from perilla seed and rubber seed which, though little known in this country at present, may perhaps prove of commercial importance in the future. There are also some revisions of the older values for the physical and chemical "constants" in cases where the adoption of improved processes for the preparation of oils and fats has rendered the earlier figures obsolete. The volume, in fact, appears generally to have been brought well up to date, and users of the work will find the new edition increasingly serviceable.

Flintshire. By J. M. Edwards. Pp. xi+172. *Peebles and Selkirk.* By G. C. Pringle. Pp. x+149. (Cambridge University Press, 1914.) Price 1s. 6d. net each.

ATTENTION has been directed on several occasions to the attractiveness and utility of the Cambridge County Geographies. These recent additions to the series have been bound in a new form, which makes them very convenient for use as guide books, a purpose they will be found to serve admirably, without in any way interfering with their popularity as interesting supplements to geography lessons in schools. Both authors may be congratulated upon maintaining the high standard set in previous volumes.

THE AUSTRALIAN ANTARCTIC EXPEDITION.

THE scientific value of the Australian Expedition, described by Sir Douglas Mawson in the September number of the *Geographical Journal,* though obtained by great toil and hardships, which were almost fatal to the leader and led to the tragic deaths of two of his companions, promises to be very great. Before this expedition, as the maps show, little was certainly known about the Antarctic continent for quite 70° of longitude, from some distance west of Cape Adare to the winter quarters of the *Gauss* in 1902–3. The geography of this, as the maps show, has now been ascertained by adventurous and laborious sledge journeys from the two bases occupied by Mawson's expedition, and the following are its main results.

FIG. 1.—A view of the islets off the coast of the mainland looking west from Stillwell Island, Adelie Land. From the *Geographical Journal.*

Macquarie Island, a link between Tasmania and South Victoria Land, on which a party was

left in charge of the wireless telegraph station, has been surveyed and its natural history studied. Here, and on the mainland, rare seals, fish, and numerous birds were obtained, with a large collection of eggs, most of which were previously unknown. Sounding and dredging were carried on, with excellent results, in the sea between Australia and the Antarctic continent. The rocks of the mainland appear to be largely crystalline, probably Archæan, with some sedimentaries (among which the Beacon Sandstone apparently occurs), containing coal and carbonaceous shales. Capping them are great masses of columnar dolerite (Fig. 1).

The climate of all the region explored seems to be even worse than that in the Ross Sea district. Blizzards are almost incessant, even in summer: the average annual velocity of the wind

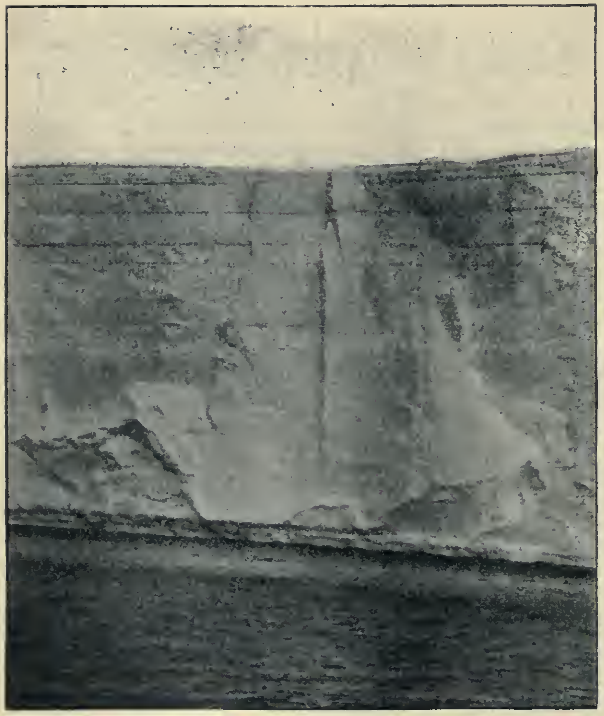

FIG. 1.—The face of the Shackleton Shelf. Each band represents an annual snowfall addition. From the *Geographical Journal*

being 50 miles an hour, and it often rises to above 100 miles. In winter the air is full of particles of ice, and the electricity generated is so great that hands, noses, and projecting parts of the clothes show pale gleams like St. Elmo's fire.

This portion of the Antarctic continent seems to be less mountainous than South Victoria Land, but its snowfields rise inland to heights of from 2000 feet to above 4000 feet; one of the exploring parties attaining in that direction an elevation of nearly 6000 feet. An ice barrier, like the well-known one in Ross Sea (named Shackleton's Shelf) defends most parts of the coast, and gives a still more conspicuous instance than that affords of projecting tongues of ice formed by the huge land glaciers, which force their way through the barrier, and protrude many miles, in one case quite sixty, out to sea. In other words the barrier exchanges the piedmont for the more normal glacier type. But in other respects the history of this floating ice corresponds with that of the Ross Sea Barrier. Its upper part, probably all visible at its extremity, is not land-ice, but stratified frozen snow, as shown in Fig. 2, formed by the accumulated annual snowfalls: the great part of the original land-ice having been melted off by the sea-water. Thus the rock *débris* incorporated in the lower part of that ice (and in these regions there cannot be much in the upper) must be distributed over the sea bottom—a fact of which the advocates of the terrestrial origin of all boulder clays will do well to take cognisance. Thus a fine piece of work—geographical, meteorological, botanical and zoological—has been accomplished, and Australia, as in the case of the Funafuti boring, has done a most notable service to science.

T. G. BONNEY.

DETERIORATIVE CHANGES IN WINE.[1]

SINCE the time when Pasteur, in his "Études sur le Vin," described a certain bitterness sometimes occurring in wine (*Maladie de l'amertume*) as being apparently due to a specific micro-organism, most of the forms of deterioration which wine undergoes have been recognised as due to biological action. Thus the *Kahmigwerden*, the *Essigstich*, and the *Milchsäurestich* of German writers, the *poux* and the *graisse* of French œnologists, are ascribed to the undesirable activity of various bacteria, moulds, and yeasts. Sourness, for example, is often due to acetic acid produced by the ferment *Mycoderma aceti* from the alcohol of the wine; whilst another mycoderm (*M. vini*) is believed to produce faulty wine by attacking the cream of tartar and albuminous extractive matters.

Some of the faults which may develop in wine, however, are attributable to causes not primarily biological. A certain kind of mustiness, for instance, is ascribed to the effect of a malodorous essential oil. The presence of iron salts, again, has been recognised as a necessary condition for the appearance of a particular kind of turbidity—the *casse ferrique*—which in certain circumstances may affect white wines. With this phenomenon oxidation processes are known to be associated, and the intervention of an oxidase, transferring oxygen from the air to substances in the wine not directly oxidisable under ordinary conditions, has been suggested to account for the results observed.

Dr. Horace Brown has studied at considerable length a variety of *casse* to which the white wines of the Cape are particularly liable. Although the wines may have been bottled perfectly bright, they have a tendency to become

[1] "An account of some investigations on the White Wines of South Africa: an Œnological Study. By Horace T. Brown. *Journ. Inst. of Brewing*, vol. xx, No. 5.

cloudy and to throw out a light deposit. This tendency is accompanied as a rule by more or less darkening of colour, and by modifications in the flavour and odour which are very characteristic. Even before any *casse* or "break" (cloudiness) is observable in them, wines undergoing this change acquire an "earthy" odour or *terroir;* and simultaneously a distinctive bitter flavour of a greater or less intensity is developed. These faults—cloudiness, earthy odour, bitterness, and modification of colour—may exist in different degrees, but are apparently all related to a common cause; and Dr. Brown's experiments indicate that this cause is not to be sought in the action of micro-organisms. The malady is conditioned by purely chemical changes. Moreover, it only occurs when the wine is in contact with air, or with free oxygen derived from some such source as hydrogen peroxide.

Naturally one of the first things to ascertain in studying the malady was the true character of the suspended matter forming the turbidity. Under the microscope it was found to consist of amorphous aggregates of minute, roughly-spherical particles, which were readily stained by Coupier's blue, dissolved easily by caustic alkali, and also, though with some difficulty, by dilute acid. Except in this last point the deposit resembles the amorphous matter which separates from beer in certain circumstances, and which has been shown by Dr. Brown himself to consist mainly of a combination of tannic acid with albuminoids. The actual amount of the deposit necessary to give a distinct turbidity to wine is relatively very small: in one instance the weight of the substance when dried was only 6·4 milligrammes per litre of wine. The organic portion of the deposit contained nitrogen equivalent to 55·9 per cent. of albuminoids. When incinerated, the dry substance of the deposit yielded 12·9 per cent. of inorganic material, four-fifths of which was ferric oxide. In fact, a striking feature about all the deposits in this kind of *casse* is the comparatively large proportion of iron which they contain.

It was found, further, that an essential factor in the production of *casse* was the presence of a little iron in the *ferrous* state. This apparently acts as a carrier of atmospheric oxygen to certain oxidisable substances in the wine, much in the same way as traces of ferrous salts behave in the well-known "Fenton" reaction.

Systematic experiments showed not only that air and ferrous salts are necessary, but that certain oxidisable substances in the wine are also required. Of these the most notable is tannic acid; and the author concludes that the material forming the turbidity or deposit is in fact "a colloidal combination of iron with products derived from the limited oxidation of tannins and certain wine-albuminoids." This does not, of course, tell us all that it is desirable to know about the deposit and the conditions of its formation. The question of the nature and amount of the nitrogenous substances in the wine, and the part they play in the production of the changes, has still to be investigated. As the author remarks, wine-making has its own particular "nitrogen question," and it is at present virgin ground.

Good evidence was obtained to show that the oxidising agent concerned is not a vegetable oxidase. Freshly expressed grape juice contains no oxidase, though it may dissolve some from the grape skins if left in contact with them. In any case there appears to be no connection between the occurrence of oxidase and the *casse ferrique*. The immediate cause of this deterioration is the alternate reduction and oxidation of iron, with consequent transference of oxygen to the changeable tannins and other constituents of the wine.

Now if this is true, it points the way to preventive and remedial measures. One such measure, obviously, is to avoid so far as possible the must or wine taking up iron at any stage of the making or storing. If, however, an excess of iron cannot be helped, it would be expected that the addition of a reducing agent to maintain the iron permanently in the ferrous condition would prevent the occurrence of the malady. This was found to be so, the action of sulphites in this respect being very pronounced. Again, since tannic acid is one of the essentials, its removal should be beneficial; and in fact the addition of casein to the wine has a favourable influence which is attributed to an adsorptive separation of tannin by the casein. As regards the other essential condition—the presence of air—the author recommends that aeration of the wine should be guarded against during the maturing and bottling operations, and that the bottles should be completely filled. In this connection it is noted as unfortunate that the visitor to the Cape generally makes the acquaintance of South African wines for the first time on the ship going out. The bottles are frequently not completely filled, and this, with the alternations of temperature and the swing of the ship, helps to produce the malady in question, especially in the more delicate white wines.

The faults mentioned are so common in the white wines of South Africa that the author at one time regarded them as due to some fundamental causes, such as soil and climate, which were beyond control. But the occurrence of perfectly "clean" wines, the production of such wines under his own auspices, and the results of the investigation which has been outlined, have altered this view. Not Providence, but the producer, is responsible—or at least, the producer and the merchant must share the responsibility.

The scientific study of this question made by Dr. Brown, necessarily incomplete though it is, has given definite knowledge where hitherto information has been vague or absent, whilst the practical application of this knowledge indicates the direction in which remedial measures are to be sought. It is to be hoped that the author will be able to extend the research to the "nitrogen question" already mentioned, and with equally definite results.

C. SIMMONDS.

A PHYSIOLOGICAL PUZZLE.[1]

WHAT the magicians did in ancient days before Pharaoh in the way of turning sticks into snakes has often been done since, or its converse of turning snake into stick, but it remains in great measure a physiological puzzle. If the cobra in its threatening attitude be deftly caught behind the head and gently pressed, it soon becomes stiff, and will remain so for a considerable time, either coiled up or drawn out straight. It has passed into the strange state of animal hypnosis. In 1646 the Jesuit father, Athanasius Kircher, described the famous experiment, "de imaginatione gallinæ." He laid a hen on the table, held it firmly for a little, and drew a chalk line in front of its eyes, with the result that it remained as if in katalepsy. Czermak showed in 1872–3 that this could be done with many birds, and that the chalk line was quite unnecessary. The veteran entomologist, Fabre, tells us that he and his school companions used to put a whole flock of turkeys to sleep with their heads tucked under their wings. Animal hypnosis can also be induced in mammals (guinea-pig, rabbit, mouse, squirrel, bat, dog, cat), and this is usually effected experimentally by fastening them to a board and turning this suddenly upside down. Frogs are readily susceptible, and newts will also submit.

In backboned animals the state of immobility is scarcely known except in artificial conditions, and can scarcely be of much importance in life. It is otherwise, however, when we pass to the analogous "death-feigning" or katalepsy in certain beetles, water bugs, stick-insects, and spiders. The immobility occurs in natural conditions, and it seems often to save the life. The case of the female Galeodes is of special interest, since the more than recalcitrant female passes into a convenient hypnosis when she is suddenly seized by the weaker male. This may be induced artificially in the sexually mature female by gripping her suddenly in the dorsal region of the abdomen with a pair of fine forceps and raising her from the ground. She remains quite passive until she is restored to earth. It is very interesting to note that older females, who have paired, do not pass into katalepsy, but turn fiercely on the forceps. In the same connection it is worth recalling that when we lift a shore-crab, holding the shield between finger and thumb, and wave it in the air, it becomes immobile, but the two sexes dispose their limbs in different ways, the female bending them in over the abdomen, as if protecting the eggs. The familiar case of the fresh-water crayfish is interesting, because the creature does not pass suddenly into hypnosis, but usually resists for a considerable time. It may be fixed in any position of equilibrium—on its head, on its back, or even in its normal pose. The stick-insect, Dixippus, which feeds at night, normally assumes its protective immobile attitude under the stimulus of light, but a mechanical stimulus also serves. Schmidt has recently shown that the insect can be fixed in any grotesque attitude for hours on end. It has been shown that the transition from one state to the other can in this creature be effected almost in a moment.

In a case like the stick-insect we cannot but regard the kataleptic habit as of protective value; it adds to the safety which the protective form and the protective colour also help to secure. The creature behaves as if it knew, for it almost always disposes itself parallel to the twig to which it is attached. Schleip also points out that when it lets go on being touched, the elongated, straight disposition of the appendages makes it easier for it to slip down among the twigs. In Galeodes, as we have noted, the sudden passivity of the female is of importance in reproduction, and a similar phenomenon has been observed in the female octopus. In many cases, however, it seems quite impossible to maintain that the katalepsy is protective at all. Thus Fabre notes that *Scarites buparius*, one of the large ground-beetles, which a shake sends into a lasting katalepsy, is voracious, well-armoured, nocturnal, and unpalatable. What has it to do with "death-feigning"? Cases of this sort suggest that the kataleptic tendency may be simply a concomitant of a certain type of nervous constitution, and that it is only occasionally turned to advantage.

According to Mangold, the characteristics of human hypnosis are: that it is a sleep-like state, induced by suggestion; that it implies a rapport between the hypnotiser and the patient, and an increased amenability to suggestion; that it involves an inhibited power of locomotion and of "righting" the body, a change in muscular tonus—from initial increase to somewhat sudden decrease—and a change in sensitiveness which may amount to anæsthesia and analgesia. Suggestion is a psychically-conditioned effect, for which the physiological stimulus seems to be inadequate. Little is known in regard to the hypnosis of the highest animals, like dogs and cats, the amenability of which to human influence is well known, but in ordinary cases it may be concluded, according to Mangold, that animal hypnosis differs from man's in the absence of the suggestion, the rapport, and the deeper stages. It may be induced in animals without a cerebrum, which indicates that the psychological factor is unimportant. Physiologically considered, however, the more typical forms of animal hypnosis must be ranked beside human hypnosis, and studied in this light.

The resemblances are many. The sleep-like state is induced in man by suggestion or psychical inhibition, in animals by mechanical inhibition, but in both cases sensory stimuli may assist. These stimuli may be optic (fixing the gaze on some object), or tactile (stroking the skin), or otherwise. Sometimes an absence of wonted stimuli may induce the state, as in the case of absolute silence. The awakening may be brought about by sounds, shaking, currents

[1] "Hypnose und Katalepsie bei Tieren im Vergleich zur menschlichen Hypnose." By Ernst Mangold. Pp. 82+18 figs. (Jena: Fischer, 1914). Price 2.50 marks.

of air, or electric shocks; or it may occur spontaneously. There is great specific and individual diversity in susceptibility; the easier the inducing of the hypnosis, the deeper and more lasting it is. The muscular tonus changes characteristically (now great stiffness and again "waxy flexibility"); resistance to fatigue is increased. Reflexes are to some extent affected by the altered tonus. Sensitiveness to touch and to pain may be greatly lessened, and operations may be performed during hypnosis. But the senses remain awake, and, except in the deeper phases in man, memory partly persists. Anæmic symptoms are sometimes observed, but there is no regular alteration in the everyday functions, such as the beating of the heart or the respiratory movements. Since animal and human hypnoses agree in all these respects, Mangold has confidence in his thesis that they are thoroughly analogous phenomena.

Finally, in his interesting study, he proposes a classification:—

1. Experimental hypnosis induced by psychical inhibition (suggestion hypothesis): (*a*) in man, and (*b*) perhaps in some of the highest mammals;

2. Experimental hypnosis induced by mechanical inhibition: (*c*) in mammals, birds, reptiles, and amphibians, and (*d*) in crustaceans and insects;

3. Natural hypnosis induced by "biological" stimuli: (*e*) death-feigning in crustaceans and insects, and (*f*) katalepsy in stick-insects.

DEEP SEA EXPLORATION.[1]

IN their book entitled "The Depths of the Ocean," which was noticed in NATURE of October 24, 1912, the late Sir John Murray and Dr. Hjort gave a general account of the expedition of the *Michael Sars* in the North Atlantic, and discussed the most striking results which had been obtained. The material collected had, however, been only partially worked out when that book was published. The more detailed scientific reports are now to be issued in a series of volumes containing memoirs by different specialists. The present volume is the first of these reports to be published, and deals with some of the zoological results of the expedition.

The Cephalopoda are described by Prof. C. Chun. A large number of species were obtained, several of which are described as new, but perhaps the most interesting feature of the collection is the series of early stages of *Spirula australis*, Lamarck. These were obtained in the neighbourhood of the Canary Islands, where they were taken in plankton nets. There were three larval stages, of which the youngest is 6 mm. long and has five chambers projecting at the posterior end of the body; the next has six visible chambers, and the third is 9 mm. long with seven chambers. In addition to these larvæ, young stages with dorsal mantle lengths of 12 mm., 16 mm., 18 mm., 23 mm., and 26 mm. respectively were obtained. Excellent figures of the external appearance of these larvæ and young stages are given. Their internal anatomy has not, however, yet been examined. The memoir ends, to use Prof. Chun's own words, "with the description of a new and wonderful type of Cirroteuthidæ, which may probably be counted among the most valuable spoils of the expedition. The specimen is a perfectly gelatinous, semi-transparent cephalopod, the fragility of which recalls that of a ctenophore." To this interesting animal, which is fuly described and well-figured, the name of *Cirrothauma Murrayi, n. gen.* and *n. sp.* is given.

The Cirripedes are described by the late Dr. P. P. C. Hoek, the forms obtained being all previously known, and Dr. Kr. Bonnevie deals with the Pteropods. Dr. Bonnevie's memoir contains an elaborate and useful discussion of the two species *Limacina balea* and *L. retroversa*, about which very great confusion has existed. Dr. Bonnevie shows clearly that the two forms are distinct, and he describes the limits of variation in certain characters of the shell of each species.

The Scyphomedusæ, Pennatulacea, and Hydroida are treated in three memoirs by Dr. Hjalmar Broch. It is to be regretted that Dr. Broch commences his first paper by an unfortunately worded attack upon the scheme of plankton nomenclature which was introduced a good many years ago by Dr. G. H. Fowler. The "epiplankton" of Fowler is certainly not the same as the "meroplankton" of Haeckel, as Dr. Broch seems to think, but is that part of the "holoplankton" which lives between the surface and 100 fathoms. This is clearly explained in Steuer's "Planktonkunde" (p. 370), to which work Dr. Broch refers for support. Steuer himself would seem to have adopted Apstein's term "passiv limnetische Planktonten," for the forms in fresh water which attach themselves to other organisms, remarking that these forms *have been called* "epiplanktonic." In one instance (p. 616) only, so far as his index shows, he uses the term in the latter sense without qualification, and he nowhere gives any indication as to when or by whom it was first introduced. If it is shown that the word "epiplankton" had been employed in another sense previous to its use by Fowler, then it may be necessary to find a new term for what Fowler calls "epiplankton."

In the *Michael Sars* collections Dr. Broch finds ten species of Scyphomedusæ, of which two, *Nausithoē atlantica* and *N. globifera*, appear to be new, five species of Pennatulida and a considerable number of hydroids obtained partly from drifting sea-weed and partly from hauls of the young-fish trawl. An interesting figure, drawn by the artist on the *Michael Sars*, is given, in which an attempt has been made to represent the appearance of the Pennatulid *Umbellula güntheri* when in a state of phosphorescence.

The Murænoid Larvæ, which formed a most important collection, are described by Einar Lea. The general results as regards the occurrence of

[1] Report on the Scientific Results of the *Michael Sars* North Atlantic Deep-sea Expedition, 1910, carried out under the Auspices of the Norwegian Government and the Superintendence of Sir John Murray, K.C.B., and Dr. Johan Hjort. Vol. iii., part 1, Zoology. (Published by the Trustees of the Bergen Museum.)

the earliest larvæ of the common eel in mid-Atlantic, in the region south-west of the Azores, were first described by Dr. Hjort in the pages of NATURE (November 24, 1910), immediately after the return of the expedition. In the present memoir the preliminary description then given is extended, and a large number of other eel larvæ in various stages of development are described. An attempt is made, with considerable success, to correlate the distribution of the murænoid larvæ with the hydrographical conditions (salinity, temperature, and depth) at the positions where they were captured.

The last memoir is a short paper by Ørjan Olsen on the Pycnogonida, of which *Collossendeis michaelsarsi* and *Nymphon longituberculatus* are new, and are described in detail with good figures.

The volume is produced in excellent style, and the illustrations are without exception well done. The whole series of reports, it is explained, will comprise five volumes, the total cost of which will not exceed 20*l.* It is added that separate volumes will not be offered for sale, an arrangement which will probably seriously curtail the distribution, and consequently the usefulness, of the work.

E. J. ALLEN.

BELGIAN PROFESSORS AND STUDENTS AT CAMBRIDGE.

UNIVERSITIES always have had small beginnings, and the attempt to build up an informal Belgian university at Cambridge is no exception to the rule. After the fall of Louvain, Cambridge formally asked the university authorities of that town to bring over such students and professors as could come with the view of carrying on their studies here, so that the continuity which every university greatly values should not be interrupted. It was the time of the Papal election, and Cardinal Mercier, the head of the University of Louvain, was away in Rome, and there was a good deal of difficulty in getting into touch with him, and before anything was settled Liège had also fallen. The hospitality of Cambridge was then extended to the university of that town. After some negotiations it was found impossible for either university to transfer its corporate and official existence beyond the Channel, and it therefore became impossible to attempt to organise official courses of study, to institute examinations, or to grant diplomas.

This, however, has not prevented the formation of unofficial courses, combining so far as possible systematic instruction on the lines of the Belgian universities with the individual requirements of refugee students and the restrictions of a necessarily rather incomplete Belgian teaching staff. The necessity of some kind of organised occupation was fully recognised, both by the professors assembled at Cambridge and by the Belgian Government. Cambridge hoped to take some part in protecting the students from the demoralising and dangerous consequences of enforced idleness —a condition likely to be prolonged for months even after the conclusion of the war, owing to the devastation of houses and property in the Belgian seats of learning.

The presence of professors representing almost all faculties has rendered it possible to form courses in several of them, though no one faculty can boast a quite complete organisation. The faculties of philosophy and letters (so important to a large section of students, viz., those who in ordinary conditions would just have entered upon their university education), and those of law and of engineering are so far the most favourably placed. Each of them is represented by several professors. Those who act as secretaries for their respective faculties are Prof. Carnoy (Louvain) for philosophy and letters, Prof. Dupriez (Louvain) for law, and Prof. Breithof (Louvain) for engineering. The faculties of medicine and science, represented by Prof. van Gehuchten (Louvain) and Prof. Colson (Louvain) respectively, are at present being organised, and the number of their students is constantly growing. It is hoped to organise the teaching in these faculties more completely with the assistance of professors who may feel disposed to take up their residence in Cambridge and to take their share in the direction of studies. A fairly large number of students of the commercial and consular sciences has also assembled, and as the published list of lectures shows this faculty is doing well.

It should also be mentioned that for each Belgian faculty "in being" there is a corresponding British committee consisting of a president and a secretary, whose pleasant duty it is to arrange lecture-rooms, libraries, laboratory facilities, etc., for both the Belgian professoriate and the Belgian students.

Cambridge has indeed room for far more Belgian students than she is likely to receive. Many of the colleges are more than half empty, and the Lodging-House Syndicate estimate that there are a thousand sets of students' rooms vacant in the town. The stout-hearted landladies are very patriotic, and they are willing to give board and lodging to Belgian students at the rate of 15*s.* to 20*s.* a week, which can scarcely be very remunerative to these stricken ladies. Everyone is willing "to do a bit," and only the other day a chimney-sweep after having finished his work at one of these lodging-houses turned to the landlady and said: "Got any Belgians here?" and when she said "Yes," replied: "Then I makes no charge."

Of course a large number of the professors and students are literally destitute, but the University has collected a certain sum which enables our honoured guests to be clothed and fed, and even to provide the students with pocket-money every Saturday morning.

One rule was adopted from the very beginning and has been rigidly adhered to, and that is, *that only such students would be helped at Cambridge who had papers showing that they were physically unfit for military service, or had been rejected for other reasons by the Belgian authorities.* All students, therefore, who wish to avail themselves of the hospitality offered by the University of Cambridge and of the courses arranged by the

Belgian professors are requested to present themselves for medical examination before the proper authorities, and to obtain, in the event of their being rejected, a certificate to that effect. These arrangements have been made after direct consultation with the Belgian Government, which was good enough to send to Cambridge some few weeks ago, from Havre, an ex-Minister of Justice, who clearly explained the view of the Belgian authorities, and these views have been loyally adopted and followed in Cambridge.

Any student who wishes to avail himself of the opportunities offered by Cambridge should communicate with Mr. J. T. Sheppard, King's College, hon. sec. of the General Committee, or Mr. E. Bullough, Gonville and Caius College, hon. sec. of the Academic Committee. Genuine students at Belgian universities, who are members of the Allied Forces, *i.e.* French, Russian, Japanese, Servians, Montenegrins, are welcomed on the same terms as the Belgians. All are expected to observe the not very rigorous rules of the university which for a time is their host. Students at Belgian universities belonging to neutral countries, Sweden, Spain, Mexico, etc., are welcomed, but they must pay their way.

Classes in English for Belgian students have for some weeks been in progress, and they are graded carefully according to the needs of our guests. Those who have an adequate acquaintance with our language are following the ordinary university courses.

As an example of what is going on we append the list of lectures for the engineering course, and that for the students in commercial science. It seems to be a custom of the Belgian universities to have one complete week-day holiday in the week, and this day is not the same day in the varying faculties. It may be of interest to those who read NATURE abroad to add a list of the resident Belgian professors in Cambridge, but this is necessarily incomplete.

Dr. Arien (Louvain), Prof. Bomerson, Prof. Breithof (Louvain), Prof. Carnoy (Louvain), Prof. Colson (Liège), Prof. Corbiau, Prof. De Groote, Prof. Déjace (Liège), Dr. Devigne (Liège), Prof. Léon Dupriez (Louvain), Prof. Van Gehuchten (Louvain), Prof. Gillet, Prof. Van Hecke (Louvain), Prof. Canon Van Hoonacker (Louvain), Prof. de La Vallée-Poussin (Ghent), Prof. Magnel, Prof. Nisot, Prof. N. Sibenaler, Prof. Steels, Prof. Van den Ven (professor of Byzantine Greek), Prof. Vanderstappen.

COURS ORGANISÉS À CAMBRIDGE POUR LES ETUDIANTS DES ECOLES D'INGÉNIEURS ET DE LA FACULTÉ DES SCIENCES.

A. *Ecoles d'Ingénieurs.*

(Local : Engineering Laboratory, Free School Lane.

LUNDI.—10h. à 11h. Calcul infinitésimal (Mr. V. Nisot). $11\frac{1}{2}$h. à 13h. Résistance des Matériaux (traction, compression, cisaillement, flexion et torsion) (Mr. A. Van Hecke). 16h. à 18h. Géométrie descriptive, Géométrie descriptive appliquée, Graphostatique et travaux graphiques (Mr. F. Breithof). 16h. à 19h. Projets de résistance des Matériaux et de Stabilité des Constructions (Mr. Magnel).

MARDI.—16h. à 18h. Géometrie descriptive, Géométrie descriptive appliquée, Graphostatique et travaux graphiques (Mr. F. Breithof). $17\frac{1}{2}$h. à 19h. Théorie du travail de déformation des solides élastiques (Mr. Magnel).

MERCREDI.—11h. à 13h. Essai des Matériaux (Mr. A. Van Hecke). 16h. à 19h. Projets de résistance des Matériaux et de Stabilité des Constructions (Mr. Magnel).

JEUDI.—11h. à 12h. Calcul infinitésimal (Mr. V. Nisot). 16h. à 18h. Projets de résistance des Matériaux et de Stabilité des Constructions (Mr. Magnel).

VENDREDI.—11h. à 13h. Essai des Matériaux (Mr. A. Van Hecke). 16h. à 18h. Projets de résistance des Matériaux et de Stabilité des Constructions (Mr. Magnel).

SAMEDI.—11h. à 13h. Stabilité des Constructions (Ponts et Charpentes (Mr. A. Van Hecke). $17\frac{1}{2}$h. à 19h. Théorie du travail de déformation des solides élastiques (Mr. Magnel).

Mécanique appliquée (Mr. N. Sibenaler) aux jours et heures à déterminer. Matériaux de Construction (chaux et ciments) (Mr. A. Van Hecke), aux jours et heures à déterminer.

B. *Faculté des Sciences.*

(Local : Laboratoire de Chimie, Pembroke Street.)

MARDI.—11h. à 12h. Chimie organique (Mr. E. Colson).

SAMEDI.—11h. à 12h. Chimie organique (Mr. E. Colson).

Ces cours ne sont pas destinés à remplacer l'enseignement donné par les Ecoles d'Ingénieurs et par la Faculté de Sciences en Belgique, ni à préparer directement aux examens légaux. Ils ont pour seul but de maintenir les étudiants belges. réfugiés en Angleterre, dans les habitudes de travail et de contribuer à leur formation scientifique.

COURS ORGANISÉS POUR LES ETUDIANTS BELGES DES DIFFÉRENTES ECOLES SUPÉRIEURES DE COMMERCE.

Première Année.

LUNDI.—9h.-10h. Economie politique (Mr. Déjace). 10h.-11h. Sciences Commerciales : Comptabilité (Mr. Vanderstappen).

MARDI.—9h.-10h. Droit Civil (Mr. Bomerson). 10h.-11h. Sciences Commerciales : Arithmétique (Mr. Vanderstappen).

MERCREDI.—9h. - 10h. Sciences Commerciales : Comptabilité. 10h.-11h. Sciences Commerciales : Arithmétique (Mr. Vanderstappen).

VENDREDI.—9h.-10h. Droit Civil (Mr. Bomerson, à l'Ecole de Droit). 10h.-11h. Sciences Commerciales : Comptabilité (Mr. Vanderstappen).

SAMEDI.—9h.-10h. Sciences Commerciales : Algèbre financière (Mr. Vanderstappen). 10h.-11h. Economie politique (Mr. Déjace).

Seconde Année.

LUNDI.—9h.-10h. Economie Politique (Mr. Déjace). 10h.-11h. Sciences Commerciales : Fonds publics (Mr. De Groote).

MARDI.—9h.-10h. Sciences Commerciales : Comptabilité des Sociétés Commerciales (Mr. De Groote). 10h.-11h. Droit Commercial (Mr. Bomerson).

MERCREDI.—9h. - 10h. Sciences Commerciales : Algèbre financière (suite de 1re année). 10h.-11h. Sciences Commerciales : Comptabilité des Sociétés Commerciales (Mr. De Groote).

VENDREDI.—9h. - 10h. Sciences Commerciales : Algèbre financière (suite de 1re année) (Mr. De Groote). 10h.-11h. Droit Commercial (Mr. Bomerson).

SAMEDI.—9h. - 10h. Sciences Commerciales : Comptabilités spéciales (Mr. De Groote). 10h.-11h. Economie politique (Mr. Déjace).

Les cours de Sciences Commerciales se donnent à l'Ecole de Droit, Downing Street.

PROF. AUGUST WEISMANN.

THERE is a strange and peculiar pathos in the death of this great man, formerly the friend, we may hope to the last the friend, of so many English naturalists, and in the thought that the gulf which had opened between us can never be bridged. For Weismann was among those who publicly renounced the marks of distinction which had been conferred upon them in this country.

In the limited space which is available, it is only possible to touch upon the main subjects of Weismann's scientific career. His earliest researches were physiological and histological, the first publication, on hippuric acid (1858), being followed by a series of six papers on the nervous and contractile tissues (1859–1862). Abandoning this subject, except for a single paper on muscle published in 1865, he threw himself with the utmost energy into his classical work upon the embryonic and post-embryonic development and metamorphosis of insects, producing five memoirs between 1862 and 1864, and a sixth in 1866. In the great monograph on the post-embryonic development of the Muscidæ (1864) the building up of the perfect form in the pupa is studied in detail, and it is shown that, in insects with a complete metamorphosis, the tissues undergo a breaking down or histolysis into an apparently simple and primitive mass, from which the imago is built up afresh by, as it were, a second embryonic development. Thus the long series of slightly modified progressive steps by which, in the more ancestral groups, the earliest stage is transformed into the latest, has been shortened, in the more recent forms, into a single intermediate stage in which everything is broken down and built up again from the beginning, establishing the truth of Aristotle's statement that "the chrysalis has the potentiality of the egg."

Insect development was followed by a great series of memoirs (1874–1880) on the minute Crustacea—Daphnids and Ostracods—and these again by the epoch-making researches into the sexual cells of the Hydrozoa, published in four papers between 1880 and 1882, and, in 1883, in the great quarto monograph, "Die Entstehung der Sexualzellen bei den Hydromedusen." With the appearance of this work Weismann's eyesight became too weak for prolonged microscopic research, and he turned to other and more general problems of thought and inquiry.

Weismann was attracted early in his career towards the problems of the history and causes of evolution. "The Origin of Species" appeared in the year following the publication of his first paper, and in 1868 he brought out "Ueber die Berechtigung der Darwin'schen Theorie," followed in 1873 by his paper on the influence of isolation, written in answer to Wagner. The "Studien zur Descendenz-Theorie" (1875) included a variety of subjects treated from the evolutionary point of view—the seasonal dimorphism of butterflies, the markings of caterpillars, phyletic parallelism, the transformation of the Mexican axolotl, and the mechanical conception of nature. This important and stimulating work, translated into English with many additional notes by Raphael Meldola, and with a preface by Charles Darwin, was published in 1882. The present writer well remembers the interest with which he looked forward to the parts as they successively appeared, and the instant resolution to continue some of the lines of work.

The central thought which branched forth so luxuriantly during the last thirty years of Weismann's life sprang from his researches on the sexual cells of the Hydrozoa. By these he was led to conclude that, however ordinary their appearance, the germ-cells contain something essential for the species, something which must be carefully preserved and passed on from one generation to another. It was this conclusion, so Weismann told the present writer in 1887, which led directly to the hypothesis of "The Continuity of the Germ-plasm," with all its far-reaching consequences. In Darwin's pangenesis the germ-cells are derived from the body-cells, whereas in Weismann's contrasted hypothesis the body is an outgrowth from the germ. From this conception Weismann was led to contrast the mortal soma with the potentially immortal germ, and to question the hereditary transmission of acquired characters. Excluded from the Darwinian interpretation of germinal variation as a consequence of gemmules dispatched to the germ by environmentally modified body-cells, Weismann looked for the origin of variation in the kaleidoscopic combination of innumerable ancestral factors brought about by sexual reproduction. He thus sought to explain the meaning of sexual reproduction itself as well as the events which lead up to the fusion of the male and female germ-cells.

The subjects thus briefly enumerated, treated in eight memoirs published between 1881 and 1888, were translated and appeared in a collected form in this country as "Essays upon Heredity and Kindred Biological Problems" (1889). The translation of four additional memoirs (1886–1891) was published as a second volume in 1892, the year in which he produced "The Germplasm," translated by Prof. W. Newton Parker, and published in this country in 1893. An elaborate and remarkable hypothesis, "Germinal Selection" (1896) was followed by the comprehensive treatise on the evolution theory, which brought his long and fruitful life-work to a close. The two volumes passed through three editions between 1902 and 1913, the English translation by Prof. and Mrs. J. Arthur Thomson appearing in 1904, the year of the Festschrift, which celebrated Weismann's seventieth birthday.

Weismann was a naturalist keenly interested in living nature, as may be inferred from "Das Thierleben im Bodensee" (1877), the fruit of many a holiday spent in the study of aquatic life. He was a delightful and sympathetic companion, possessed of a noble simplicity. To younger men he was generous and sympathetic, and many will remember the encouragement they received from

his kindly appreciation. Apart from scientific work Weismann found his chief recreation in music, and with Huxley he could quote Landor's line—

I warmed both hands before the fire of life.

Throughout a long and energetic life Weismann worked with enthusiasm and success at the subjects nearest to his heart. Many have done the same, but there are few whose chosen labours have done so much to stimulate the work and the thought of others. E. B. P.

NOTES.

THE collections made by the well-known naturalist and sportsman, Mr. C. V. A. Peel, during the travels and hunting expeditions of twenty-four years, have for long formed a centre of attraction in the city of Oxford. They are housed in a specially-built museum in the Woodstock Road, and include many objects of considerable scientific interest. Among the mammals preserved in the collection are well-mounted examples of the African and Indian elephants, a fine head of the so-called "white" rhinoceros, and a good specimen of the Somaliland eland. Many other species of African antelopes are well represented. The collections are also rich in birds, reptiles, and fishes, the latter including some fine and well-preserved examples of the Salmonidæ. The insects and arachnida, several of which were new to science, collected by Mr. Peel in the "horn" of Africa during the years 1895 and 1897, formed the subject of a paper in the Zoological Society's Proceedings for 1900. His adventurous journeys in that region were fully described by him in his book, "Somaliland," published in 1899. The more important invertebrate captures have been lodged in the Hope Collection at Oxford, and in the British Museum (Natural History), but the remainder, together with the extensive series of vertebrates above referred to, and the building in which they are displayed, have now been generously presented by Mr. Peel to the city of Oxford.

IN reply to a question as to British manufacture of synthetic dyes asked in the House of Commons on Monday, November 23, Mr. Runciman said:—"Since the beginning of the war the earnest attention of his Majesty's Government has been given to the best means of averting the grave danger of stoppage of employment in the textile and other industries which depend upon a supply of colours owing to the interruption of imports from Germany. Emergency measures are already being taken to secure for the time being the continuity of supply of dyestuffs by encouraging the immediate development of existing sources in the United Kingdom and elsewhere. In addition, however, the inquiries of the Government have led them to the conclusion that the excessive dependence of this country on a single foreign country for materials of such vital importance to industries in which millions of our workpeople are employed constitutes a permanent danger which can only be remedied by a combined national effort on a scale which requires and justifies an exceptional measure of State encouragement. Accordingly the Board of Trade has entered into consultations with the principal interests concerned with a view to the elaboration of a scheme for the establishment of an undertaking for the production of synthetic dyes and colours. In the main it is hoped that the capital required will be forthcoming from the industries by which dyes and colours are mainly used, but the Treasury is prepared within certain limits, and subject to certain conditions, to afford financial support to a well-considered scheme which will be permanently under British control. I am not prepared at the moment to enter into fuller details, because several matters are still the subject of confidential negotiations, but further information will be made public as soon as practicable."

THE death is announced, at sixty-six years of age, of Dr. G. F. W. Thibaut, registrar of the University of Calcutta since 1906, and formerly assistant to Prof. Max Müller, in the preparation of the later volumes of the great edition of the "Rig Veda," as well as the smaller text edition, and principal of the Muir Central College, Allahabad.

WE regret to see the announcement of the death on November 20 of Dr. J. Burney Yeo, Emeritus Professor of Medicine, King's College, London, and author of "A Manual of Medical Treatment," "Food in Health and Disease," "The Therapeutics of Mineral Springs and Climates," and numerous articles and papers published in medical and other journals.

THE death is announced from Bulawayo of Mr. R. N. Hall, author of "Prehistoric Rhodesia" and a number of papers on South African races and traditions. Mr. Hall arrived at the conclusion that the old mines and ruined temples of Rhodesia, including the Zimbabwe temple, date from ancient times, and were due to Semitic immigrants—a view opposed to that reached by Dr. R. Maciver in "Mediæval Rhodesia," in which it is held that the buildings at Zimbabwe are the work of a native race of comparatively modern times.

THE most important contribution to the August issue of the *National Geographic Magazine* is an account by Messrs. Ellsworth and Emery Kolb of their experiences in the Grand Cañon of Arizona. The writers have lived for twelve years at the head of the Bright Angel trail, and from this point have made repeated excursions into this stupendous gorge. The first part of the article describes a trip to what is considered the most beautiful of the tributary cañons, that of Cataract Creek; the second an exploration of the cañon of the Little Colorado; the third a repetition of Major Powell's famous journey down the Green and Colorado rivers. The article is illustrated by a splendid collection of photographs procured at imminent risk to life and limb. The monograph fully describes the geography, scenery, and geological features of this remarkable gorge.

IN the issues of the *National Geographic Magazine* for September and October, the immense stock of photographs at the disposal of the National Geo-

graphic Society of Washington has been drawn on to supply a more vivid and instructive record of the countries engaged in the present war than has hitherto appeared in any British publication. France, Belgium, Germany, Hungary, and England are each in its turn illustrated by admirable views of scenery, architecture, and country life. Prof. R. G. Usher, professor of history in the University of Washington, dealing with England, "the oldest nation of Europe," gives a survey of its historical progress and industrial resources in relation to the present war. He sums up the situation by remarking: "While no one who is truly candid will deny that England has still much to attain in political and social consciousness and a long road to travel before the national consciousness will become instinctive upon aught but the simplest subjects, he will still be compelled to admit that England has progressed further in spiritual national consciousness than any other community in the world simply because the early attainment of territorial and racial unity enabled the ancestors of the present Englishmen to begin living together long, long before the final elements of other nations had been assembled."

An interesting phase in the evolution of art is discussed by Mr. F. G. Speck in his monograph on the double-curve motive in north-eastern Algonkian art, published as Memoir 42 by the Department of Mines, Canada. After fully describing, with abundant illustrations, the development of this form of decoration, he arrives at the conclusion that we find in it an originally non-symbolic decorative element, presumably an indefinite plant or floral figure, common to all members of the north-eastern Algonkian group both north and south of the St. Lawrence. Passing from this primary area, the motive has been borrowed by other western tribes, mostly Algonkian, and subjected to local modification. Among the Penobscots and perhaps their eastern neighbours the double curve has acquired, to a certain degree, a symbolic value due to contact with the more politically complex Iroquois. These positions, he admits, may require modification when the study of symbolism among the tribes east of the Penobscots, and the inter-relation between their art as a whole and that of the Iroquois, come to be more carefully investigated.

The twenty-second report of the Board of Health on leprosy in New South Wales for the year 1912 has been issued. On January 1 of that year only eighteen persons remained under detention at the lazaret. During the year five persons were reported to the Board as being suspected lepers, of whom four were certified as suffering from leprosy. Details are given of the condition of these new patients and of the methods and results of the treatment of the old cases.

The National Council for Combating Venereal Diseases was inaugurated at the Royal Society of Medicine on November 11. The gathering was a distinguished one, and representative of widely different interests. The aims and objects of the council are the following:—(1) To provide accurate and enlightened information as to the prevalence of these diseases, and as to the necessity for early treatment. (2) To promote the provision of greater facilities for their treatment. (3) To increase the opportunities of medical students and practitioners for the study of these diseases. (4) To encourage and assist the dissemination of a sound knowledge of the physiological laws of life in order to raise the standard both of health and conduct. (5) To co-operate with existing associations, to seek their approval and support, and to give advice when desired. (6) To arrange, in connection with such organisations, for courses of lectures, and to supervise the preparation of suitable literature. (7) To promote such legislative, social, and administrative reforms as are relevant to the foregoing aims and objects.

In the course of a paper on the birds of Costa Rica, published in the September number of *Zoologica*, Mr. L. S. Crandall remarks that the alleged scarcity and shyness of the brilliantly coloured king-vulture are not borne out by his experience, several of these birds allowing themselves to be approached within a distance of forty yards while feasting on a carcase. In a second article Mr. C. W. Beebe discusses the Himalayan and Far Eastern kalij-pheasants of the genus Gennœus, and concludes that the number of species has been much exaggerated.

At the conclusion of an article on the responses or reactions of animals and plants to stimuli—as exemplified by changes in function, structure, and colour induced, either directly or indirectly, by external conditions—published in the *American Naturalist* for November, Prof. V. E. Shelford remarks that, in his opinion, the doctrines of purposeful advantageous response, of natural selection, and of the continuity of the germ-plasm cannot be accepted in their entirety. "Each appears to have arisen from a recognition of certain more or less unconsciously selected and uncritically determined phenomena by each of several men who secured different facts and attempted explanations."

In the November number of *Wild Life*, Mr. Russell Roberts, who, we believe, is now serving with the army, resumes the account of his personal experiences of African big game, dealing in this instance with the black rhinoceros, of which several striking photographs are given. The author totally discredits the alleged excessive ferocity of this species, remarking that reports to this effect are for the most part due to want of sufficient acquaintance with the animal. A wonderful photograph of a sedge-bird, by Mr. Lodge, and a second of waterfowl on the lake in Woburn Park are other features of this issue. An article on the Zoological Gardens is marred by the statement that certain Australasian marsupials range as far *east* as New Guinea.

San Francisco has started a new journal, to be published quarterly by the California Fish and Game Commission, under the title of *California Fish and Game*, the first number of which appeared in October. California, it seems, has not yet fallen into line with the neighbouring States in the matter of the prohibition of the sale of wild ducks and other wild table-birds; and it has been made a ground of complaint

that wild ducks reared in Oregon and Washington migrate into California, where they are ruthlessly shot and sold. A Bill was introduced into the local legislature last year with the object of remedying this state of affairs, but was defeated as the result of a *plébiscite*. The greater portion of the contents of the first number of the new issue is devoted to arguments in favour of amending the present anomalous condition of affairs.

WE have much pleasure in congratulating the Royal Zoological and Acclimatisation Society of Victoria on the attainment of its "jubilee." In the fiftieth report of the council, for 1913, it is stated that the first buildings in the then newly-formed gardens at Melbourne were erected in June, 1862. The early efforts of the society were entirely restricted to acclimatisation, and it was not until 1870 that "Zoological" was added to its title, and that foreign animals were imported solely for the purpose of public exhibition. Judging from the photographs in the jubilee report, the collection of such imported animals must now be a fine one, but to an English eye the greatest attraction of the Melbourne Gardens must be the native Australasian species, among which we may specially refer to a group of tree-kangaroos or tree-wallabies, photographed amid the branches of a tree, in the report.

ACCORDING to the report of the general meeting held on November 17, the Zoological Society is suffering severely from the collateral effects of the war, the number of visitors to the gardens during August, September, and October being 307,826, or 124,154 fewer than during the corresponding period of 1913. The total number of visitors during the year has so far been 1,011,526, and the take of gate-money 23,786*l*., or a decrease in the number of visitors of 75,059 and in the receipts of 2879*l*., as compared with the first ten months of last year. Nevertheless, the fact that on October 25 the number of visitors who had passed the turnstiles during the year reached a million is a record which has been equalled only twice during the last eighty-six years. Eighteen new fellows were elected, and twenty-one candidates for the fellowship or honorary membership and eight for the corresponding-membership were proposed. The number of fellows hitherto elected during the year is 263, or three fewer than in the corresponding portion of 1913, this being, however, an increase of forty-seven above the average at the corresponding date for the last ten years. During August, September, and October 620 additions had been made to the menagerie—444 by presentation, 51 by purchase, 58 on deposit, 29 by exchange, and 38 born in the gardens.

IN the *Ophthalmic Review* for September, Dr. Edridge-Green publishes a short account of his theory of vision, and adduces the facts and arguments which have led him to its adoption. According to this theory the cones are the only terminal perceptive visual organs, the function of the rods being confined to the formation and distribution of visual purple. Vision he supposes to take place by stimulation of the cones through the photo-chemical decomposition of the liquid in which they are bathed, this liquid being sensitised by the visual purple. As against the argument that the visual purple is absent from the macula lutea, the region of most distinct vision, he adduces two observations by Devereux Marshall and himself on the eyes of monkeys which had been kept in the dark for forty-eight hours before being killed. He states that in these circumstances the yellow spot was the reddest part of the whole retina owing to the diffusion of visual purple from the surrounding parts of the retina between the cones. It is a pity that these observations have not yet been confirmed. Assuming their correctness, Dr. Edridge-Green brings forward many other considerations which tell in favour of his view. An important point in his argument is the absence of qualitative difference between central and peripheral vision, and he is supported by Tschermak, Hering, Hess, and Garten in his assertion that the difference between the vision of foveal and parafoveal areas is merely quantitative. The difference between the sensibility of the light and dark adapted eye he shows to be analogous to the difference in the spectral distribution of chemical effect with varying intensities of illumination. Several subjective visual phenomena are shown by him to agree with the theory.

A USEFUL paper by Mr. B. C. Wallis entitled, "The Distribution of Rainfall in the North-eastern United States: its Causes and Results," is published in the *Scottish Geographical Magazine* for November, based upon observations contained in the annual report of the United States Weather Bureau. The area embraces districts in which corn, cotton, and tobacco are cultivated, and various maps and diagrams show by means of "equipluves," or lines of equal average rainfall coefficients or percentages, the areas and dates of the wettest and driest months, and consequently the districts where such industries can best be carried on. The diagrams show, among other things, (1) that the maximum rainfall occurs between 130 and 140 per cent. of the normal, and that the minimum occurs between 70 and 80 per cent. of the normal, and (2) that in the north the rise in the rate of precipitation is faster than the fall, while in the Ohio valley and to the south-east the opposite is the case. The method is admittedly not new; it is fully explained in the Quart. Journ. Roy. Met. Soc. for October last (p. 311), and in an instructive note (p. 322) Mr. C. Salter states that a very similar method (the results of which were embodied in a paper to the society on November 18) has been for some years adopted by the British Rainfall Organisation. The usual *monthly* rainfall averages are expressed as percentages of the *annual* value at each station; in this way some "exceedingly interesting facts" are disclosed, with many fewer stations than are necessary when dealing with maps of actual monthly averages.

AN abstract of the results obtained by Mr. H. L. Curtis, of the Bureau of Standards, during his tests of the resistivities of nearly seventy insulating materials, appears in the Journal of the Washington Academy of Sciences for October 19. In all cases contact with the material was made by means of mercury electrodes, and the effects of surface leakage were eliminated by the use of a guard ring. The temperature of the specimen and the humidity of the

surrounding air do not affect the order of magnitude of the results, but for the best insulators the time of application of the voltage has a serious influence on the values obtained. Some of the most useful results are:—Fused quartz, special paraffin, and ceresin, all over 10^{18}; micas from 10^{17} to 10^{13}; sulphur, 10^{17}; bakelite, 10^{16} to 10^{11}; glass, 10^{14} to 10^{12}; unglazed porcelain, 10^{14}; paraffined wood, 10^{12} to 10^{11}; marble, 10^{11} to 10^{9}; and slate, 10^{8} ohms per centimetre cube. One of the most noticeable features of the table given by the author is the great difference between the insulating properties of different specimens of materials going by the same name.

A VERY interesting example of an experimental steam engine and accessories has just been supplied to the Marine School, South Shields, by Messrs. W. Sisson and Co., Ltd., of Gloucester. An illustrated description of this engine appears in *Engineering* for November 20. The engine is of the quadruple expansion type, and has four cylinders operating on four cranks, set at such angles as to give the best balancing results. The arrangements permit of the engine being run as a triple-expansion or compound engine, as may be found expedient for experimental purposes. The high-pressure cylinder is jacketed, and is provided with Meyer's expansion gear, operating on piston valves. The first intermediate cylinder is also steam-jacketed, and has a piston valve of the maker's special labyrinth type. The second intermediate and low-pressure cylinders have single-ported, flat-faced slide valves. Each cylinder has Stephenson's link-motion reversing gear. The engine drives either a dynamo or a Heenan and Froude dynamometer. The air-pump is of the ordinary single-acting type, and the surface condenser is independent of the engine.

A GREAT deal of experience has now been acquired regarding the cost of operating and maintaining systems of substations required in electric railway installations, and Dr. H. F. Parshall read a paper at the Institution of Civil Engineers on November 17 having for its object the assisting towards the standardisation of electric railway substation practice. The number of independent variables when a complete system with substations has to be dealt with is so great that the mathematical expression, from which might be deduced the minimum cost, would in practice be open to some suspicion. Hence the author gives in the paper a complete balance-sheet embodying every item for each case; without any great amount of labour, the methods and results given may be applied to practically any class of electric railway installation. Curves are also given showing the arrangements of substations that will operate different train services on different electrical systems, and at various voltages with a minimum total operating cost. Curves are included illustrating the advantages gained by working at high voltages, and these confirm Dr. Parshall's view that with the present arrangement of rotary-converter substations, there is little advantage in a higher voltage than 2400 for the track conductor.

ERRATUM.—On p. 318, col. 2, line 9 from bottom, for "miles" read "metres."

OUR ASTRONOMICAL COLUMN.

COMET NEWS.—Comet Delavan (1913*f*) is a morning object but situated low down. The following two-day ephemeris has been communicated by the Observatory of Copenhagen, and is a continuation of that which appeared in the *Astr. Nachr.*, No. 4756:—

Ephemeris 12h. Mean Time Berlin.

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
Nov. 25	15 37 56	+6 9·3	
27	42 16	5 2·0	5·2
29	46 31	3 56·5	
Dec. 1	50 39	2 52·6	5·2
3	15 54 41	+1 50·2	

Last week the elements and ephemeris of Lunt's comet (1914*d*) were given in this column. It seems that this comet was discovered independently by several observers, and the Lick Observatory Bulletin No. 262 gives the elements and ephemeris of Comet 1914*e* (Campbell), which refers evidently to the same object. In this bulletin it is stated that the first telegraphic announcement from the Harvard College Observatory described it as a bright comet seen in the southern constellation Doradus by Leon Campbell at Arequipa. As the ephemeris given in this column last week differs slightly from that printed in this bulletin, a portion of it is reproduced below:—

Greenwich Mean Midnight.

	R.A. (true) h. m. s.	Dec. (true) ° m. s.
Nov. 25·5	21 54 45·0	+9 58 43
27·5	56 1·3	10 19 52
29·5	57 20·8	10 40 28
Dec. 1·5	58 42·9	11 0 35
3·5	22 0 7·7	+11 20 17

In *Knowledge* for November, Dr. Crommelin gives an interesting account of former appearances of Encke's comet, together with a chart illustrating the approach of this object to Mercury about twelve days after its perihelion passage, which occurs on December 5 next. The comet, he states, is likely to be a conspicuous object in November. The following is a portion of the ephemeris which he publishes:—

Ephemeris for Berlin Noon.

	R.A. h. m. s.	Dec. ° ′
Nov. 26	14 41 46	−10 16
30	14 57 33	14 20
Dec. 4	15 17 20	18 3
8	15 41 12	21 18
12	16 7 27	23 54
Dec. 16	16 34 6	−25 50

Mr. Denning, in the *Observatory* for November, communicates a short article on Encke's comet, and gives a table of all the comet's returns, with the dates of its redetection and periods.

SPARK SPECTRUM OF NICKEL UNDER PRESSURE.—Attention has often been directed in this column to many investigations regarding the fact that the wave-lengths of spectrum lines, determined from measurements in the solar absorption spectrum, display small differences when they are compared with the measurements of the same lines in spectra secured from terrestrial light sources. Numerous observers have attributed these discrepancies to the effect of pressure, but more recently Mr. Evershed has ascribed the solar displacements to Doppler effects. It is of importance, therefore, to pursue the study of the effect of pressure on the behaviour of lines in spectra, and in this connection the investigation of the spark spectrum of nickel which has been completed by Mr. E. G. Bilham

(*Phil. Trans.*, Roy. Soc., Series A, vol. ccxiv., pp. 359–71) will be found a useful piece of research. In the present investigation the effect of pressures up to ten atmospheres above the normal atmospheric pressure has been studied, the work having been carried out at the Imperial College of Science and Technology at South Kensington. Details regarding the method employed, the spectroscope, measuring apparatus, etc., are stated briefly, followed by descriptions of the character of the lines studied, results of measures, classification of shifts, and the behaviour of some special lines.

Summarising the results, it may be stated that the lines exhibit a variety of behaviour, and have been divided into five classes depending on the types of reversal and broadening. The enhanced lines were observed to decrease in intensity and broaden symmetrically with increase of pressure. The general effect of pressure on the relative intensities of the lines is similar to that of including self-induction in the spark circuit; pressure also causes gas lines to disappear. The displacement of all lines is towards the red. The average shifts are the same for symmetrical as for unsymmetrical reversals, but the shifts are larger for unreversed than for reversed lines, and are greatest for lines broadening unsymmetrically towards the red. Mr. Bilham finally directs attention to two lines (3514·14 and 3608·98 approx.) the abnormal behaviour of which under pressure suggest that they are enhanced lines. Two excellent plates accompany the paper, reproducing three portions of the spectrum of nickel under the pressure of one, six, and eleven atmospheres, and the abnormal behaviour of the last two lines mentioned above.

THE BERKELEY ASTRONOMICAL DEPARTMENT.—The results of the researches carried out in the Berkeley Astronomical Department, under the auspices of the University of California, are printed in the established Lick Observatory publications. Vol. vii. of the Publications of the Lick Observatory, recently issued, is devoted completely to a number of researches carried out under the director, Prof. A. O. Leuschner, at the above-mentioned institution. The volume consists of ten sections, some of which have already been issued in separate parts, but others have been delayed in printing owing to lack of funds. The papers are chiefly devoted to methods of determining orbits, the short methods of computation by Prof. A. O. Leuschner being the more extensive. Among the other contributions are the elements of Asteroid 1900 GA by A. O. Leuschner and Adelaide M. Hobe, preliminary elements of comet 1900 III. by R. H. Curtiss and C. G. Dall, tables for the reduction of photographic measures and investigation of the Repsold measuring apparatus by Burt L. Newkirk, and a research on astronomical refraction by Russell T. Crawford.

GEOLOGICAL WORK IN INDIA AND ITS BORDERLANDS.

THE series of publications maintained by the Geological Survey of India allow scope for memoirs on all branches of geology. We may select for mention the following typical papers from recent issues of the Records.

In vol. xli. (1912), p. 266, T. D. La Touche describes the Lonar Lake in Berar, in the Central Provinces, and ascribes its steep-sided basin to the sinking back of a mass of lava which once uplifted the surface as a shallow dome. The rocks round the depression are amygdaloidal lavas; but no sign of crater-formation can be traced. W. Christie (p. 276) reports on the sodium carbonates that give a commercial interest to the lake. He points out that potassium, as usually happens, is retained by the insoluble products of the decomposition of the lavas, so that sodium is the main alkali supplied.

The geological results of the Abor military expedition are stated by J. Coggin Brown (vol. xlii., p. 231), whose notes, although taken during rapid movements in a mountainous country, provide a fairly continuous section up the Dihong river. Limestone boulders with crinoids have been found (p. 240), indicating the northern edge of the Gondwana continent. Both in Canada and Burma we have learnt how such traverses along natural highways may help, when correlated, to explain the structure of wide areas.

The director, H. H. Hayden, discusses (vol. xliii., p. 138) the relationship of the Himalaya to the Indo-Gangetic plain, and emphasises, in the consideration of geodetic results, the low density of the alluvium of the plain and of the Siwalik beds that probably underlie it. He concludes that there is no need to suppose the existence of a huge trough filled with alluvium at the foot of the Himalayan range. While Hayford calculated that the layer of isostatic compensation, where the rocks are subject to equal pressure from all directions, lies in North America at a depth of 122 km., Hayden (pp. 145 and 154) suggests that it may occur in India at a very much greater depth. Where slow earth-movements are still in progress, compensation may not be attained in the layers near the surface of the earth. He concludes (p. 167) that "the geodetic evidence seems to confirm the generally accepted view that the Indo-Gangetic depression is a broad basin, shallow on the outer side and sloping gently inwards towards the Himalaya" at a little more than 2°. The range is separated from it "by a steep wall resulting from the series of reversed faults which separate the older geological systems from the younger." This matter has been discussed by Sir T. H. Holland in his address to the geological section of the British Association in 1914.

J. Coggin Brown publishes a series of contributions to the geology of the province of Yünnan, in Western China, and R. C. Burton describes the volcanic rocks (vols. xliii., pp. 173, 206, and 327, and xliv., 1914, p. 85). In these papers recent changes in the course of the Irrawaddy are mentioned, and the river is said to have been shifted by earth-movements in very recent times into higher country to the west of its former line of flow. The volcanoes of the Têng-yüeh area were active in recent or late Cainozoic times; their cones and craters are preserved, and hot springs still occur. Their disposition and the nature of their products indicate (p. 226) that they are a prolongation of the chain which runs through Java and Sumatra. F. R. Reed adds greatly to the third paper by determinations of the Ordovician and Silurian fossils (these results being termed "provisional" in the text and "provincial" on the cover of the records). An interesting Baltic relationship is pointed out (p. 334). A marked change of conditions occurred in Upper Permian times, when the marine limestones with Fusulina and Schwagerina, which mark the Permo-Carboniferous system, are replaced by terrestrial conglomerates and sandstones, with finally a small marine incursion, giving rise to lagoons and salt-beds (vol. xliv., p. 112).

G. E. Pilgrim contributes a paper of the widest interest on the correlation of the Siwaliks with mammal horizons of Europe (vol. xliii., p. 264). The table forming plate 26 shows the Tertiary river deposits of India, opening with the Gaj Beds as Lower Burdigalian or Upper Aquitanian. The Murree Beds are Burdigalian to Tortonian; the Lower Siwaliks extend from the Tortonian to the top of

the Sarmatian of Europe, and the Middle Siwaliks from the base of the Pontian to what is here taken as Lower Pliocene—that is, Placentian. The Siwalik system ends as "Uppermost Pliocene." The Siwalik system is 14,000 to 16,000 ft. in thickness. Another philosophic paper is by G. De P. Cotter, on the value of Nummulites as zone fossils (vol. xliv., 1914, p. 52). This includes a discussion of Hein's view that nummulites depend a good deal on lithological facies. The author believes (p. 67) that the same uncertainty occurs in dealing with Orbitoides (including Orthophragmina and Lepidocyclina).

Aerolites receive much attention in these recent volumes. G. Cotter describes records in India since 1906 (vol. xlii., p. 265); J. C. Brown deals with the fragments that came from a meteor seen to explode at Banswal, near Dehra Dun, on January 18, 1913 (vol. xliii., p. 237); and W. A. K. Christie describes "A Carbonaceous Aerolite from Rajputana," which fell from a meteor at Chhabra, in Tonk, on January 22, 1911. The carbon of this chondritic mass amounts to 2·7 per cent., and the stone is surpassed in this respect by that of Alais alone. The composition of the carbonaceous matter is not graphitic, and is very uncertain.

Among the papers published separately as Memoirs of the Geological Survey of India we may note Prof. C. Diener's general description of "The Trias of the Himálayas." The author (p. 55) draws the boundary between Permian and Trias below the Otoceras beds in the Himalayas, and between the Bellerophon Limestone and the Lower Werfen beds in the Eastern Alps. In correlating the strata, his survey extends through the Malay Archipelago to the Pacific region. The Mediterranean facies of the Trias is shown (p. 149) not to extend into Afghanistan. "The northern borderland of the Indian Triassic province corresponds to the southern shore of the Angara continent (Suess)" (p. 152).

H. H. Hayden's "Geology of Northern Afghanistan" (vol. xxxix., part 1), contains fine illustrations of the crags and "bad lands" of a typically dry country, dissected by seasonal rains. The highest Carboniferous beds are of the Fusulina Limestone type, and the Cenomanian transgression affects the region. T. H. D. La Touche's memoir on the geology of the northern Shan States of Burma (vol. xxxix., part 2) should be studied in connection with J. Coggin Brown's work on Yünnan, cited above. P. N. Datta was associated with the author in the prolonged field investigations. The ruby mines of Burma occur in this region (pp. 34 and 371), and it is now suggested that the gem-bearing limestone is a band of sedimentary origin. The pisolitic ferruginous clays among the recent deposits (p. 322) are compared with the laterite of India; and the dams of calcareous tufa in the streams, originating in calcium carbonate carried down from limestone plateaus, are of interest for comparison with those of Bosnia and Dalmatia (p. 324). The glacial Talchir beds are traced into the little-known state of Korea in the Central Provinces by L. L. Fermor, in a memoir on the coal-resources of the district (vol. xli., part 2); and J. Coggin Brown reports on the Burma earthquakes of 1912 (vol. xlii., part 1).

The folio memoirs issued under the title of "Palæontologia Indica" are continued by G. E. Pilgrim's report (vol iv., Mem. 2) on the vertebrate fauna of the Gaj series, the stratigraphical results of which are utilised in the author's paper on the Siwalik beds, mentioned above. Prof. A. C. Seward, of Cambridge, describes "Lower Gondwana Plants from Kashmir" (vol. iv., Mem. 3) *Glossopteris indica* prevails, and the author throws doubt on the existence of *G. decipiens* as an independent species. He also deals with "Mesozoic Plants from Afghanistan and Afghan-Turkistan" (vol. iv., Mem. 4), which are beautifully illustrated by T. A. Brock. An interesting map on p. 46 shows, with the aid of a table (p. 45), the wide range of many Mesozoic species or of closely allied forms. *Coniopteris hymenophylloides,* for example, is found in Australia, Arctic Europe, Great Britain, and generally throughout Asia. The highly specialised molluscan fauna of the Spiti Shales is studied by Karl Holdhaus (series xv., vol. iv., part ii., fasc. 4), who concludes (p. 398) that these Jurassic strata probably belong to the upper part of the system.

In the Records of the Mysore Geological Department, vol. xi., issued in 1912, W. F. Smeeth (p. 49) refers the laterites of the State to two series, one modern, produced by the superficial decay of various types of rock, and one older, the "great Mysore sheet," originating in materials precipitated from the waters of lakes, and afterwards laid dry and subjected to laterising conditions. On p. 56 Smeeth urges that the so-called fundamental gneiss of Mysore is intrusive in the Kolar schists, and that "Mysore may be regarded as a house in which the superstructure has been underpinned and a new foundation substituted for the original one." The intrusive nature of the gneisses is further emphasised by P. S. Tyengar and B. Jayaram in vol. xii. of the Records, issued in 1914 (pp. 64 and 77).

J. B. Scrivenor has issued through the Government Printing Office at Kuala Lumpur a paper on the geology and mining industries of Ulu Pahang, in the Malay States, a region traditionally supposed to possess immense mineral wealth. After three years' investigation, the author found but little tin-ore, and he concludes that the old workings for gold were made by persons as economical in their habits as those who carry on the work in the very poor alluvial ground to-day (p. 12). He directs attention (p. 32) to the soils of the andesitic Pahang series as likely to furnish a compensation in agricultural prosperity. The petrographic sections, including radiolarian chert, and the landscape illustrations, reproduced in collotype by Bemrose of Derby, are of remarkable beauty. Another work by J. B. Scrivenor, on the geology and mining industry of the Kinta district, Perak (Kuala Lumpur, 1913; price 3 dollars), is equally well illustrated. The author points out (p. 20) how road-cutting and hydraulic mining have been facilitated by the tropical processes of weathering, whereby the ground-water carries away silica in solution, and "hard, unyielding masses are reduced to the consistency of putty." The most important conclusion in this memoir is that the clays and boulder-clays of Perak, which are mined for the detrital tin-ore which they contain, are not of recent origin. They have been penetrated by the local Mesozoic granite, and rest on the Carboniferous Kinta Limestone. Excellent reasons are given (pp. 38–43) for correlating them with the Permian glacial beds of India. It is remarkable that the tin-bearing and tourmalinised Mesozoic granite must have been preceded in this area (p. 35) by a similarly tin-bearing granite, which formed a contact-aureole, and from which the granite boulders and the cassiterite in the glacial clays have been derived.

G. A. J. C.

RAINFALL IN THE PHILIPPINES.

THE Manila Weather Bureau has published a very useful paper on the annual amount and distribution of rainfall over that archipelago, prepared under the direction of the Rev. J. Algué, S.J., by the assistant-director, the Rev. M. S. Masó, S.J. It includes tables showing, *inter alia,* the monthly and annual values for separate years and means for the whole period embraced, which, in most cases, refers

to years since 1902. In an interesting discussion of the data in English and Spanish it is explained that owing to the N.–S. extension of the archipelago and to the main trend of the mountain ranges in the same direction there is much variety in the distribution of the rainfall which is quite opposite in some instances in the eastern and western regions. The latter experience a dry winter and spring and a wet summer and autumn, while in the eastern regions rain is prevalent in autumn and winter. February–April are generally the driest months over the whole archipelago, but as soon as the sun reaches the northern hemisphere thunderstorms and heavy showers become more frequent.

The average yearly rainfall over the whole area is 2400 mm., the extreme values being 900 mm. at Zamboanga (south-west Mindanao), and 4500 mm. at Baguio (west-central Luzon). With some exceptions the average for the northern, eastern, and western coasts exceeds 2000 mm.; it seldom reaches that amount in the valleys, but attains to 2000–3000 mm. in the highlands, and even reaches 4000 mm. in the Baguio plateau at an altitude of 1400 metres. In parts of the east and south-east coasts of Luzon, eastern Samar, and north-east Mindanao, the average is above 3000 mm. There are no large, specially dry regions; whenever a relative failure of rainfall occurs it is generally felt throughout the whole archipelago.

NORTH AMERICAN FROGS AND TOADS.

THE life-histories of North American frogs and toads form the subject of a memoir entitled "North American Anura — Life-histories of the Anura of Ithaca, New York," by Mr. A. H. Wright, just received from the Carnegie Institution of Washington. In the introduction to this highly interesting and well-illustrated work the author acknowledges his indebtedness to Boulenger's "Tailless Batrachians of Europe," published by the Ray Society in 1897–98, which has given the original impetus to and has been taken as the model for his study. The region investigated is at the southern end of Cayaga Lake, and most of the observations were made in the vicinity of Ithaca, New York. The number of Anurous Batrachians included within these limits is small, and only three genera, the widely distributed Bufo, Hyla, and Rana, are represented. The species are the common toad, *Bufo lentiginosus americanus*, the peeper, *Hyla pickeringi*, the tree-toad, *Hyla versicolor*, the leopard- or meadow-frog, *Rana pipiens*, the pickerel-frog, *R. palustris*, the green-frog, *R. clamata*, the bull-frog, *R. catesbiana*, and the wood-frog, *R. silvatica*.

The life-histories of these eight species are very fully described, and are shown to correspond fairly closely with those of their European analogues, on which attention has been bestowed at a much earlier date. Copious notes are given on their first appearance in spring, on their mating, oviposition, and development. Following the example given in the "Tailless Batrachians of Europe," keys are supplied for the identification of the eggs and of the tadpoles. It is to be regretted that the spermatozoa have not been studied. Compared with the European species the tadpole of *R. silvatica* is shown to correspond with that of *R. agilis*, *R. pipiens* and *R. palustris* with *R. arvalis*, *R. clamata* and *R. catesbiana* with *R. esculenta*; *B. americanus* approaches *B. calamita*, and *H. versicolor* *H. aborea*; whilst *H. pickeringi* suggests Bufo in its mouth-parts. Beautiful photographs from life represent specimens in nuptial embrace, the eggs, the tadpoles at various stages of development, males in the act of croaking, etc.

PHYSICS AND ASTRONOMY AT THE BRITISH ASSOCIATION.

THE proceedings of Section A of the British Association in Australia included many interesting papers, and some valuable discussions. The section was fortunate in having a thoroughly representative attendance of English physicists and astronomers, who had made the journey overseas. Amongst those who were present may be mentioned Sir Oliver J. Lodge, Sir Ernest Rutherford, Prof. W. M. Hicks, Prof. A. Gray, Prof. A. W. Porter, Prof. H. H. Turner, the Astronomer Royal, Prof. E. W. Brown, Prof. J. C. Fields, Prof. H. S. Carslaw, Prof. W. E. Cook, and Dr. G. C. Simpson. Dr. C. G. Abbot and Prof. E. Goldstein attended as foreign guests. The local secretaries were Prof. Lyle at Melbourne, and Prof. Pollock at Sydney. The president of the section, Prof. F. T. Trouton, was prevented by illness from making the journey, and his absence was greatly regretted. His duties thus devolved upon the vice-presidents, and Prof. Porter usually acted in his place and bore the brunt of the work. Public interest in the meetings was naturally affected adversely by the outbreak of war, and the attendances at this section were much smaller than has been usual of late years. This was the more unfortunate, because comparatively few papers of a purely specialised and technical character were read, and except on one morning the section was able to meet as a whole.

The meetings opened on Friday, August 14, at Melbourne, with the president's address, which was read by Prof. Porter (see NATURE, August 20, vol. xciii., p. 642). This was followed by the report of the committee to aid the work of establishing a solar observatory in Australia. Prof. Duffield communicated a letter that had been received from the Commonwealth authorities in which it was stated "that in the scheme for the organisation of services in connection with the seat of Government at Canberra, provision has been made for the establishment amongst general astronomical studies of a section to be devoted to solar physics in particular." He also announced that the Premier had consented to receive a deputation from the British Association on the subject. (The deputation, led by Sir Oliver Lodge, waited upon the Premier on the following Tuesday; it was introduced by Mr. Deakin. It was very favourably received, but in the unfortunate circumstances it was felt to be impossible to press for any definite assurances of immediate action.) In this connection a paper on Mount Stromlo Observatory was read by Mr. P. Baracchi, director of Melbourne Observatory. The paper dealt with the suitability of the climatic conditions at Canberra for astronomical work. In 1910 a position was selected about six miles from Canberra, and a small observatory was erected at which observations were made in 1912–13. Evidence was collected which showed that the site was favourable and suitable for the installation of a modern observatory of the first class.

Dr. C. G. Abbot, director of the Astrophysical Observatory of the Smithsonian Institution, read a paper on the variability of the sun. He said that from experiments conducted simultaneously at Mount Wilson, in California, and Bassour, in Algeria, it was found that the intensity of solar radiation (outside the earth's atmosphere) varied through a range of 10 per cent. on different days. The deviations were observed at both stations, so that if, for example, high values were obtained in California, high values were obtained simultaneously in Algeria. The variability is irregular in amount and period, but the range may be as much as 5 per cent. in the course of a week. A connection between the monthly mean values of

the solar radiation and the number of sun-spots was also traced, an increased spottedness of the sun's disc being found to correspond with an increased radiation. It appears, therefore, that the sun, besides varying from day to day, varies also from year to year in accordance with the march of the sun-spot cycle. In addition, observations had been made on the contrast of brightness between the centre of the sun's disc and the limb for different wave-lengths; this also appears to undergo an irregular variation similar to the variation of the total radiation. Further researches on these problems are in progress, including some balloon ascents with self-registering apparatus, in which a height of twenty-two miles has been obtained. Dr. Abbot urged the importance of securing the co-operation of stations widely distributed over the globe to eliminate any local atmospheric influences, and he suggested that work in this branch of solar physics might well be taken up by the proposed new observatory in Australia. A long discussion followed the paper, and, in answer to questions, Dr. Abbot explained the general lines of work which he would like to see carried out in Australia. Dr. Simpson and Mr. Gold discussed the bearing of the results on meteorology. Dr. Abbot showed that a close parallelism existed between the spottedness of the sun and the mean temperature in the United States, the main disturbing factor being the presence of volcanic dust in the atmosphere after some of the great eruptions. These two causes accounted for most of the main features of the temperature curve. Prof. Eddington suggested that a similar irregular variability might be looked for in other stars having spectra resembling the sun's; apparently the amount of variation would be sufficiently great to be detected by differential measures of stellar magnitudes.

The morning's proceedings concluded with a paper by Mr. P. Baracchi on the present state of the determinations of Australian longitudes. The stations at Port Darwin and at Southport (Queensland) are the terminals of two chains of telegraphically determined longitudes, one carried eastward and the other westward from Greenwich. The connection between these two meridians obtained by means of measured longitudinal arcs completes a whole longitude circuit of the globe with a closing error of less than 100 ft.

On Tuesday, August 18, a joint meeting was held with Section B (Chemistry), for a discussion on the structure of atoms and molecules. Sir Oliver Lodge presided. Sir Ernest Rutherford, who opened the discussion, directed attention to the recent accumulation of evidence of the independent existence of the chemical atom. It is no longer merely an hypothesis introduced to explain the laws of chemical combination; we are able to detect and count the individual atoms. We can determine the actual mass of an atom certainly to within a few per cent. The idea that the atom is an electrical structure received a great impetus by the detection of the electron by J. J. Thomson; and, moreover, the Zeeman effect showed that it must be in part electrical. The atomic character of negative electricity is well established; we always find the negative electron, however produced, carrying a definite charge. We have, unfortunately, not the same certainty with regard to the behaviour of positive electricity, for it cannot be obtained except associated with a mass comparable with that of a hydrogen atom. In J. J. Thomson's model of the atom the positive electricity was supposed (for mathematical reasons) to be distributed throughout a large sphere with the negative corpuscles moving inside it. This hypothesis played a useful part in indicating possible lines of advance; but it does not fit in with more recent discoveries, which point to a concentrated positive nucleus. We have now two powerful methods that aid us in determining the inner structure of the atom—the scattering of high-speed particles in transit through matter, and the vibrations of the interior parts of the atom. In C. T. R. Wilson's photographs of the tracks of the α particles through a gas, we notice many sudden bends in the paths; in order to account for these deflections it is found necessary to believe that there is a concentrated nucleus atom (having a certain number of units of charge), in which the main part of the mass resides; outside this there are a number of electrons. The whole dimensions of the nucleus are very small indeed compared with the distance of the outer electrons. From the scattering experiments it appears that the law of force right up to the nucleus is the inverse square law; no other formula would give accordance with the observations. The radius of the nucleus is of the order 10^{-12} cm. in the case of gold, and for a lighter element it is smaller still. Another fact that appears from the scattering experiments is that the number of electrons (outside the nucleus) is about half the atomic weight. There is now fairly good evidence that, if the elements are numbered serially in order of atomic weight, the numbers will actually express the charge on the nucleus. The rate of vibration of the inner parts of the nucleus can now be measured by means of the characteristic X-rays emitted. Each substance has two strong lines in its X-ray spectrum, and as we pass from element to element in order of atomic weight the frequencies of these change by regular jumps. H. G.-J. Moseley has investigated all the known elements in this way, and he is even able to show at what points elements are missing, because at such points the X-ray frequencies make a double jump. In this way he has found that between aluminium and gold only four elements are now missing. It is deduced from these considerations that there is something more fundamental than atomic weight, viz., the charge on the nucleus, and that this is the main factor which controls the frequency of the interior vibrations, the mass having only a slight influence. There are certain elements with identical chemical properties, but different atomic weights; thus radium-B (atomic weight 214) and lead (207) are chemically inseparable and have the same γ-ray spectrum. It is quite clear that some new conception is required to explain how the atoms, having the structure we have supposed, can hold together. N. Bohr has faced the difficulty by bringing in the idea of the quantum. At all events, there is something going on which is inexplicable by the older mechanics.

Prof. Armstrong referred to the new attitude with which the chemical elements were regarded; he had long been prepared to believe that they may eventually prove to be compounds. With regard to the existence of elements of different atomic weights chemically indistinguishable, it is too early to conclude that no method of separation and distinction can be devised. The deduction from the X-ray spectra that very few elements are still missing is scarcely justifiable; it may well be that most of those that are known belong to a *preferred type*, and that this particular series is nearly complete. For the chemist any theory of atomic structure must take fully into account the peculiar valency relationships; the system is admittedly one of extraordinary perfection and simplicity; it should be pointed out, however, that so-called structural formulæ are to be regarded as condensed symbolic expressions of the general behaviour and not as representing the actual structure. Thus the conventional representation of benzene by a plane regular hexagon is quite impossible if the affinities of a carbon atom act tetrahedrally. The variable valency of certain

elements is another difficulty; the variation seems to be determined by some reciprocal relationship between the interacting elements, valency being a dependent variable and not an absolute property. Fresh significance has lately been given to the problems of valency by the conception, due to Barlow and Pope, that it is to be regarded as a function of the volume occupied by the atom. They have in this way succeeded to a remarkable extent in correlating crystalline form with molecular structure.

Prof. Hicks dealt with the subject from the spectroscopic side, *i.e.* from the consideration of an atom as a configuration capable of emitting definite sets of free vibrations. He reviewed the evidence as to the position of helium in the order of the elements. It is assumed by many physicists, including Rutherford, Bohr, and Moseley, that H and He are consecutive elements, having nuclear charges of one and two units respectively. There are several reasons, however, for supposing that there are places for at least two intermediate elements between them; in particular, the theory of Rydberg requires that the atomic number of helium should be 4. In addition to the electrons and positively-charged nuclei, we have to recognise the presence in certain substances of magnetic doublets the strengths of which are multiples of a definite unit, called by Weiss the magneton; whether the magneton has an independent existence or is a consequence of electronic motion is an open question. The formation of spectral series is a very difficult question; neither Thomson's nor Rutherford's model of the atom has shown any aptitude for explaining spectra, and it would seem that the actual structure must be something much more complicated. There is now a general consensus of evidence, theoretical and experimental, that in the case of series the cause of spectral emission is a change in a few atoms (at any one moment) from one configuration to another, with sudden emission of energy. The contrary view, that it is due to small internal vibrations in all the atoms, presents too great difficulties. It does not follow, however, that the whole of the spectral lines are of the character of the series lines, and Nicholson's theory of the coronium and nebulium spectra points to the existence, under the special conditions in the corona and nebulæ, of emission of a different type. Prof. Hicks also reviewed Bohr's theory of spectra, and, whilst admiring its suggestiveness, pointed out the arbitrary character of some of the assumptions, and its limitation to series of the Balmer type.

Mr. H. G.-J. Moseley explained the results of his classification of the elements by their X-ray spectra. The principal frequency ν is given approximately by the formula $\sqrt{\nu} = \text{constant} \times (N - B)$ where B is a constant and N an integer increasing by a unit as we pass from element to element up the periodic table. The order of the elements determined by N is nearly that of increasing atomic weight; there are one or two exceptions, and in such cases the order given by N is evidently the correct order corresponding to chemical properties. For example, the atomic weight gives the order Cl, K, Ar, whereas the X-ray frequency gives the order Cl, Ar, K. The latter is the order required by the periodic table.

Prof. Nicholson defended the main principles of Bohr's theory. Its most striking success is that it gives with great accuracy two fundamental constants—the universal constant of spectra and (as Prof. Fowler has shown) the mass of the electron in terms of the hydrogen atom. But analysis shows that we cannot obtain other spectra from it, *e.g.* the ordinary helium spectrum, without abandoning at least one of Bohr's premises, which is vital to the deduction of the hydrogen formula. Referring to the elements postulated by him in the corona and nebulæ, Prof. Nicholson was prepared to admit that they might not be chemical elements in the ordinary sense; they might rather be the bases of elements. The atomic weights of these elements have been measured by Buisson and Fabry by an ingenious method and agree with those calculated theoretically from the spectra. Nuclear structure (as distinct from the resultant charge) appears to play a considerable part in series spectra, and, in opposition to Rutherford's view, it seems that the nucleus of a hydrogen atom must be something more complex than the positive electron.

Prof. Bassett discussed the bearing of the periodic law on the number of the elements. The periodicity is not of the simple character at first supposed. There are two short periods of 8 elements followed by two long periods of $(2 \times 8) + 2 = 18$ elements. These are followed by much longer periods, possibly of $(2 \times 18) + 2 = 38$ elements. It is tempting to suggest that hydrogen represents a period of 3 elements, because then the short periods would be represented by $(2 \times 3) + 2 = 8$, following the same rule.

Prof. Kerr Grant summarised the difficulty as to the stability of a system consisting of one nucleus and one electron. It was difficult, too, to account for the non-magnetic character of the hydrogen atom with this structure.

The discussion occupied the whole morning, and was followed with keen interest. So many different points of attack on the problem were represented that it could scarcely be expected that any one aspect would be argued out to a conclusion by the different speakers, but, regarded as a symposium, the discussion provided a most useful survey of the present state of our knowledge. A full report is to be printed in the annual volume of the British Association.

The section met again in the afternoon, when Prof. E. Goldstein read a paper on salts coloured by the kathode rays. When the rays fall on certain salts coloration is produced immediately. These colours disappear on prolonged exposure to daylight or when the salt is heated; the rate of disappearance varies greatly for different substances. The characteristic colour and the behaviour on heating afford a means of identifying the substance, and impurities present in very minute quantities can often be discovered in this way, for a very small admixture of the salt suffices. It was at first supposed that the phenomenon was due mainly to a chemical reduction; Giesel and Kreutz obtained analogous colours by exposure of the salts to the vapour of sodium and potassium. But there are important differences between the Giesel colours and those here considered. For example, the former are much more stable when exposed to daylight. Prof. Goldstein showed that stable coloration identical with that obtained by Giesel can indeed be produced by the kathode rays, but as the result of prolonged bombardment in which the salt becomes heated strongly. He calls these "after-colours of the second class" to distinguish them from those of the "first class," which appear immediately on exposure. The colours of the first class depend not only on the metal, but on the acid constituent; indeed, they can be produced in some organic salts which contain no metallic base. There can thus be no question of chemical decomposition; but apparently the matter passes into some changed—possibly polymerised—state which deserves a careful study. Amongst other things the new state is characterised by greatly increased absorption of light. Connected with the loss of coloration by exposure to daylight there is generally a phosphorescence, which follows the exposure. It is possible to produce the same colours by ultra-violet

light, and probably the action of the kathode rays is not direct, but is due to the radiation of ultra-violet light by molecules struck by them. The destruction by the longer waves of daylight of effects produced by the light of short wave-length is a phenomenon of which many other examples occur. The paper was illustrated by specimens of the coloured salts.

Prof. Hicks spoke on the magneton as a scattering agent for α and β particles. The paper dealt with the orbits of charged particles coming into the field of the magneton and the nature of the scattering was explained. Prof. T. R. Lyle gave a demonstration of a mechanical analogue of wireless telegraph circuits.

On Wednesday morning a discussion took place on the problems of Antarctic meteorology. The meeting was fortunate in having the attendance of a number of men of science who were personally familiar with the Antarctic regions. Dr. G. C. Simpson, who opened the discussion, dealt with the main problem of the general circulation of the atmosphere in the southern hemisphere. Dr. Lockyer has suggested that there is an intense anticyclone over the Antarctic continent from which cold air feeds into a ring of large cyclones having their centres about 60° S., and extending northwards as far as 40° S. Prof. Meinardus also has postulated a series of cyclones over the Southern Ocean travelling from west to east; but he finds it difficult to accept anticyclonic conditions over the continent, owing to the great excess of precipitation there which gives rise to the glaciers and snowfields. From a detailed discussion of the conditions in the Ross Sea area Dr. Simpson deduces that the conditions over the continent are anticyclonic. In the lower atmosphere the strong south-easterly blizzards are the result of the large differences of temperature between the barrier and the Ross Sea. In the upper atmosphere the air feeds in again to the Antarctic, as is shown by the cloud observations. Meinardus's objection that in such a circulation the precipitation would not exceed the evaporation is met by a consideration of the great cooling of the air due to radiation. With regard to the existence of a belt of cyclones over the ocean, it appears quite impossible to reconcile wind and barometer observations with any circulation of wind about a low-pressure centre moving from west to east. Further the simultaneous barometer readings at Melbourne, New Zealand, and Cape Adare give no certain indication of the same cyclone affecting the northern and southern stations. Dr. Simpson pointed out an important negative correlation between the pressure at Cape Evans and in Australasia, and urged the importance for Australian meteorology of extensive observations on the Antarctic continent.

Mr. Griffiths Taylor pointed out the importance of the proximity to Australia of this colossal source of cold energy. The Antarctic continent is a much greater land-mass than the Tibetan Plateau; the latter controls the monsoons and has an enormous effect on the Indian climate. Meteorologically the influence of the Antarctic tableland must be a most important fact. Mr. Hunt, Captain Davis, Mr. H. T. Ferrar, Prof. Rudmose Brown, and Mr. Gold also took part briefly in the discussion.

Prof. H. H. Turner then gave an account of the work of the Seismological Committee, referring particularly to the situation of difficulty and anxiety created by the death of Prof. Milne. Progress has been made in the study of the distribution of earthquake centres, and Prof. Turner exhibited a map showing the geometrical relation of these to the land distribution on the globe.

The sitting terminated early, as the members had to leave for Sydney in the afternoon.

The meeting at Sydney opened on Friday, August 21. Sir E. Rutherford spoke first on the origin and nature of the γ rays from radium. Dr. Dyson then read a paper on the stars near the north pole. So far as proper motion is concerned, the area within 9° of the pole is more thoroughly known than any other part of the sky, since the stars down to a faint limit of magnitude, 3700 in number, were observed by Carrington about 1855, and have been re-observed at Greenwich forty-five years later. This region has also been well studied as regards magnitudes, both photographic and visual, the photographic determinations having been made at Greenwich and the visual determinations at Potsdam. From the difference between the photographic and visual magnitudes (called the colour-index) a classification according to spectral type is possible. The proper motions of these stars have been discussed by a statistical method with the view of finding the distribution of the stars in space, particular attention being paid to the differences shown when the stars are grouped according to colour-index. The results which were given by Dr. Dyson are too complex to be summarised here. They bring out in a very striking way the fact that the reddest stars are in the mean at a great distance from us—farther even than the white stars—and that it is the stars in the middle of the spectral series (types F and G) that are closest to the sun. There is good evidence of a considerable diminution in the density of the distribution of the stars between the distances of 100 and 500 parsecs, and the numerical results agree substantially with the diminution found by Kapteyn.

Messrs. Petrie and Chapman gave an account of a curious actinic effect of the juice of *Euphorbia peplus*. The dried juice acts on a sensitive photographic plate in the dark. The effect can be transmitted through black paper impervious to light or through thin aluminium or gold foil. Yet no action on ionised air can be detected with an electrometer. The property is retained after prolonged heating, and a sample dried five years ago is still as active as ever. The juices of many other species of Euphorbia and similar plants have been tested, and have been found to have no comparable action.

Prof. A. Gray read a paper on the attractions of ellipsoidal shells. The principal theorems in the attractions of ellipsoids were deduced by a new and elegant geometrical method.

Papers were also read by Prof. O. U. Vonwiller on the photo-electric effect in selenium, and by Prof. W. G. Duffield on the pressure upon the poles of a carbon arc.

The next meeting was on Monday afternoon, August 24. Prof. Turner gave a paper on discontinuities in meteorological phenomena. The usual methods of harmonic analysis proceed on the assumption that the periodicities looked for persist through the time covered by the observational data. In the case of certain astronomical phenomena, particularly the sunspot cycle, Prof. Turner had arrived at the conclusion that abrupt discontinuities took place from time to time, a change of period taking place at the discontinuity. A simple method was described by which such discontinuities could be detected, and the evidence suitably exhibited. The method was illustrated by applying it to rainfall and other meteorological data for which long records were available. Breaks in the period are found to occur about every seven years. These critical years were determined independently from three separate sets of data, and a good general agreement exists between them.

Prof. Eddington gave an account of a determination of the oblateness of the stellar system. It is well-known that the distribution of the stars is decidedly flattened towards the plane of the Milky Way, and recent counts of stars, made by Chapman and Melotte

at Greenwich, provide a means of making a numerical estimate of the amount of flattening. These statistics extend so far as the seventeenth magnitude, and are directly referred to standard photographic magnitudes. Although magnitude-counts alone are not sufficient to determine the general law of density of distribution of the stars at different distances, yet by comparing the counts in the galactic plane and near the galactic poles the general shape of the surfaces of equal density can be found. The average oblateness is about 1 : 3·5, that is to say, the same falling off in density will be found $3\frac{1}{2}$ times as far away in directions in the galactic plane as at the galactic poles. But the oblateness is not uniform; at greater distances the surfaces of equal density are less flattened; the number given refers to a distance equal to the average distance of stars of about the eleventh magnitude. This value of the oblateness is considerably higher than was anticipated. The Milky Way itself is not included in this estimate, and it probably forms a flat girdle outside the oblate system considered in the paper.

The concluding sitting of the section on Tuesday morning, August 25, attracted a very large attendance, the room being filled to overflowing. Sir Oliver Lodge opened a discussion on radio-telegraphy; he was followed by Mr. Balsillie, Prof. Howe, Dr. Eccles, and others. The meeting was held jointly with Section G (although, owing to their heavy programme, that section was also meeting independently at the same time), and an account of the discussion has appeared in NATURE under the proceedings of the Engineering Section. The large attendance was a tribute to the personality of the opener, but the subject evidently appealed strongly to the general public; from the scientific point of view it was equally satisfactory, and many points of great interest were brought forward.

After the discussion, Prof. Pollock gave an account of some measurements of the wave-length in air of electrical vibrations associated with a thin terminated straight rod.

Mr. Moseley read a paper on high-frequency spectra. The references in the discussion on the structure of the atom to the remarkable results derived from X-ray spectra had aroused much interest; and this fuller account of his researches—postponed from a previous day—was eagerly anticipated. He described the production of the characteristic X-rays of the substance by Kaye's method, and the measurement of their wave-length by reflection of the image of a slit from the surface of a crystal. The elements (from aluminium to gold) were numbered in order with a few gaps left for missing elements; taking this atomic number as ordinate and the square root of the X-ray frequencies as abscissæ, the resulting curves are practically straight lines. In most cases there are two lines in the spectra, and the frequencies of the strong component lie along one straight line in the diagram, those of the weak components along another. It is found (in order to preserve the continuity of the straight lines) that a number must be left vacant for a missing element of the manganese series between molybdenum and ruthenium, and another between tungsten and osmium. These gaps are also indicated by Mendeléeff's table. Much confusion exists in the rare earths as to how many separate elements exist, and the method is able to throw light on this question; there is one element missing between neodymium and samarium. A recent addition to the elements—celtium—is not confirmed by this investigation; the X-ray spectrum indicates that it is a mixture of previously known earths

Prof. Porter read a paper by Mr. Paris and himself on the scattering of light by small and large particles of conducting and non-conducting substances. Suspended particles of sulphur, silver, and copper were used, and the intensity and degree of polarisation of the light scattered in different directions were measured. For the metallic particles, the size could be determined; the diameters in different experiments ranged from 80 to 310 $\mu\mu$. From the direction of maximum polarisation the conductivity of the particles could be measured. It appears that the conductivity diminishes with the size of the particles; and it is suggested that the number of free electrons present in the finely divided metal is smaller than when the material is in mass.

Dr. Rankine described methods of measuring the viscosities of chlorine, bromine, and iodine at a number of different temperatures He discussed the relations between the viscosities of the three gases and showed that they correspond with laws which he had previously found to apply to the inert gases.

During part of this final morning the department of mathematics met separately, Prof. Carslaw presiding. The following papers were read:—Mr. Chaundy, "Symbolic Solution of Linear Partial Differential Equations of the Second Order"; Prof. Fields, "Properties of Algebraic Numbers Analogous to Certain Properties of Algebraic Functions"; Prof. Carslaw, "The Green's Function for the Equation $\Delta^2 u + k^2 u = 0$"; Prof. Hudson, "The Evolute of the Limaçon"; Mr. Macaulay, "The Algebraic Theory of Modular Systems"; Mr. Macaulay, "A Property of Double Points."

Several papers were taken as read during the different sittings. These included a number of local papers, the authors of which were unable to attend. Mr. Herens and Prof. Laby had a paper on an absolute determination of the thermal conductivity of air; Prof. Laby and Mr. Stuart on the nature of γ rays; Prof. Laby and Mr. Adams on the electric resistance of steel tapes; Mr. Hogben, a map of the principal earthquake centres of the south-west Pacific; Mr. Kidson on the general magnetic survey of Australia; Prof. Laby and Mr. Herens on the thermal conductivity of air; Prof. Porter and Mr. Simeon on the change of thermal conductivity during the liquefaction of a metal; Mr. Wellisch on experiments on the active deposit of radium. These papers were all taken as read.

A brief reference must also be made to other activities of the section, outside the ordinary meetings for papers and discussions. To meet the special circumstances of the Australian meeting an extra sitting of the section was arranged at Brisbane, when Prof. E. W. Brown delivered an address on the motion of the moon. Evening discourses and public lectures on physical and astronomical subjects were delivered during the visit by Sir O. Lodge, Sir E. Rutherford, Prof. Turner, Dr. Dyson, and Prof. Eddington. At Sydney the local Astronomical and Mathematical Societies held special meetings which many of the visitors attended and took part in, and in more informal ways the members found much scope for useful activity outside the official programme. A subcommittee, under the chairmanship of Prof. Love, organised a series of experiments to be carried out during the voyage to Australia, and a number of the visiting physicists undertook to utilise the opportunity in this way. No official information as to this work is as yet to hand, but we understand that a good deal was accomplished. Of special interest was Prof. Duffield's investigation of the value of gravity at sea by means of Hecker's apparatus; the experiments were carried out on the outward voyage on the *Ascanius*, the owners (Alfred Holt and Co.) having made very generous provision of facilities for the work.

BOTANY AT THE BRITISH ASSOCIATION.

THE botanical benefits derivable from a visit to Australia began to manifest themselves as soon as we left the shores of England. Taking advantage of the facilities offered by the Blue Funnel Line, it was possible, as a member of the advance party on board the *Ascanius*, to make collections of the plankton daily throughout the voyage from England to Australia, by the Cape.

The writer made qualitative collections with the help of apparatus provided by Prof. Herdman, whose quantitative work went on in spite of the rough weather in the "roaring forties" which laid Dr. Ostenfeld low with a comminuted left patella, to the great regret of all, and especially of the botanists whose invited guest he was. His absence from the field and from the meeting in Australia was felt throughout our visit.

A call at Las Palmas and at Cape Town, of a few hours' duration only, in each case, allowed us to see something of the flora of the Canaries and of Cape Colony respectively. The forests of the silver-leaf tree—*Leucadendron argenteum*—covering the slopes of Table Mountain, were a striking feature in the fine drive of fifty miles on the coast road at the Cape. The time spent in responding, on our first day out, to the S.O.S. signal of the *Gothland*, on the Bishop Rock in the Scilly Isles, could not be made up owing to rough weather east of the Cape, so that we missed the garden-party of 2500 invited by the Governor to meet us at Perth, and we arrived only just in time for the delivery of Prof. Herdman's lecture on "Why We Study the Ocean."

Elaborate preparations had been made to enable us, by train and motor-car, to see something of the types of flora in different parts of West Australia under the able, constant, and ideal guidance of Mr. C. Andrews. Botanists owe him a deep debt of gratitude for placing his thorough knowledge of the flora, as well as his time, so readily at the disposal of the party. Mr. Andrews added to our obligations by writing a well-illustrated article on the flora of West Australia for the Handbook of the State, of which each member received a copy. With such a rich flora (4000 species), of which two-thirds is endemic, a week was tantalisingly little, and we could do little more than note, and collect for subsequent study, specimens of the striking xerophilous, endemic flora made famous by the researches of Robert Brown, J. D. Hooker, Diels, and others. The Proteaceæ, Myrtaceæ, Leguminosæ, and Rutaceæ are orders which stand out by their frequency and ecological adaptations. The flora round King George's Sound at Albany proved a great treat. *Cephalotus follicularis* and *Phylloglossum drummondii* (a club-moss most botanists have never seen living), in plenty, *Boronia megastigma* as abundant as a meadow grass, Xanthorrœa and Kingia in various stages of development, *Macrozamia fraseri*, Eucalyptus of many kinds and limitless in quantity, must suffice to suggest the richness of the botanical features enjoyed.

It was fortunate in one sense that we were, we learnt, six weeks too soon for the blaze of colour and variety of form characteristic of the early summer of West Australia. It is not too much to say that nothing in the whole meeting exceeded the hospitable welcome and generous excursion arrangements made by the Government and people of this State. We returned from the scrub to find the war clouds bursting and to see in Perth a fine illustration of patriotic feeling indicative of the unity of the British Empire.

There was so much of interest on every side that early in our visit it was realised it would be wise to economise our plates by systematising the photographic work of the party. Dr. Holt, the Recorder of chemistry, accordingly suggested a selective distribution of the work, with a subsequent exchange of prints. This idea was extended by the writer to cover the work of the different sections throughout the visit to Australia. A note was inserted in the Journal inviting photographing members to co-operate; and many promised their support.

The botanists were particularly fortunate in finding at all the centres visited preparations made for excursions to districts characteristic of the local flora. To Prof. and Mrs. Osborn we owe a deep debt of gratitude for their help and hospitality at Adelaide. The visits to the mangrove swamp (Avicennia), at the Grange (Henley Beach), to Mt. Lofty Range, and through the Mallee scrub to Mannum, are three excursions not likely to be soon forgotten, made more instructive by the maps and notes prepared by Prof. Osborn.

It was not until we reached Melbourne that the Botanical Section (K) came officially into existence. So far we had been fully occupied in the field. Here, as later at Sydney, it was difficult to find time for the many valuable contributions offered. Miss E. R. Saunders, a vice-president of the section, gave a lecture on a common garden plant, its history and behaviour, illustrated by lantern-slides. This was followed by a well-illustrated account by Dr. C. J. Bond on sex dimorphism in some abnormal begonia flowers. Prof. A. J. Ewart and Miss O. B. Davies described the flora of the Northern Territory, Mr. C. S. Sutton that of Melbourne, while Mr. Hiern contributed a paper on the Australian Ebenaceæ. Contributions were also made by Prof. F. O. Bower, the president of the section ("Modern Derivatives of the Matonioid Ferns"), by Prof. Ewart ("Oxidase Enzymes"), by Miss E. N. Thomas and Miss A. J. Davey ("The Seedling Anatomy of certain Pseudo-Monocotyledons"), Dr. E. N. Berridge ("Casuarina"), Miss Rees ("Fossil Fruits"). Prof. Gunner Andersson, of Stockholm, suggested a field of work for Australia in his account of the climate in northern temperate and arctic zones during the latest Pleistocene age. Dr. Ostenfeld's paper on the geographical distribution of the sea-grasses, in which he directed attention to the incompleteness of the knowledge of Australian forms, was communicated by Dr. Rendle, who initiated a joint discussion with Section D (Zoology) on the origin of species. This formed one of the most interesting features of the Melbourne meeting, and took place before a crowded audience. A general report will follow.

Prof. Seward's lecture on the fossil plants discovered by Capt. Scott's last expedition in the Antarctic regions aroused much interest. Miss Lorrain Smith described the relationship of fungus and alga in the lichen thallus, and concluded that the relationship is one of nutrition. The fungus is certainly dependent on the alga, but the alga is dependent on the fungus for its nitrogen and partly for its carbohydrates. The botanical excursions at Melbourne proved highly attractive. The outstanding one, for elaborateness of preparation, was that to the National Park, a great national reserve of 150,000 acres, reached by rail, boat, and horseback from Melbourne. To Prof. Ewart and his assistant, Mr. O'Brien, to Mr. Kershaw, curator of the museum, Mr. Catani, and Mr. Audass, botanists owe many thanks for the success of the Melbourne portion of the Australian visit.

The presidential address, already reprinted in NATURE, was reserved for Sydney. This was followed by a series of papers on Eucalyptus, contributed by Messrs. J. H. Maiden, R. T. Baker and H. E. Smith,

R. H. Cambage and Dr. Cuthbert Hall. Time, and Mr. Maiden's too numerous duties as local secretary, prevented adequate discussion of these valuable papers on one of Australia's most variable, abundant, and adaptable genera.

Prof. Seward represented the section in a joint discussion with Sections C, D, and E on the past and present relations of Antarctica. A verbatim report of this debate was authorised by the council.

Prof. Margaret Benson spoke on recent advances in our knowledge of Sigillaria. Papers were also contributed by Prof. T. G. B. Osborn on types of vegetation on the coast in the neighbourhood of Adelaide, and on the life-history of *Ophiobolus graminis,* by Mr. A. G. Hamilton, a well-known local botanist, on the xerophytic characters of *Bossiaea scolopendria.*

Dr. J. B. Cleland described certain features in the spores of Basidiomycetes. Mr. F. Turner illustrated his botanical survey of New South Wales by many specimens, as did Mr. R. P. Gregory in the account of his investigations on inheritance in certain giant races of *Primula sinensis.* A long motor drive through fine scenery to Bulli, the source of Sydney's water supply, under Mr. Maiden's guidance, proved a charming addition to our excursion experiences. Field excursions in plenty, systematic botany contributions, especially by botanists working in Australia, valuable Mendelian contributions in this Mendelian year, seem to be the outstanding features of the Botanical Society's activities in Australia. Some of us had the good fortune to visit Brisbane, Townsville, Cairns, Port Darwin, Java, Peradeniya, and Singapore, in nearly all of which not only was the local flora seen, but also the botanical gardens were visited. To Mr. F. M. Bailey, the Government botanist of Queensland, and his family, to Mr. Shirley, and to Mr. Burkill, of Singapore, we owe thanks for many kind attentions. At all "call" places on our way home we were welcomed, entertained, and shown features of botanical interest, making it not a little difficult to settle down once more to normal life.

T. J.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Liverpool.—Dr. W. Ramsden, senior demonstrator in physiology, University of Oxford, has been elected to the Johnston chair of biochemistry in the University rendered vacant by the resignation of Dr. Benjamin Moore.

London.—The resignation of Prof. F. T. Trouton, F.R.S., from the professorship of physics at University College has been accepted by the Senate.

More than 1000 applications for commissions in the Army have been forwarded to the War Office from cadets and ex-cadets of the University contingent of the Officers Training Corps, and other students and graduates since the outbreak of war.

Sir Alfred Pearce Gould is acting as Vice-Chancellor during Sir Wilmot Herringham's absence at the front.

The Rev. Dr. J. P. Mahaffy has been appointed Provost of Trinity College, Dublin, in succession to the late Dr. Traill.

It is stated in *Science* that Mr. W. K. Vanderbilt has given 27,150*l.* toward the purchase by Columbia University of a half block of land adjoining other land owned by the university; and that the University of Pennsylvania receives 10,000*l.* by the will of the late Miss Anna Blanchard, of Philadelphia.

The Department of Agriculture and Technical Instruction for Ireland is offering for competition in 1915 among students of science and technology a limited number of scholarships and teacherships-in-training tenable at the Royal College of Science, Dublin. The scholarships are of the value of 50*l.* per annum, and, in addition, entitle the holder to free instruction during the Associate course, and third-class railway fare for one journey each session to and from Dublin. A teachership-in-training entitles the holder to free instruction during the Associate course, a maintenance allowance of 21*s.* per week for the session of about forty weeks each year, and third-class railway fare for one journey each session to and from Dublin. Candidates must have been born in Ireland, or have been resident in Ireland for three years immediately prior to June 1, 1915. They have to satisfy the Department as to their knowledge of English and of one other language. Applications for admission to the examination must be made not later than April 29, 1915, on Form S. 34, copies of which may be obtained upon application to the Secretary, Department of Agriculture and Technical Instruction for Ireland, Upper Merrion Street, Dublin, or to the Registrar, Royal College of Science, Upper Merrion Street, Dublin.

The report on the work of the Department of Technology of the City and Guilds of London Institute for the session 1913–14 has now been published. At the recent examinations, 23,119 candidates were presented in technology from 467 centres in the United Kingdom, and of these 14,570 passed. These figures show an increase of 1241 in the number of examinees, and of 952 in the number of those who passed. By including 753 candidates from India, from the overseas Dominions, and from other parts of the British Empire, 998 candidates for the special examination in magnetism and electricity, held by arrangement with the Postmaster-General, 67 for special examinations in cookery and needlework, and 1839 for teachers' certificates in manual training and domestic subjects, the total number examined was 26,776. The report states there can be no doubt that the teaching of technology has improved greatly during the past few years; but it is noted that the examiners have still to direct attention to the insufficient knowledge that some candidates possess of the principles of their subjects, and to the lack of practical knowledge shown by others, and they think the unsatisfactory answers in consecutively numbered papers which have been found to be the work of students of the same class indicate faulty teaching as the source. The purpose of technical instruction being the better training of the artisan to understand and appreciate the scientific principles that underlie his trade or craft, the attention of teachers should especially be directed to the necessity for a more thorough training of students in fundamental principles. The inability of candidates to express themselves clearly is perhaps not so noticeable as in past years, but the examiners have again to point out the difficulty that simple mathematical calculations present to many candidates —a defect which can only be attributed to insufficient preliminary training.

SOCIETIES AND ACADEMIES.

London.

Royal Society, November 12.—Sir William Crookes, president, in the chair.—W. L. **Balls** and F. S. **Holton**: Analyses of agricultural yield. Part I.—Spacing experiments with Egyptian cotton. The aim of the experiments is the statistical analysis of the yield of agricultural crops, in terms of plant development, by careful recording of all stages. The effects of environmental conditions on crop development can then be

satisfactorily analysed. The effects of varying spacing, date of sowing, and season, upon Egyptian cotton, have been subjected in this way to critical examination by the authors. A secondary aim has been to appreciate the reasons for conventional agricultural practice. For each of twenty different spacings, the numbers of flowers daily, and of fruits, together with the weights of cotton and seed per fruit, have been recorded. The extent to which each of these components enters into the building up of the final yield is shown. The dense planting conventionally practised by the Egyptian fellah is shown to give the maximum possible yield per unit area under the limitations of field cultivation, though the normal extension of the root-system of an isolated plant can utilise more than ten times the soil-surface allotted to it in field-crop. Most of the phenomena of field-crop physiology in the fruiting season are thus shown to be traceable to root-interference.—J. **McIntosh** and P. **Fildes**: The fixation of arsenic by the brain after intravenous injections of salvarsan. After intravenous injections of salvarsan and neosalvarsan in man and animals no arsenic can be found in the brain. This phenomenon is not due to lack of affinity between the brain and the drugs, but to an inability on the part of the drugs to penetrate into the substance of the brain. Fixation of arsenic by the brain occurs as readily as by the liver, as shown by experiments *in vitro* and the toxic effects of intrathecal injections. Penetration of neosalvarsan into the brain cannot be obtained even by frequently repeated intravenous injections.—A. E. **Everest**: The production of anthocyanins and anthocyanidins. Part II. The author brings forward further evidence to support the conclusions arrived at by him in his previous paper (Roy. Soc. Proc., B, 1914, vol. lxxxvii., p. 144), namely, that the red, blue, and violet flower and fruit pigments (anthocyans) may be produced by reduction of flavone and flavonol derivatives in acid solution. Experiments are described which show that pure disaccharides of the flavonol series pass without hydrolysis to anthocyanins. The flavone and flavonol pigments having been previously synthesised by Kostanecki, the processes described by the author complete the synthesis of the anthocyan pigments.—H. M. **Woodcock** and G. **Lapage**: Living observations on the life-cycle of a new flagellate—*Helkesimastix faecicola*—together with remarks on the question of syngamy in the trypanosomes. *H. faecicola*, ng., n.sp., occurs in goat-dung and sheep-dung; it is a "passenger," being carried through the alimentary canal in an encysted state. The authors have cultivated this flagellate in various media. They have observed the entire course of the life-cycle in life, from excystation to encystment.—S. W. **Patterson**: The antagonistic action of carbon dioxide and adrenalin on the heart. Carbon dioxide alone depresses all the functions of the isolated heart. Adrenalin, besides dilating the coronary vessels, has a specific action in increasing the rate and strength of ventricular contraction. The effect of carbon dioxide and adrenalin combined is still to allow of more rapid and stronger contraction and rapid relaxation, and also to lengthen the diastolic period. Thus, greater filling of the heart takes place, and the heart is in a better condition for putting out a maximal output.

Zoological Society, November 10.—Prof. E. W. MacBride, vice-president, in the chair.—R. I. **Pocock**: Some unrecorded structural differences between the pine-marten (*Martes martes*) and the beech-marten (*Martes foina*). The two species, apart from the known differences in the skull and teeth, may be distinguished by the size of the ears, which are broader and longer in *M. martes* than in *M. foina*, and by the dimensions of the pads on the feet, which are considerably larger and less overgrown with hair in *M. foina* than in *M. martes*.—Dr. F. E. **Beddard**: Anatomy and systematic arrangement of the Cestoidea. A new genus and species of the family Acoleidæ was described, based upon a large number of examples obtained from the Canadian tree-porcupine (*Erethizon dorsatum*.—H. R. **Hogg**: Report on the spiders collected by the Wollaston and British Ornithological Union Expeditions in Dutch New Guinea. This collection confirms a good deal of the work of previous authors, and at the same time brings to light much that is new. Leaving out the Attidæ, there are representatives of nine families, comprising twenty-six genera (of which one is new) and forty-five species or subspecies of which some nineteen are new.

Physical Society, November 13.—Dr. A. Russell, vice-president, in the chair.—D. **Owen**: A bridge for the measurement of self-induction. An alternate-current bridge method is proposed for the determination of self-induction in terms of capacity and resistance. The inductance L is given by the relation $L=K_3r_1R$; in addition to which it is also necessary for balance of the bridge to satisfy the condition $K_3r_1=K_4r_2$. The conditions of balance may be secured without mutual interference. The end point is rapidly attained. The possibility of effecting a balance is unlimited by the value of the unknown L. The method is independent of frequency, and it is unnecessary to employ a pure sine voltage. Good results may be attained with a buzzer as source and a telephone receiver as detector. The dependence of sensibility of the bridge on the frequency is discussed, and over a wide range the sensibility is high. The effects of residual inductance in the resistance coils and leads, and of absorption in the condensers, may be allowed for, the formula then becoming $L=K_3r_1(R-R_0)$. Tests are quoted showing that with the same pair of condensers measurements over the full range from one microhenry upwards may be made. For inductances of the order of 10 microhenries the error may be kept within a few parts in 1000; whilst if the inductance is as high as a few millihenries the error of any measurement may be reduced below one part in 10,000. The application of this bridge to the determination of capacity in terms of self-inductance is discussed, and an example is given of a test of the temperature variation of capacity of a standard mica condenser over the range 0°–30° C.—B. W. **Clack**: The coefficient of diffusion in dilute solutions. Modifications have been made in the apparatus previously described to determine the value of the coefficient of diffusion of salts through water, by means of which the steady state is hastened and results obtained more quickly. The single wide tube previously employed is replaced by a battery of shorter and narrower tubes. The error due to end-correction is investigated and results are given for the salts KCl, KNO_3, and NaCl for various concentrations down to very dilute solutions.

Royal Meteorological Society, November 18.—Dr. H. N. Dickson, vice-president, in the chair.—Dr. H. R. **Mill** and C. **Salter**: Isomeric rainfall maps of the British Isles. The average monthly rainfall expressed as a percentage of the average annual fall of each of about 300 stations forms the basis of a set of twelve monthly and four seasonal maps. The most striking features are the occurrence of two types of seasonal march; one chiefly characteristic of western or wet districts, having a winter maximum and a summer minimum, the other chiefly confined to eastern or dry districts, having a winter minimum, and a summer or autumn maximum. The equinoctial maps show the transitional stages between these two extremes, the spring months having everywhere a low rainfall

and small range with a central maximum inland and a peripheral minimum on the coast, and the autumn months a large rainfall with a central minimum and a peripheral maximum. The maps show that the relation of heavy rainfall with high-lying land is a relation of cause and effect, the relation of the winter maximum with the heavy rainfall is therefore an indication of a common cause. High land is only associated with heavy rain because it meets rain-bearing winds, and the true connecting circumstances are the position of high land and its relation to the prevailing winds. The occurrence of rain with easterly winds, affecting principally the east coast, makes it impossible to view the British Isles as having a rainfall *régime* solely produced by south-westerly winds. The far greater frequency of southerly and westerly winds than of easterly and northerly, and the fact that the latter occur mainly at certain seasons, go far to explain the features both of the average rainfall maps and of the isomeric maps.—J. I. **Craig**: A see-saw of temperature between England and Egypt. Diagrams were given of lines of thermal equi-correlation with Egypt.

PARIS.

Academy of Sciences, November 9.—M. P. Appell in the chair.—Emile **Picard**: Concerning the hydrodynamical paradox of d'Alembert. Remarks on a recent note by M. Pierre Duhem.—Pierre **Duhem**: Remark on the hydrodynamical paradox of d'Alembert. —A. **Laveran**: Remarks on the prophylaxy of typhus in armies in the field. That the infection of typhus is carried by lice has been proved by Nicolle at Tunis, and confirmed by American physicians in Mexico. Under the conditions necessitated by fighting in trenches the chance of an epidemic is greatly increased. Special importance, therefore, attaches to personal cleanliness in the troops at the front.—M. **Balland**: The preservation of food for army service. A method has been proposed according to which meat, rice, and agar-agar are sealed in a tin, the cooking being carried out after sealing the tin. It is pointed out that the official method in the French Army, in which the meat is cooked before canning, gives a more concentrated product, and the addition of rice and agar-agar is deprecated.—A. **Brachet**: The action of butyric acid upon the development of the eggs of the sea-urchin.—H. **Bourget**: Observations of the transit of mercury across the sun made at the Observatory of Marseilles. Observations of the contact times were carried out under good atmospheric conditions.—D. **Eginitis**: Observations of Delavan's comet made at the Athens Observatory with the Doridis equatorial (Gautier, 40 cm.). Positions given for September 18, 19, and 30, and October 1. The comet was visible to the naked eye, with a tail of 5°, and of apparent magnitude 5.—B. **Globa-Mikhailenco**: Equilibrium figures of a fluid mass in rotation, infinitely near an elliptical cylinder. —A. **Mesnager**: A rapid method for the calculation of arches. A diagram is given for the rapid graphical determination of the bending moment.—Charles **Rabut**: The Eauplet bridge and the deformation of arcs.—M. **Amans**: The problem of flight.—F. **Garrigou**: A simple method of obtaining the notion of relief in radioscopy. —Louis **Gentil**: The structure of the plateau of Oulmès, Central Morocco.—Charles **Nicolle**, G. **Blanc**, and E. **Conseil**: Some points in the experimental study of exanthematic typhus. The lice do not transmit the disease before the eighth day after infection; they transmit it on the ninth and tenth day after infection. This was also found to be the case with the excreta of lice nourished on infected blood. Experiments on hereditary infection in lice gave negative results in all cases.—MM. **Cailland** and **Corniglion**: Contribution to the study of the treatment of tetanus. The treatment adopted for two cases was a daily intra-muscular injection of 1 per cent. solution of carbolic acid, either alone, or in conjunction with (for two graver cases) intra-venous injection of lantol or colloidal rhodium. All four cases were cured, although two other cases treated with anti-tetanic serum and chloral died after three days. In the four patients cured the definite symptoms of tetanus were well developed before the treatment was started. The same method has also been successfully applied to five cases of tetanus at Cannes. In all there have been nine cures in nine cases.—Aug. **Lameere**: The male of Dicyema.

DANTE'S ASTRONOMY.

Dante and the Early Astronomers. By M. A. Orr (Mrs. John Evershed). Pp. xv+507. (London: Gall and Inglis, n.d.) Price 15*s.* net.

DANTE'S cosmological ideas and his exposition of medieval astronomical knowledge have been discussed by several of the numerous commentators of his writings. It is, however, useful to have them collected in one place and discussed by a writer having a sound knowledge of modern astronomy. Mrs. Evershed has therefore done good and valuable work by producing the present volume. After a rapid sketch of the principal celestial phenomena visible to the naked eye without instruments, she gives a popular account of the progress of Greek astronomy. The "list of principal authorities" at the beginning of the book shows that this account is mainly founded on some of the principal modern books and monographs on this subject. There are very few ancient writers in the list, *e.g.* Hipparchus, Ptolemy, Seneca, and others are conspicuous by their absence. On the other hand, Cicero, "De Senectute" is included, though there is not a word about astronomy in this little book except an allusion to Gallus, who was fond of predicting eclipses.

On the whole, the account of Greek astronomy is correct, but it would have been a help to readers who may desire further information if references to the sources employed had been given in each chapter; for instance, on p. 299 (note) the authority is no doubt Smyth's "Cycle of Celestial Objects," vol. ii., p. 332, which should have been quoted. Want of knowledge of the original writers occasionally leads the author astray, as, for instance, when she gives a picture of the great equatorial at Peking, and seems to think that this was a copy of one of Ptolemy's instruments. There is no mention of equatorials in the Almagest, and it is not even certain that the Arabs constructed them, though it is probable enough, since the idea of the Peking instrument appears to be due to a Persian, Gemal-ed-din. On p. 122 it is said that Hipparchus gives a list of sixteen time-stars culminating at intervals of an hour exactly, and that his knowledge of spherical trigonometry enabled him to calculate the time of night to within one minute. But there were forty-four of these stars, and their use did not involve any calculation, as they only served to regulate the water-clocks.

Passing to the Middle Ages, the importance of astrology in those days is duly pointed out. But it is not correct to call the art of predicting the fate of an individual "judicial astronomy," as the author persists in doing. It was called "judicial astrology," not to distinguish it from the science of stellar motions, but to show that it was a special branch of the more exalted, philosophical astrology, which sprang from the loftiest views of Greek thinkers about the unity of the Kosmos and the inter-dependence of all parts thereof. The astronomical work done by the Arabs is briefly mentioned, and it is justly emphasised that Dante owed his knowledge of Alexandrian astronomy solely to the text-book of Alfraganus (Al Fargani), which he had thoroughly mastered, so that we have in the "Divine Comedy" and the "Convito" an excellent picture of the state of science at the beginning of the fourteenth century. It is only very rarely that Dante gives any astronomical information not to be found in Alfraganus, one of the principal cases being the statement that the length of the tropical year is 1/100th of a day less than 365¼ days. The author says it would be interesting to know where Dante found this value. We think there can be little doubt that he got it from the "Computus Maior" of Johannes Campanus, a Canon of Paris, in the thirteenth century, which is extremely likely to have been known to Dante's teacher, Brunetto Latini, who lived some years in France, though he does not mention the small amount of 1/100th day in his "Trésor," where he gives only round numbers.

After giving a classified list of the allusions to sun, moon, planets, and stars in the "Divine Comedy," the author discusses the time-indications given through references to the positions of the heavenly bodies in the course of the poet's journey. They show that Hell, a conical cavity reaching to the earth's centre, was entered in the evening and left twenty-four hours later, while the ascent to the other side of the earth took nearly as long. Purgatory is a conical mount on an island in the midst of the watery hemisphere at the antipodes of Jerusalem. The time spent on it brings us to the morning of the seventh day, and the ascent through the seven spheres of the planets, the sphere of the Fixed Stars, and that of the Primum Mobile to the Empyrean took eighteen hours. As regards the assumed date of the journey, it has generally been supposed that this was the spring of the year 1300, to which the historical allusions decidedly point. But in 1897 Sig. Angelitti, of the Naples Observatory, published a paper in which he showed that the positions of the moon, Venus, and Saturn given in the poem agree wonderfully well with their actual places at the end of March, 1301. The greatest difficulty to those who accept the year 1300 has

always been that Venus in March of that year was invisible, while she ought to be a morning star in Pisces, which she was twelve months later. But it was pointed out six years ago that Dante very likely took the position of Venus from a perpetual Almanac compiled by a Jew. In the Hebrew original all the cycles begin in 1301, while in the Latin translations they begin in 1300, except those of Venus and the sun, which begin with 1301. It is therefore quite possible that Dante took the places of Venus for 1301, believing them to be for 1300, and Angelitti's tempting theory must therefore be abandoned, to the regret of the author of the present work, in which we cordially join.

J. L. E. D.

FOUNDATIONS OF SYSTEMATIC BIOLOGY.

Abstammungslehre—Systematik—Paläontologie—Biogeographie. Unter Redaktion von R. Hertwig und R. v. Wettstein. Pp. ix+620. (Leipzig and Berlin: B. G. Teubner, 1914.) Price 12 marks.

"TO no nation, except the German," says General von Bernhardi, "has it been given to enjoy in its inner self that which is given to mankind as a whole. We often see in other nations a greater intensity of specialised ability, but never the same capacity for generalisation and absorption." That is the German way of expressing the German capacity for organisation and compilation, which, when it produces works such as that of which the present volume is a portion, performs a valuable service to the intellectual world. The whole work, "Die Kultur der Gegenwart," purports to be a systematic survey of modern culture on a historical basis, portraying the fundamental achievements of the diverse centres of civilisation in their relation to the whole as it exists now or promises to be developed hereafter. The division allotted to the organic natural sciences comprises four volumes, of which this is logically the last. Volume ii., the only other as yet issued, was reviewed by us in April, 1914 (vol. xciii., p. 107).

In view of the claim mentioned above, it is interesting to note that the contributors are not all German, for besides R. Hertwig, L. Plate, A. Brauer, A. Engler, and K. Heider, there are the Austrians, R. v. Wettstein and O. Abel, the Dutchman, W. J. Jongmans, and the Dane, J. E. V. Boas. It is, moreover, pleasing to observe that these authorities do not neglect the workers in other countries, but, by the lists of leading books which they furnish, prove that in this department, at all events, all nations take their share, and that the fellow-countrymen of Darwin have no reason to feel ashamed. The truth is that, though in art there must be nationality, science has become absolutely international: the observation made by a Dane to-day is checked by a Japanese to-morrow, and an American then carries it a step further.

It would not be possible, even in several pages, to give a critical summary of what is itself a summary, and an admirably critical one, of the whole world's work in that which, from a theoretical point of view, is the most important branch of biology. Few men could have written a more lucid, a more just, or a more thought-compelling account of the doctrine of descent than Prof. Richard Hertwig. "It is," he concludes, "the only possible theory . . . and the one that has given the weightiest impulse to this science. The crowd of exact investigations that has resulted from Darwin's writings may seem to have gone beyond or even away from him; but these last years show an unmistakable return to the views of the great British naturalist."

The articles on geographical distribution by Profs. Brauer and Engler, on palæontology by Profs. Abel and Jongmans, on the classification and phylogeny of plants by Prof. von Wettstein, and on the phylogenies of invertebrate and vertebrate animals by Profs. Heider and Boas, may be open to criticism in details, but afford on the whole admirable digests, made interesting by the fact that the distinguished authors have taken their own lines on disputed questions. It is, however, the chapter by Prof. L. Plate on the principles of taxonomy with special reference to the classification of animals that fills the most urgently felt want. The mere description of new species, as carried out by too many writers, is far from being good systematic work, or even scientific work at all. But the true systematist has perpetually to exercise his mind with the most complicated problems of his science, cannot venture to eschew metaphysics, and has even to rival the poet in his use of the imagination. All systematists who would understand their own task should read Dr. Plate's illuminating review of modern methods and ideas.

J. L. de Lanessan. Pp. 352. (Paris: Librairie Felix Alcan, 1914.) Price 6 francs.

(4) *A History of Education in Modern Times.* By Prof. F. P. Graves. Pp. xv+410. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 5*s.* net.

(5) *Methodik und Technik des naturgeschichtlichen Unterrichts.* By Prof. W. Schoenichen. Pp. xiv+611+30 plates. (Leipzig: Quelle and Meyer, 1914.) Price 12 marks.

(1) THERE is always an interest, and often no little instruction, to be derived from a study of the science and religion of ancient civilisations, especially when considered in their inter-relations. One of the newest of sciences, anthropology, appears to be rooted in the earliest strata of thought, as, for instance, among the natives of Central Australia. Greek speculation upon the origin and development of mankind was not limited to fairy-tales of the Golden Age type. From Herodotus onward their best minds had a very shrewd idea of the real process, such as we have come to see it. Lucretius repeated, with original observations of his own, the anthropological theories of Epicurus. But these are the culmination of Greek scientific thought in this direction. They were foreshadowed by Aeschylus and Herodotus, and developed later. It seems that the Greeks, who certainly had considerable opportunities, thanks to their trade, travel, and warfare, collected a considerable body of data relating to savage and barbarous peoples in the west, the east, and the south. There was, of course, another school, the Platonic; it was true then, as ever since, that a man is born either an Aristotelian or a Platonist. Then, too, as now, the Platonist built upon teleology. Mr. Sikes has done well to collect every statement in Greek literature that throws light on the scientific ideas of that "most quick-witted and curious of human races," concerning the origin and development of their own species. It should be read by all anthropologists, whether their Greek is "less" or more.

(2) But the Greek mind was more interested in the problems of cosmic and ultimate metaphysics, and the issues waged between Determinists and Creationists, or, whatever the two fundamental types of mind be termed. These issues seem destined to be eternal. So Dr. Paul Carus, following up his interesting propaganda of many years, writes some notes upon representative quotations from exponents of both sides. "Mechanicalism" and teleology are first contrasted. The "contributions," as they may be called, to his volume include some very interesting expressions of opinion, especially Mark Twain's philosophy and La Mettrie's famous exposition of man "as a machine." It is curious that La Mettrie, when persecuted for his opinions, found refuge in Prussia and received a pension from Frederick the Great.

In another chapter Prof. W. B. Smith's eloquent article from the *Monist* works up to the conclusion that "it is a false antagonism between the causative and the teleological conceptions of the universe." Dr. Carus's text is that "nothing moves, nothing stirs nor happens that does not act in agreement with the laws of motion, and there is no harm in it that man's activity takes place in perfect agreement with mechanical laws. A man's a man for a' that!" As for the ancient and modern puzzle—dualism or monism—he says, using Ezekiel's metaphor, "There are not two things, the spirit and the wheels, but there is one reality." "Both spirit and machine are one, and the universal dominance of the laws of form determining the detailed uniformities of motion, commonly called mechanics, is by no means a depressing or melancholy thought. The laws of form are the very means in which spirit reveals itself."

(3) That versatile writer, Prof. de Lanessan, has written a critical history of the relations between these two modes of thought. He considers that evolutionary determinism (*transformisme*) and animistic supernaturalism (*créationisme*) are ultimately the only possible theories of the universe. He traces their elements back to the priestly caste of Mesopotamian culture, and carries his account up to Darwin. Considerable space is rightly given to de Buffon, the teacher of Lamarck. Except in the most recent times, the great majority of determinist thinkers have fallen back upon animism to explain the ultimate origin of the universe, or the presence in it of mind. Prof. de Lanessan promises a second volume, dealing with the developments subsequent to Darwin.

(4) If objective science be described as the obverse of human mentality, education is its reverse. From another point of view, as old as the Greeks, education and socialisation—"politics" in the Greek sense—are complementary. Prof. Graves has written the history of education before the Middle Ages, and from that period to the eighteenth century. He now completes his survey by a volume describing the progress of educational theory and practice, the latter in particular, from the eighteenth century (inclusive) up to the present day.

It is curious to reflect that the "classical" education, still the pabulum of English upper-class youth, was denounced more than a century ago by the French reformer, Rousseau. Equally

interesting is the fact that practically all subsequent educational reformers have been the intellectual heirs of the French iconoclast, such as Pestalozzi, Fellenberg, Froebel, Herbart, and Montessori. While giving prominence to the evolution of education in America, Prof. Graves does not neglect this or other countries, and his account of the German experiments at Neuhof, Königsberg, and Keilhan is detailed. He has an interesting chapter on the introduction in recent years of scientific subjects into curricula, and another on the application of psychological results to the methods of education. The book includes an excellent selected bibliography, very useful in view of the enormous literature of the subject.

(5) The series of scientific and mathematical handbooks edited by Dr. Norrenberg is an encyclopædia for teachers. The fifth volume, on methods of instruction in natural history, by Prof. Schoenichen, of Posen, contains more than six hundred pages, crammed with detailed advice and facts. The author attempts, with success, to cover the whole ground of zoology, botany, and biology generally as an educational subject, and from the teacher's point of view. From psychological pedagogy to gardens and vivaria, he omits nothing that can come into the ken of the schoolmaster. Courses are laid down for the various classes in the Gymnasium, the Real-gymnasium, and the Real and Oberrealschule. The suggestions about methods of drawing, and those on excursions and collecting are excellent. A notable feature is the description of models, their manufacture and use.

Fas est et ab hoste doceri; the book is a triumph of method. A. E. Crawley.

OUR BOOKSHELF.

The Rubber Industry in Brazil and the Orient. By C. E. Akers. Pp. xv+320. (London: Methuen and Co., Ltd., 1914.) 6*s*. net.

Mr. Akers contrasts in this book the unscientific, and unbusinesslike, rubber-collecting industry of Brazil with the rubber-planting enterprises of the British and Dutch East Indies, which are conducted on more or less scientific lines and with the commercial skill and acumen which distinguishes the two peoples concerned with these East Indian Colonies.

Compared with their competitors in the East, the rubber producers in Brazil have one great advantage—their trees are mature and in their natural habitat. This advantage is believed to account for the general opinion that Brazilian Para rubber is better than the plantation article from the East Indies. Many competent judges maintain that this advantage is illusory, and that properly-prepared East Indian plantation rubber, from well-established trees of fair age, is just as good as "fine hard Para," and that the premium obtained by the latter in the markets is the result of conservative prejudice on the part of manufacturers. However that may be, the advantage, supposing it is real, is bound to disappear, in view of the increasing age of the plantations in Ceylon and Malaya, and the untiring efforts of the planters there to improve and unify their methods of preparation.

In all other respects, such as cost and efficiency of labour, good administration and government, business skill and foresight, and last, but not least, the realisation of the necessity for scientific and technical research, the advantages lie with the East Indian producers, and Mr. Akers makes it clear that unless there is a drastic change in the conditions of working in Brazil, the rubber industry there is bound to disappear in the face of the competition of the East Indian plantations.

Mr. Akers probably records little that is new to rubber planters, but his book is none the less interesting on that account, and it can be cordially recommended to all who are interested in the development of this great industry, in which British enterprise and technical skill have played so large a part.

The Beginner's Garden Book: a Text-book for the Upper Grammar Grades. By A. French. Pp. viii+402. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1914.) Price 4*s*. 6*d*. net.

There is always much to learn from an American teacher of a rural subject. The science may be superficial, yet he manages to get his students to think about their work and to find reasons for the way in which the work is done. This book is a case in point. It takes the form of an address by a teacher of school gardening to boys engaged in the cultivation of school gardens. The American origin of the book little interferes with its use in this country. The English is almost free from Americanisms, and the cultivation of all our more commonly grown vegetables and flowers is described. The treatment of fruit culture and bastard trenching is inadequate, and grafting and budding are not even mentioned, but, on the other hand, several matters are dealt with that do not often find a place in gardening manuals. The chapters on the saving of seed and on gardening under glass are excellent. A good deal of gardening can be learnt by merely looking at the numerous illustrations.

An Introduction to Geology. By C. I. Gardiner. Pp. xiv+186. (London: G. Bell and Sons, Ltd., 1914.) Price 2*s*. 6*d*.

Mr. Gardiner is well known as a field-observer, and has added largely, both by himself and with Prof. S. H. Reynolds, to our knowledge of Silurian areas. He now attracts others to his favourite studies by a clearly written introduction to geology, which will be of especial interest to dwellers in the English midlands. General principles are supported by more detail than is usual in elementary works, and this method carries convic-

tion as to the reality of the facts described. For instance, both a map and a photograph are given of Churchdown, the conspicuous outlier that rises above the Lias plain near Gloucester; while the description of the successive layers in the Victoria Cave furnishes an impressive picture of the history of British man. The statement of the loss of land along the Yorkshire coast demonstrates the effectiveness of forces now in action, and two successive views are given of the destruction of a chalk headland near Swanage.

The illustrations are practically all new, including a fine view into Lulworth Cove, taken from the hill at its west end. The printers have twice gone astray on the difficulties of Rhynchonella (pp. 60 and 79), and a bracket needs extension on p. xi to include the Cainozoic systems; but the mode of production shows how generously publishers are prepared to meet the demand for readable works on nature-study. G. A. J. C.

Catalogue of the Ungulate Mammals in the British Museum (Natural History). Vol. iii. Artiodactyla, Families Bovidæ, Subfamilies Æpycerotinæ to Tragelaphinæ (Pala, Siaga, Gazelles, Oryx Group, Bushbucks, Kudus, Elands, etc.), Antilocapridæ (Prongbuck), and Giraffidæ (Giraffes and Okapi). By R. Lydekker, assisted by G. Blaine. Pp. xv+283. (London: British Museum (Natural History), 1914.) Price 7*s.* 6*d.*

THE third volume of the British Museum catalogue of Ungulates completes the account of the antelopes (saiga, gazelles, oryx group, bushbucks, kudus, elands, etc.) and deals also with prongbucks and giraffes. Like its predecessors it is a fine piece of work with terse descriptions and scholarly synonymy. Its usefulness has been notably increased by the inclusion of fifty excellent figures, mostly of heads. As a work of reference it will be of great value and interest to those who have collected trophies of this sort. The prongbuck, the position of which has been the subject of discussion, is ranked by Mr. Lydekker as the only living representative of a separate family, Antilocapridæ. Another interesting type, the Okapi, represents a genus along with the giraffe in the family Giraffidæ. Among the many other interesting forms may be mentioned, Ammodorcas, Æpyceros (the Pala), the Saiga, and the Chiru.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Age of a Herring.

To my doubts as to the truth of Dr. Hjort's theories of the herring's age, Dr. Hjort and Mr. Einar Lea have now replied (NATURE, November 5) by recapitulating their main arguments. I can do little more than reiterate my own unaltered incredulity. My position is simply this, that a theory has been put forward which seems to me, *a priori*, extremely improbable, and that the statistical data on which it is based are, to my mind, not strong enough to support it. The large assertion that the Norwegian spring herring have consisted, in preponderating or overwhelming proportion, year by year from 1908 to 1913, of fish spawned in 1904, is based (so far as I can discover) on only nineteen samples, or little more than two a year, averaging somewhat above 300 herring each. Dr. Hjort and Mr. Lea have no difficulty in showing that their 1913 herring, grouped according to scale-rings or alleged years of growth, form a curve which is a bad fit to a probability curve; but they do not remind us that this so-called sample is no sample at all, but is a conglomeration of three separate samples from far-distant localities. Dr. Hjort's full data have not been published, so far as I know, for the years since 1909; let us try to discover how, for the year 1908, he arrives at the figure 34·8, which he gives (*cf.* NATURE, August 27, p. 672) as the percentage proportion, in the entire stock of Norwegian spring herring, of fish spawned (according to the evidence of their scale-rings) in 1904. I find that this determination was based on two samples only,[1] from different localities, one consisting of 881 fish, the other of 549. In the former sample the percentage of 1904 fish is given as 15·9, in the latter as 65·2. The former determination, by Mr. K. Dahl, seems a little shaky: for an independent determination of a part of the same sample, by Mr. Einar Lea,[2] gave the alternative value of 10·2. But be that as it may, I find that Dr. Hjort's result is obtained by the simple method of adding together the two samples, one of 881 fish showing 15·9 per cent., the other of 549 fish showing 65·2 per cent., and so the resulting mean value of 34·8 per cent., decimal and all, is straightway arrived at. It does not need the eye of a mathematician to see that, in a problem of biological statistics, such a method of calculation is inadequate; and that it neither proves nor even renders probable the conclusion drawn from it, namely, that four-ringed herring (whatever those four rings may mean) constituted 34·8 per cent. of all the spring herring in Norway, in the year in question.

D'ARCY W. THOMPSON.

The Cross X as a Symbol for Multiplication.

HISTORIANS of mathematics attribute the first use of the cross × as a symbol for multiplication to William Oughtred ("Clavis Mathematicae," London, 1631). See W. W. R. Ball's "Short Account of the History of Mathematics," fifth edition, 1912, p. 239; M. Cantor's "Geschichte der Mathematik," Bd. ii., 1892, p. 658; J. Tropfke's "Geschichte der Elementar Mathematik," Bd. i., 1902, p. 135. In some places, as, for instance, in Oughtred's "Circles of Proportion" (London, 1632, p. 38), the two bars of the cross are not quite straight, giving the symbol the appearance of the small letter *x*. In some of John Wallis's writings, as, for example, his "Elenchus geometriae Hobbianae," etc. (Oxford, 1655, p. 23), the symbol is not the usual cross, but is plainly the capital letter ⋊ turned on its side. In a paper by Lord Viscount Brouncker in the Philosophical Transactions (vol. ii., 1668, p. 646), the capital letter X occurs regularly as the symbol for multiplication. These and similar cases lead to the inference that the cross and the letter *x* were considered practically one and the same symbol for multiplication.

In this connection we desire to point out that the small letter *x*, and also the capital letter X, occur as symbols for multiplication before Oughtred (1631) in

[1] Hjort, "Rapports et Procès-Verbaux, vol. xx., p. 29. (Copenhagen, 1914.)

[2] "Public. de Circonstance," No. 53, p. 94. (1910.)

Edward Wright's translation of John Napier's "Mirifici logarithmorum canonis descriptio," brought out in its second edition at London in 1618, where we read p. (4): "The note of Addition is (+) of subtracting (−) of multiplying (x)." This is taken from a part of the book under the heading, "An Appendix to the Logarithmes," the authorship of which is not given, but is probably to be attributed to Samuel Wright, who is reported to have been the editor of the book. Accordingly, the symbol × occurring in Oughtred is probably a modification of the letter *x* that was first introduced at least thirteen years earlier, and probably by Samuel Wright.

FLORIAN CAJORI.

Cambridge, November 25, 1914.

ANTARCTIC ADVENTURE.[1]

THIS full account of the life and work of Scott's northern party is a welcome addition to the longer story of their work by Commander Victor Campbell in "Scott's Last Expedition." It was originally intended by Captain Scott that this party, of six men all told, should make their base on King Edward Land. When ice conditions prevented this they searched in vain along the coast of Victoria Land for a suitable landing until they had no alternative but to make use of Cape Adare, Borchgrevink's old winter quarters. Commander Campbell was well aware of the drawbacks to this place, from which it is impossible to sledge overland in any direction, but he had no choice in the matter. Either the party must land there or return to New Zealand in the *Terra Nova*. The winter at Cape Adare was spent in comparative comfort and the account reads like that of any other antarctic winter under modern conditions of equipment. A well-equipped party, in good health, need suffer no particular inconvenience nowadays in a polar winter. Sledging in spring along the sea-ice to the north proved impracticable, and in this respect Commander Campbell and his men had the same experience that almost all explorers have had in the south. No travelling can be more precarious than that over sea-ice in the vicinity of open water.

But it is the story of the second year's adventures which is the most interesting part of this book, for it was then that the author and his companions went through an almost unique experience. The only comparable story in the annals of the south pole is the wintering of Gunnar Andersson and two companions of Nordenskjöld's Swedish Antarctic Expedition in 1903 in a stone hut at Hope Bay, Louis Philippe Land.

The *Terra Nova* had picked up the six men at Cape Adare early in January and landed them four days later at Evans' Coves, about 270 miles to the south. From there they were to be taken by the ship on her return to New Zealand in March. The *Terra Nova* failed in three attempts to reach them, and so they were left to their own resources. But we cannot understand why these six men were landed with only six weeks' sledging provisions, and skeleton rations for another four weeks. Nor does Mr. Priestley's account make this arrangement clearer to us. He admits, in fact, that Commanders Pennell and Campbell had agreed that if the shore party were not picked up by March 18 they were to resign themselves to spend another winter as best they might. At the time, no doubt, they both thought this eventuality a remote one: "we would all have sworn that if there was one place along the coast which would be accessible in February, this would be the one."

FIG. 1.—A glacier table. From "Antarctic Adventure."

But it was a risk that should never be taken in polar exploration if it can possibly be avoided.

The party spent the winter in a snow cave hollowed out of a drift, eking out their scanty rations with seal meat. They had a hungry winter, but appear to have been cheerful and in comparatively good health throughout. Commander Campbell and his comrades deserve congratulations for this achievement. In October they sledged southward along the coast to the main base of the expedition at Cape Evans. Doubtless this journey was impractical in winter, but we would have liked to read the reasons which decided Commander Campbell to winter under these difficult, not to say precarious, conditions, at Evans' Coves rather than attempt the retreat to Cape Evans, some 250 miles, in late autumn. It is not on account of new discoveries and scientific work accomplished that this volume is important, for of new discoveries the northern party had few,

[1] "Antarctic Adventure. Scott's Northern Party." By R. E. Priestley. Pp. 382 + maps and illustrations. (London: T. Fisher Unwin, 1914.) Price 15s. net.

and very seldom does Mr. Priestley reveal the result of their scientific work during the first winter: during the second, of course, little could be accomplished. But the interest of the volume lies in its being a full account of how six men lived through an antarctic winter practically on what land and sea produce, and so proved that this can be done with comparative safety. That is the importance of Mr. Priestley's book, and as such, it should be studied carefully by every future explorer in polar regions. The author has been careful to record every expedient and makeshift he and his comrades found useful in their long struggle against adverse circumstances, and it is all these trifling details that give great value to the book. The work is well illustrated and contains three maps.

SECRET REMEDIES.

It will scarcely be questioned that the freedom allowed to quackery in this country is unreasonable. To estimate properly the effect of drugs on the progress of disease in the human body is one of the most difficult of tasks, even for highly trained observers; yet any person vending alleged remedies is permitted to assert the efficacy of his nostrums in the cure of ailments, and to use the public as *corpus vile* for them, practically without let or hindrance. Not only so; he often mulcts the public heavily for the privilege.

This is the conclusion forced upon the reader by a perusal of the Report of the Select Committee appointed to inquire into the question of the sale of patent and proprietary medicines. The anomalies and curiosities of the law and practice concerning these commodities are, the Committee finds, "numerous and remarkable," but as they are not specially pertinent to these columns, the interested reader is referred to the Report itself for examples.

The medicines in question differ widely in character. "At one end of the scale is the valuable scientific preparation; at the other is the mere vulgar swindle." They are classified by the Committee as follows:—

Class A: Non-Secret.—(1) Proprietary preparations consisting of genuine drugs, synthesised or extracted by skilled chemists and tested by therapeutists. Examples are aspirin, adrenaline, and urotropine. (2) Remedies which owe their value to skilful combination, such as mixtures of bismuth salts with pepsine. (3) Known drugs, with the formula disclosed, but mixed for convenience with inert substances the nature of which is a trade secret—*e.g.*, "tabloids."

It is considered that, with some possible exceptions, there is nothing in this class which calls for interference in the public interest.

Class B: Secret.—(1) Simple household rem-

edies, often originally manufactured from a doctor's family prescription, and undoubtedly beneficial for uncomplicated ailments. The chief criticism made upon the sale of medicines belonging to this group is that their retail price is out of all proportion to their cost, and that they are often recommended for cases they cannot benefit, thus causing the purchaser to run risk of serious injury by delay in seeking proper medical treatment. (2) Dangerous remedies which should not be sold at all, or only on a doctor's prescription; or which should not be sold for the purpose for which they are offered. (3) Fraudulent remedies: these are a large group, consisting of abortifacients, alleged cures for cancer, consumption, diabetes, paralysis, epilepsy, deafness, and so on, together with electric belts, apparatus for supplying oxygen to the system (otherwise than by respiration), "ionised" water, and the like. With a touch of humour, the Committee remarks that "the discovery of radium will probably add a number of remedies to this group." It has, in fact, already added some. The treatment of "remedies" included in this category need involve no doubt or hesitation. "They are, and are known by their makers to be, cruel frauds." The sale and advertisement of them should be prohibited under drastic penalties. Finally, (4) there is a large group of remedies making grossly exaggerated claims. In respect of these, it is regarded as beyond doubt that the public is defrauded on a large scale by promises which cannot be fulfilled.

A good deal was said during the inquiry about the difficulty, and even the impossibility, of completely analysing certain medicines—a matter which is vital to many proposals for dealing with secret remedies by law. It was pointed out that even such familiar and apparently simple articles as extracts of dandelion and gentian are really highly complex bodies, the exact composition of which is still unknown to chemistry, and when several such extracts are present in a mixture detection of all becomes difficult, and accurate determination of any may be out of the question. But whilst this is true enough, the focussing of the discussion upon this point puts the matter out of perspective. There are limits to the powers of analysis, but in a large majority of cases the essential nature of the principal constituents of any medicine can be detected with almost perfect certainty and determined with reasonable accuracy, given skill, time, and a sufficient quantity of material.

Several abuses in connection with secret remedies are indicated. Thus the composition has sometimes been changed whilst the name remained unaltered; *e.g.*, acetanilide has been replaced by phenacetin, and the potent drug morphine has been added in one case, removed in another, without the change being brought to the purchaser's notice. Again, one medicine is recommended as "a safe and simple remedy" for both asthma and bronchial affections, though these are medically of quite different types, the former being a nervous disease, the latter an inflammation of the mucous membrane.

The Committee gives cogent reasons against adopting a suggestion made by medical witnesses and others, namely that every remedy sold should be compelled to bear a label stating its exact composition. This would inflict hardship; it would not necessarily convey useful information to the purchaser, who could not be expected to know chemical names such as, for example, "hexamethylene-tetramine"; moreover, an accurate statement might be in itself misleading. It is proposed, however, that an exact and complete statement of the ingredients and their proportions should be lodged with a department of the Government, and controlled by a confidential analysis. All patent, secret, and proprietary remedies should be registered with this department, and a special Court or Commission should have power to prohibit the sale or advertisement of such remedies, either in the public interest or on the ground of non-compliance with the law. New legislation is urgently needed to deal with a state of things which has become intolerable.

The findings and recommendations of the Committee are too lengthy to summarise further here. It may be said generally that the Report is fair but firm, and shows that its compilers, whilst considering legitimate interests, have not allowed themselves to be hoodwinked by the quack.

ORGANISATION OF SCIENCE.

JUST before the beginning of the war much fruitful discussion was going on in the columns of NATURE, the *Morning Post,* and *Science Progress* on the subject of the encouragement of science; and those who are interested in the theme should read Dr. R. S. Woodward's address on the needs of research, delivered on the occasion of the dedication of the Marine Biological Laboratory, Woods Hole, Massachusetts (*Science,* August 14, 1914).

Dr. Woodward begins by exposing some of the popular fallacies regarding research—that it "is akin to necromancy"; and that "the more remarkable results of research are produced not by the better balanced minds, but by aberrant types of mind popularly designated by that word of ghostly, if not ghastly, implications, namely, 'genius.'" He has also exposed the absurdity that research institutions should busy themselves in soliciting suggestions from the amateur public outside, that is, "in casting drag-nets in the wide world of thought, or in dredging, as biologists would say, with the expectation that out of the vast slimy miscellanies thus collected there will be found by the aid of a corps of patient examiners some precious sediments of truth." He thinks that "important advances in knowledge are far more likely to issue from the expert than from the inexpert in research."

Dr. Woodward traverses the idea "that research is a harmless and a fruitless diversion in the business of education"; and gives some figures

as to the comparative expenditure of the United States on education and research respectively.

The number of higher, or degree-giving, establishments in the United States is now upwards of six hundred; the aggregate annual income of these is upwards of one hundred millions of dollars; and the number of officials connected with them is upwards of thirty thousand. On the other hand, the number of independent research organisations in the United States is less than half a dozen; their aggregate annual income is less than two million dollars; and the number of officials primarily connected with them is less than five hundred.

Something very like this holds also in Britain, and indeed throughout the world. Men cannot be made to understand, even with the astonishing results which investigation has placed before us, the supreme importance of such effort. They still conceive that it is more important to teach boys how to do things than actually to get the things done.

The war now raging will at least demonstrate one thing to humanity—that in war, at least, the scientific attitude, the careful investigation of details, the preliminary preparation, and the well thought-out procedure bring success, where the absence of these leads only to disaster. So also in everything. After all, the necessity for research is the most evident of all propositions. But the question (which I hope will receive still more careful attention when the war is over) is, What can the State do to make the machinery of investigation the most efficient possible? The mere citing of popular misconceptions is not enough; we need to have specific programmes. The October number of *Science Progress* contains one such programme, which I hope will receive the attention of men of science. Whether all the items are accepted or not remains to be seen; but until the discussion is earnestly undertaken, we can scarcely hope that the State will give more help than it has done hitherto. Dr. Woodward puts his finger upon a weak point in men of science as a body. "We are," he says, "as a class of too recent monastic descent to fit comfortably in our present social environment." That is just it. We are not strong enough in making our demands heard; and, in my opinion, this is not a virtue, but a neglect of duty.

RONALD ROSS.

ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

THE anniversary meeting of the Royal Society was held on Monday, November 30, when an address was delivered by the president, Sir William Crookes, and the report of the council was presented. After referring to the financial strain under which the society and the National Physical Laboratory have been placed by the war, the president passed to the consideration of the constitution of the atom and the work of the medallists. Subjoined are the portions of the address referring to these matters:—

The subject of the constitution of the atom has come into extreme prominence—great advances have been made—while much light has been thrown on the ultimate structure of matter. Years ago, during the persistent and systematic fractionation of yttrium, I explained that I had succeeded in separating the atoms of the so-called element into groups; these groups undoubtedly exhibited different phosphorescent spectra and presumably had different atomic weights—although from the chemical point of view all the groups behaved similarly. I concluded that, of the lines and bands of the compound spectrum of an element, some are furnished by certain atoms and some by others. I pointed out that this was not likely to be an isolated case; that probably in all so-called elements the whole spectrum does not come from all the atoms—that different spectral rays come from different atoms, which may be interpreted to mean that there are definite differences in the internal motions of the several groups of which the atoms of a chemical element consist. I ventured to suggest a possible explanation of these facts, based on the assumption that acting on the original *protyle* were two forces—one of the character of Time, accompanied by a lowering of temperature, while the other, swinging to and fro like a pendulum, and having periodic cycles of ebb and flow, rest and activity, would be intimately connected with the force of electricity. I arrived at a presentation of the elements on a lemniscate path which seemed to me to throw some light on the question of their genesis. My researches seemed to show that the persistence of the ultimate character, the eternal self-existence, the fortuitous origin of the chemical elements, could no longer be regarded merely as probable.

Apparently bodies exist which possess close upon the same atomic weights and combine in definite proportions with other substances and yet exhibit certain minute differences. For these substances, which are capable of being isolated and identified, I suggested the name "meta-elements." Thus there appears to me to be a gradation of molecules of different ranks between the atom and the compound—and these aggregations of atoms in certain circumstances might well pass for simple elementary bodies.

In recent years the old idea of the ultimate atom as a solid particle, spherical or otherwise, has slowly, almost imperceptibly, given way to the more rational conception of a minute planetary or "Saturnian" system of dazzling complexity; the conception is many-minded, aided here and there by facts that failed to fall in with the old lines of thought. Among the most prominent men through which the new conception has come to light, we have Kelvin, Stoney, Thomson, and, more recently, headed by Sir Ernest Rutherford, a host of vigorous workers in the new science of radio-activity, who have built up a conception of atomic physics often "hard to be understood," but that probably is a move in the right direction. Sir Ernest Rutherford supposes the atom to be composed of a nuclear positive charge, exceedingly small compared with the sphere of action of the atom, and consisting of a number of unit charges. Surrounding this nucleus is an external shell in which a number of separate negative electrons are distributed. Prof. Soddy—whose name is closely associated with that of Sir Ernest Rutherford—is one of the earliest workers in radio-activity, and has developed a theory of the chemistry of the radio-elements based upon the periodic law and a modified form of lemniscate spiral where the existence of *pseudo*-elements having slightly different atomic weight but identical chemical properties are set out. These "isotopic" elements occupy the same place in the periodic table. He has

thus arrived, by a totally different path from the one I travelled, at the conception of an element having atoms of different weight though chemically identical. The theory has recently received some confirmation by the analyses of the lead that is found in the minerals pitchblende, thorianite, etc. In my own laboratory a spectroscopic examination of the lead from Cornwall pitchblende has shown traces of thallium not found in pure assay lead; the unexpected presence of this element may have some bearing on the slightly different atomic weight values recorded for the lead extracted from the radio-minerals.

Without risking a charge of being unduly optimistic I think I may believe we are on the brink of striking developments in our knowledge of the structure of the elusive atom. Whatever may be the outcome of researches now prosecuted with so much zeal and success, I feel that Addison was speaking with the voice of prophetic Truth when, more than a hundred years ago, he said: "Every atom is a standing miracle and endowed with such qualities as could not be impressed upon it by a Power and a Wisdom less than infinite."

Medals.

With great pleasure I announce that the Copley Medal this year is awarded to Sir Joseph John Thomson, in recognition of the value of his researches in physical science. His early work in the investigation of electrical phenomena showed he possessed a high degree of experimental ingenuity and skill: by his study of the passage of electricity through gases he elucidated the nature of the negative electrical particles, thus providing an experimental basis for the atomic theories of the nature of electricity. His treatise on the conduction of electricity through gases won for him a world-wide reputation as a physicist—to which subsequent work has added. To him is due the investigation of the nature of the positive carriers of the electric charge; his method of positive ray analysis puts a new and extraordinarily valuable tool into the hands of investigators. His experimental work has always been controlled and confirmed by theoretical considerations; his work at the Cavendish Laboratory at Cambridge has greatly extended our knowledge of the structure and nature of matter.

The two Royal Medals annually presented by the King have—with his Majesty's approval—been assigned to Prof. E. W. Brown and Prof. W. J. Sollas. Prof. E. W. Brown, who now occupies the chair of mathematics at Yale University, devoted himself for many years to the study of the movements of the moon; and by incredible industry seven years ago he brought to a successful conclusion his investigation of this fundamentally important practical problem. He has recently further studied some phenomena which known gravitation causes do not explain, and he has extended his investigations to the general theory of orbits. His work in dynamical astronomy has been remarkably fruitful, and doubtless the years to come will add lustre to his already brilliant reputation.

The Royal Medal—awarded to a worker in biological science—this year has been conferred on Prof. Sollas, who is a pioneer in many fields, and has made many valuable contributions to our knowledge of geology, mineralogy, zoology, and ethnography. His monograph on sponges is a classic on the subject. He has perfected a method of obtaining transverse sections of fossil organisms, and thus he has obtained a knowledge of the structure of certain specimens which long have been the subject of dispute. We hope that Prof. Sollas will have many opportunities of extending his investigations, which already have borne so much valuable fruit.

The recipient of the Davy Medal is Prof. W. J. Pope, who has made highly important discoveries in stereochemistry, and whose work has thrown much light upon the relation between chemical constitution and crystalline structure. In collaboration with Profs. Perkin and Wallach, Prof. Pope has published the results of many experiments dealing with the isolation and investigation of optically active compounds of nitrogen, tin, selenium, and sulphur; he explains their activity by supposing that the radicles in the active compound are tetrahedrally arranged round a central atom as in carbon compounds. With Prof. Barlow he has more recently been engaged in the establishment of a theory dealing with the connection between crystalline structure and chemical constitution. He has succeeded in reproducing the crystalline form of most substances of known composition, basing his work upon the assumptions of his theory—the experimental and theoretical results show a remarkable concordance. He has further suggested a theory of "valency volume" which is leading to important developments in the investigation of atomic volumes.

The Rumford Medal is awarded to Lord Rayleigh, in token of the council's appreciation of the mathematical and physical work associated with his name. Lord Rayleigh has, perhaps, done more than any scientific man living to stimulate research; his work in the sciences of heat and radiation has paved the way for remarkable advances, both theoretical and experimental. The Copley Medal was given to Lord Rayleigh in 1899, but the council wish to offer him some further mark of their recognition of the great value of the research which he still continues to pursue with such conspicuous success.

The Hughes Medal is this year conferred upon Prof. J. S. Townsend, of the University of Oxford, for his work upon molecular conduction in gases, and upon the nature of the disruptive discharge. Prof. Townsend has made a brilliant investigation of the phenomena of conduction by the ionisation of gases by means of Röntgen and similar radiations. The study of the diffusion of the ions of gases led to very important conclusions about the size and nature of gaseous ions—and the theory of ionisation has been greatly extended by Prof. Townsend's work.

The Darwin Medal this year is awarded to Prof. Poulton, in recognition of the value of his researches upon the curious phenomena of mimicry and protective resemblance in insects. Prof. Poulton has brought together a vast number of facts which confirm Darwin's theory on the subject, and he has recently devised and organised a remarkable series of breeding experiments with species of insects in order further to test his conclusions.

The report of the council refers, among other matters, to the effect of the war upon several undertakings with which the society is concerned. It is estimated that in connection with the International Catalogue of Scientific Literature the reduction of subscriptions and sales will mean a loss of about 4000*l.* on the three volumes in hand; and this loss will, at any rate in the first instance, fall upon the Royal Society. About forty members of the staff of the National Physical Laboratory are now serving with the colours, and this, with other results of the war, has had an adverse effect on the ordinary work of the laboratory. Should the war continue, it will be necessary to bring the question of the financial position of the laboratory before the Treasury at an early date. The donations to the society recorded in the report of the council are: 5000*l.* from Sir James Caird, in aid of physical research, the amount not to be

funded, but expended as capital at the rate of about 500*l*. a year; 2000*l*. from Mr. John Dewrance, as a gift to the donation fund to secure the payment of interest amounting to 100*l*. a year, to be expended in accordance with the terms of the trust of that fund; 4000*l*. from the Misses Lawrence, the income to be devoted to research into the causes and cure of disease in man and animals, the gift being associated with the names of their father, Sir William Lawrence, F.R.S., and their brother, Sir Trevor Lawrence; 100*l*. from the late Sir Joseph Swan, in aid of the expenses of publication; 1650*l*. from the late Mr. W. Erasmus Darwin, without conditions.

On account of the war, the usual anniversary banquet was not held this year.

NOTES.

THE Academy of Natural Sciences of Philadelphia, at a special meeting held on November 24, presented the gold medal of the Hayden Memorial Geological Award to Prof. H. F. Osborn, in recognition of his brilliant palæontological studies. The presentation address was delivered by the president, the Hon. S. G. Dixon.

AT a meeting of the organising committee of the sixth International Congress of Photography, held at the rooms of the Royal Photographic Society, on Friday, November 27, it was unanimously decided to suspend the work of the committee until such time as the officers should consider it could be resumed successfully.

ON Tuesday, November 24, the Royal Geological Society of Cornwall, at its annual meeting at Penzance, presented Mr. Henry Dewey with the Bolitho gold medal for his work and papers on the survey of Devon and Cornwall. Mr. Dewey afterwards gave an account of his experiments which led him to attribute the formation of Spilosites and Adinoles to the presence of ferric or ferrous oxides in the slates into which the igneous rocks had intruded.

THE death is reported of Dr. C. S. Minot, the distinguished American anatomist, in his sixty-second year. He graduated at the Massachusetts Institute of Technology in 1872, and then spent several years in study in Europe. At Harvard University he held minor appointments from 1880 to 1888, when he became assistant professor of histology. In 1892 he became full professor, and in 1905 migrated to the James Stillman chair of comparative anatomy. Prof. Minot was a member of numerous American and foreign learned societies, and an honorary doctor of Yale, Toronto, St. Andrews, and Oxford. He was the author of "Human Embryology," "Bibliography of Vertebrate Embryology," "A Laboratory Text-book of Embryology," and "Age, Growth, and Death."

MR. JOHN BURROUGHS, of West Park, N.Y., the veteran writer and observer whose works on natural history and other subjects have made him famous among lovers of nature and good literature in the old world as well as the new, has sent to the New York *Tribune* a convincing letter in which he explains why he and other Americans have had their regard for Germany turned to aversion by the events of the present war. The spirit of Prussian militarism is unworthy of twentieth-century civilisation; and though the military machine which crushes the innocent and unoffending, and destroys things beautiful and precious, in the hope of accomplishing its purpose, may be efficient, it is neither admirable nor human. "War," concludes Mr. Burroughs, "as now waged by the Kaiser against Belgium and France, is but a high-sounding name for the collective murder and pillage and arson of a vast organised band of outlaws, and for my part I believe it is the last spectacle of the kind, and on such a scale, that the world will ever see."

IN the October number of the *Victorian Naturalist* Mr. F. Chapman describes the impression of the fruit of a Casuarina in the basalt of Victoria. Wood of an apparently existing species of the genus has been previously recorded from beneath 90 ft. of the basalt.

IN concluding his notes on a collecting trip in Borneo, in the November number of the *Zoologist*, Mr. J. C. Moulton records the discovery of a previously unknown mountain—Mount Merinjak—in the heart of the country on the border between Sarawak and Dutch Borneo. It is a flat-topped mountain of 2220 ft. elevation.

AT the Cage-Bird Show held at the Royal Horticultural Society last week, Mr. David Ezra, of 110 Mount Street, W., exhibited specimens of living humming-birds. The birds are stated to have been in London for the last six months or so. At this time of year they are kept in steam-heated cages, each furnished with a miniature furnace. The interiors are decorated with moss and orchids, the flowers of the latter furnishing the tiny inmates with nectar. When natural nectar fails, the birds are supplied with an artificial compound of honey, sponge-cake crumbs, and babies' patent food.

THE first part of an article on Japanese Lepidoptera and their larvæ, by Mr. A. E. Wileman, published in the June issue of the *Philippine Journal of Science*, is illustrated by three coloured plates of the caterpillars and pupæ of butterflies. A grass-green swallow-tail caterpillar marked with transverse golden bands harmonises in a striking manner with the trifoliate leaves of its food-plant, which have a yellow venation. Other articles in the same issue include one on Philippine medusas and a second on Philippine alcyonarians, both by Mr. S. F. Light. Two new generic types are named and described in the former and one in the latter; one of the new medusas, *Acromitus maculosus*, appears to be a very beautiful species, with a bell of fully 90 mm. in diameter. Lemnaloides, indicative of affinity with Lemnalia, is the name of the new alcyonarian.

THE fourth number of vol. ii. of the Science Bulletin of the Museum of the Brooklyn Institute is devoted to a report of the scientific results of a collecting expedition to South Georgia in a whaling brig, under-

taken by Mr. R. C. Murphy during 1912 and 1913. The main objects of the trip were to obtain a collection of South Georgian birds, and skins, and skeletons of the sea-elephant. Unfortunately the latter part of the programme was not accomplished, although a considerable series of sea-elephant skulls was obtained. Despite the lack of definite arrangements for collecting invertebrates, a number of interesting specimens were secured, which, together with certain plants, form the subjects of notes by specialists embodied in the report. One of the new types is an eight-rayed starfish, described by Prof. Koehler, of Lyons, as *Anasterias octoradiata.* During the voyage to the south specimens of the male of the minute parasitic crustacean *Pandarus satyrus*—previously known only by females—were obtained on the fins of a shark.

The October number of the *Emu* contains a translation of an article by Mr. L. Brasil (originally published in the *Bull. Soc. Linn. Normandie*), on the emeu of King Island. In the early part of last century, when Baudin's expedition landed there, that island abounded with emeus, which were, however, soon after killed off. Péron found emeus both on King Island and Kangaroo Island, and in the account of his voyage, published a plate showing one black-breasted and a second and larger whitish-breasted bird. The former, as represented by a female specimen in the Paris Museum, certainly came from Kangaroo Island, but it has been suggested by Mr. G. M. Mathews that the white-breasted bird came from King Island, and is either the extinct *Dromaeus minor,* or a second and distinct species, *D. spenceri.* This view is disputed by Mr. Brasil, who considers that both Péron's birds came from Kangaroo Island, and suggests that the whitish-breasted specimen represents the male, and the black-breasted (as attested by the Paris specimen) the female. Whether the Kangaroo Island *D. parvulus* is really distinct from the King Island *D. minor* is left an open question.

In addition to a paper on the nomenclature of local birds and another on the probable mode of extermination of the moas, to which reference was made in the issue of NATURE of November 5, p. 265, under the title of "Ornithological Notes," the Transactions and Proceedings of the New Zealand Institute for 1913 contain communications in which several additions are made to the fauna of the Dominion and the surrounding sea. Among these is one by Mr. S. Berry, of California, on a collection of cephalopods from the Kermadoc Islands, in which two new species of Polypus (Octopus), and a new squid of the genus Abralia are named and described; two of the new forms are figured. Certain New Zealand fishes—two of which are described as new—form the subject of an illustrated note by Mr. E. R. Waite, the most generally interesting specimen being a ribband-fish (*Lophotes cepedianus*) taken in the Wellington district. Two plates illustrating a long paper by Mr. M. N. Watt on the eggs of New Zealand Lepidoptera are notable on account of the exceeding beauty of form and sculpture of some of the specimens figured. Botanists will be interested in a communication from Mr. T. F. Cheeseman on the rate of growth of the kauri pine (*Agathis australis*), and the age to which it attains. It has been asserted that one of these giant trees, with a diameter of 24 ft., is more than 4000 years old, and a second, of 22 ft. in diameter, not less than 3600. In the opinion of the author, based on the number of rings of growth and an estimate of the rate of growth at different ages, these figures should be reduced, respectively, to 1396 and 1280.

Attention has been directed on several occasions in these columns to the excellent work accomplished by the Essex Field Club. Among its many activities is the assistance the members of the club render to the Essex Museum of Natural History at Stratford. The museum is under the control and management of the Higher Education Sub-committee of the Education Committee of the County Borough of West Ham, while the care and arrangement of the collections are undertaken by the council of the Field Club in pursuance of agreements with the West Ham Corporation. The club also interests itself in a second museum situated in Epping Forest, the whole of the arrangement and organisation of which has been carried out by the honorary curators, Messrs. W., B. G., and H. A. Cole, assisted by other members of the club. At the Stratford Museum is a library of some 3000 volumes on natural history and kindred sciences, and local teachers are encouraged to make free use of them. Facilities for class teaching at the museum have been arranged, and teachers may also borrow duplicate specimens for demonstration. The excellent work in these directions which is being done by the Essex Field Club shows how much enthusiastic local societies can assist in scientific education.

In two recent papers Dr. W. E. Agar continues his studies on heredity and the life-cycle in the Daphniidæ. The larger paper, on "Experiments on Inheritance in Parthenogenesis" (Phil. Trans. Roy. Soc., No. B 323), consists of a very interesting study of inheritance in parthenogenesis. As is well known, Johannsen and others maintain that within a "pure line" there is no inheritance of size-variation; all such variability is regarded as due to environment, and not inherited. These conclusions have been criticised by Prof. Karl Pearson, who adduced the work of Warren on Daphnia and an Aphid as being opposed to them. Agar has made very full experiments with the Daphnid, *Simocephalus exspinosus,* supported by less extensive work on other Daphnids and on the Aphid Macrosiphum. He bred many generations from single females hatched from ephippia, and although when the ancestral correlations are worked out in a population derived from a number of ex-ephippio females, these correlations are considerable (0·3–0·6), yet the parental correlation is in general no greater than the grandparental, or even great-great-grandparental. When, however, a population is produced from a single ex-ephippio female, there is no correlation at all between parents or earlier ancestors and offspring. The ancestral correlation in the first case is due to the presence of many genotypes among the population; within the single genotype the correlation vanishes. The paper contains

many other interesting points which cannot be alluded to in a short space. An earlier paper (in the *Journal of Genetics*, iii. (1914), p. 179) shows that in Simocephalus the idea of an inherent reproductive cycle is mistaken, and that the production of males probably depends on certain unknown factors acting in a cumulative manner over several generations.

THE December issue of the *Fortnightly Review* contains an article by Mr. J. B. C. Kershaw on the effect of warfare upon commerce and industry. He shows that the fluctuations of our trade during the past half-century have been largely independent of the wars that have been carried on by our own and other countries. The effect of wars upon the trade of this country will be measured to a large extent by the degree of their interference with the fundamental occupation of agriculture in the countries involved, and the results will be manifest, not at the moment, but in the year or years directly following the war.

WE have referred occasionally to the useful and somewhat laborious compilations of information relating to ice in the Southern Ocean contained in the monthly meteorological charts of the Indian Ocean issued by authority of the Meteorological Committee. The chart for December gives a table showing the number of instances, for each of the twelve months in the years 1885–1913, of reports that have reached the Meteorological Office. Out of a total of 1694 reports, 258 were for the year 1893 and 305 for the year 1906. The largest number of reports have been from ships traversing the South Atlantic, and mostly between Cape Horn and 40° S., and between 30° and 60° W., and the smallest number were from ships in the South Pacific; but it is pointed out that absence of ice in certain parts cannot be taken as proof that none existed. The highest of the bergs was 1700 ft. (June, 1884, 44° S., 49° E.); those of 1000 ft. are comparatively numerous. Bergs varying from five to twenty miles in length are frequently sighted south of 40° S.; and the tables show that icebergs extending from six to fifty miles in length are "far from uncommon" in the Southern Ocean.

IN the November issue of *Symons's Meteorological Magazine* "The Practical Utility of a World Bureau of Meteorology" is again urged by Mr. W. M. Hays and Mr. H. H. Clayton (see NATURE, October 1). The suggestions include: (1) the use of telegraphic weather reports from all available parts of the globe, for framing estimates of the effect of weather changes on crops, and (2) the unification and improvement of meteorological services generally. If such a scheme were really practicable as regards daily or seasonal weather forecasts, there could be little question of its general utility. The authors' own views upon the subject are supplemented by the opinions of eminent meteorological authorities, and in our issue of February 26 Dr. Shaw referred to the desirability of daily weather reports for the whole globe. To have any chance of success, such a plan as that now in question should (we presume) be recommended by the International Meteorological Committee as a body, but all efforts towards the creation of an independent institution at six international meetings, at least, led to no favourable result. The great enterprise of the U.S. Weather Bureau in establishing a daily service for the northern hemisphere may eventually aid the solution of the much more ambitious problem.

IN NATURE for October 15 we referred to the reported invention, by an Italian professor named Argentieri, of a "pocket" system of radio-telegraphy. We now learn from an Italian source that a gentleman of this name has been demonstrating a system of telegraphy before an Italian Government Committee, but what are the advantages claimed for the apparatus, and what its success, are at present being kept a secret by the parties concerned.

THE value of magnetic tests as a means of determining the changes which occur in paramagnetic materials at high temperatures is well illustrated by a paper by Prof. Honda and Mr. T. Soné on the changes of structure of certain iron and chromium compounds, which appears in the August number of the Science Reports of the University of Sendai, Japan. From their observations it appears that although at very high temperatures magnetite, Fe_3O_4, is more stable than hæmatite, Fe_2O_3, at temperatures below 1300° C., the reverse is the case, and that magnetite, once it is heated above 1100° C., is almost entirely converted into hæmatite, and remains hæmatite on cooling again to ordinary temperatures. This deduction from the magnetic observations has been confirmed by weighings. Heating to 1300° C. appears to produce no structural change in chromic oxide, Cr_2O_3, but chromium trioxide, CrO_3, appears to undergo two non-reversible changes.

IN a paper read before the Royal Society in 1909 Mr. S. Kinoshita showed that an α particle projected through a photographic film is capable, throughout the whole of its range, of making any grain of silver chloride it strikes developable. Since then, in company with Mr. H. Ikeuti, he has been using this method of tracing the paths of the α particles, and some of his results are reproduced in the September number of the Proceedings of the Tokyo Mathematico-Physical Society. The α particles were obtained from the end of a needle which had been rubbed on a metal surface previously exposed to radium emanation. The end was brought close up to or into contact with the photographic plate. After development the plate shows under the microscope a series of developed grains lying in straight lines radiating from, and forming a halo round the region of contact, extending 0·054 millimetre beyond the outside rim of the contact patch. These grains are distributed through the thickness of the photographic film, and are due apparently to the α particles from radium-C. Another series of developed grains close to the surface of the film appears to be due to α particles projected tangentially to the surface from active material slightly above it. A few grains still further afield the authors ascribe to β particles.

SUNSET "afterglows" resembling those seen after the memorable Krakatoa eruption were recorded on various occasions during the autumn and winter of 1913–14. We have now received from Prof. Ignazio Galli the third of a series of reports dealing briefly with these observations, this report being reprinted from the *Atti della pontifica Accademia romana dei nuovi Lincei*, vii., read last June. The phenomena were noticed for the first time at Rome on July 13, 1913, and about the same time at Bagnères de Bigorre, in the Pyrenees. The most noticeable display seems to have occurred on November 29, when it was recorded in France, Italy, Belgium, and England. At Rome the phenomenon was observed in a greater or less marked degree from February 15 onwards until April 10, but while in the typical afterglow the colour passes gradually from yellow through orange, sometimes mauve to a deep crimson, only the yellow and orange, sometimes only the yellow, were observed in the western horizon at Rome towards the end of this period. On the other hand, marked effects were recorded by Krebs in Holstein on December 31, when the moon added to the effect. The February glows were observed at Brussels, and particularly on February 19 in Morocco, where they were supposed at first to be due to an aurora borealis. In China, Father Corvillard describes fine displays on October 30, 1913, and April 18, 1914. Assuming these effects to be due to volcanic dust, as in the case of Krakatoa, Prof. Galli refers them to the eruptions of Katmai, in Alaska, on June 6, 1912, Asama-Yama in June 1913, Mount Benbow, in the New Hebrides, on December 6, and Sakarishima, in Japan, on January 11, 1914. These eruptions, especially the last, were accompanied by copious emission of dust, but whether the later date observations, particularly the Chinese one of April 18, were due to the last eruption, can scarcely be decided definitely on the evidence now submitted by Prof. Galli.

AN interesting paper on the presence of salicylic aldehyde in soils is contributed to the Journal of the Franklin Institute by Dr. Oswald Schreiner and Mr. J. J. Skinner. From certain soils, especially from some which had been used for intensive culture and greenhouse work, marked traces of an aldehyde could be extracted which showed the qualitative properties of salicylic aldehyde. The aldehyde extract was found to exercise a marked toxic effect on plant growth, and as the proportion of aldehyde is largest in the case of heavily manured greenhouse soils which have become "sick," there seems to be a relationship between the "sickness" and the proportion of aldehyde present. On the other hand, only a relatively small number of the poor soils examined showed the presence of the aldehyde, owing perhaps to the presence of other toxic substances. The material extracted by the aldehyde method was in all cases extremely small, and frequently gave no aldehyde reaction, although exercising marked toxic effect. What the harmful constituent in such cases is cannot yet be stated. In many instances the extract was not only not harmful, but exercised a stimulating effect on plant growth.

To the *Popular Science Monthly* for November Mr. R. Hugins contributes an interesting article on civilisation as a selective factor, in which it is contended that, contrary to the view generally put forward by writers in recent years, more particularly by Weismann and Wallace, there has been a real improvement of civilised man by an "agency at once powerful, comprehensive, and continuous." This agency may be designated the "elimination of the anti-social." The effect of this influence in modifying individual and national character is traced in its many forms, such as the elimination of the criminal, voluntary withdrawal, including suicide, occupational and geographical withdrawal, and, possibly most active of all, military selection, which by eliminating in the past large numbers of the predatory and intractable members of society has had the curious result that there has been an actual improvement of the military value of civilised races taking place side by side with the development of the moral character of those races. The reason for this apparent paradox is to be found in the fact that the same moral qualities have been selected through the elimination of the anti-social as are essential in the best armies—virtues such as obedience, the habit of discipline, self-control, and steadfastness.

WE have received a copy of a pamphlet entitled, "English, French, and German Vocabulary for Water Supply in the Field," prepared by Mr. Philip Parker, of 25 Victoria Street, S.W., for members of the expeditionary force. The pamphlet contains, in addition to what is implied by its title, a number of sentences in the three languages well calculated to be of great use to the soldier inquiring from a foreigner with regard to water supply. The words in the vocabulary, although necessarily not numerous, appear to be well chosen; the author, however, is apparently not very well informed as to some of the foreign equivalents of chemical terms, and some of the chemical formulæ are wrong. The pamphlet concludes with some instructions for the disinfection of water by chloride of lime. These notes are somewhat laconic and appear to supplement or emphasise other instructions on the same subject. The suggestions for a rough and ready method of determining the quantity of chloride of lime required are decidedly ingenious, but we fear that not only the suggested dose, which apparently works out at about three parts of active chlorine per million parts of water after fifteen minutes' contact, but, more particularly, the time of contact (fifteen minutes) of the water with the disinfectant are considerably too low for safety. Probably two or three times the dose with ten to fifteen hours' contact would be none too much to render a polluted water reasonably safe, and surely in a matter of this kind it is better to err on the side of safety. Apart from this, the pamphlet fulfils a very useful purpose, and we congratulate the author on the service he has rendered to our troops by producing it.

OUR ASTRONOMICAL COLUMN.

COMET NEWS.—A postcard from the Central Bureau at Copenhagen gives the elements and ephemeris of comet 1914*e* (Campbell), or comet 1914*d* (Lunt). The comet is faint, being of about the eleventh magnitude, but the following ephemeris, taken from the above, may be useful for those observers equipped with large telescopes:—

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
Dec. 3	22 0 8	+11 18·9	
5	1 35	11 38·2	10·9
7	3 4	11 57·3	
9	4 36	12 16·1	11·1
11	6 10	12 34·7	
13	7 45	12 53·1	11·2
15	9 22	13 11·3	
17	22 11 1	+13 29·4	11·4

Delavan's comet (1913*f*), now to be observed before dawn, has the following positions continued from the same source as stated last week:—

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
Dec. 5	15 58 38	+0 49·4	5·3
7	16 2 29	−0 9·9	
9	16 6 16	−1 7·8	5·4
11	16 9 59	−2 4·3	

A CENTRAL BUREAU FOR TRANSMISSION OF ASTRONOMICAL NEWS.—In this column for October 15 attention was directed to the fact that in consequence of the war there was no central bureau for transmission of astronomical news. A circular has now come to hand to the effect that Prof. Elis Strömgren, of the Copenhagen Observatory, has taken over the management of the bureau. The circular, dated November 3, reads as follows:—"I have the honour herewith to inform you that according to an agreement made between Prof. Kobold, of Kiel, as the publisher of the *Astronomische Nachrichten,* and myself, the management of the 'Zentralstelle für Astronomische Telegramme' during the present war has been passed over to me. Consequently, I ask you to let communications for the Zentralstelle be addressed to me until further notice."

THE RECENT ECLIPSE EXPEDITION FROM MEUDON.—M. Deslandres records in the *Comptes rendus* for November 16 (vol. clix., No. 20), a brief account of the expedition sent by the Meudon Observatory to observe the late total solar eclipse at Strömsund, in Sweden, the observers being M. Bosler, of the Meudon Observatory, and M. Block, of the Lund Observatory. They were equipped with an equatorial of 8-in. aperture, carrying two spectrographs and a photographic camera with coloured screens; the spectrographs were so arranged to record the regions $\lambda 780$ to 500 and $\lambda 500$ to 360 separately. While the results given are considered only as preliminary, it is mentioned that the first spectrograph has recorded the existence of a new, intense, and sharp radiation superposed on the continuous spectrum of the corona. The wave-length is given as $\lambda 637·5$. This red ray, which, as is stated, is not chromospheric or has not been recorded as such, is attributed to the corona. On the other hand, the ordinary coronal radiation, the green radiation at $\lambda 530$, is stated to be absent from the plate. M. Deslandres is inclined to conclude that this new radiation is special to epochs of minimum of solar activity.

SPECTRA OF NOVÆ AT A VERY LATE STAGE.—In this column for June of last year (vol. xci., p. 382) a brief account was given of Prof. Barnard's observations in that year of the magnitudes of the new stars which had been discovered from time to time. These stars had passed outside the reach of spectroscopic observation, so little was known about their physical condition. The general observed routine of the sequence of spectra of nova indicated that they, in their last stages, presented a nebular spectrum, the most prominent line being that at $\lambda 5007$. Hartmann, however, in 1907 directed attention to the case of Nova Persei (1901) the spectrum of which in its later stages no longer exhibited the chief nebular lines, but presented a spectrum identical with that of the Wolf-Rayet star B.D. $+35°$ 4001. The question whether all novæ behave in a manner like Nova Persei becomes of great importance, because it may help to elucidate any explanation of the origin of novæ generally. In this connection the 60-in. reflector of the Mount Wilson Observatory, combined with a slit spectroscope carrying a 60° prism, and collimator and camera lenses of about 16 cm. focal length, has been put to a useful purpose by investigating the spectra of faint novæ. In the *Astronomical Journal* for October (vol xl., No. 3, p. 294) Messrs. W. S. Adams and F. G. Pease describe the results of their photographic research, which they carried out at the end of last and the beginning of this year, in connection with four faint novæ. The following table gives the names of the new stars in question, their magnitude, the durations of exposure, and the date:—

	Magnitude	Duration of exposure Hours	Date
Nova Aurigæ of 1891 ...	14	16	1914 March 18–22
Nova Persei of 1901 ...	12·4	8	1913 November 27
Nova Lacertæ of 1910..	12·5	11·5	1913 October 29–31
Nova Geminorum No. 2 of 1912	10	2	1914 February 22

The results of the investigation may be summed up as follows:—The authors find that the spectra of Nova Aurigæ and Nova Persei are essentially identical with the spectra of some of the Wolf-Rayet stars, as Hartmann noted in the case of Nova Persei. Nova Lacertæ and Nova Geminorum are not yet old enough to have reached the stage when the chief nebular lines disappear, so that they cannot yet exhibit the permanent spectrum of spent novæ. It is suggested that the permanent spectrum of novæ, taken in connection with their agreement with some of the Wolf Rayet stars, and the well-known agreement of distribution relative to the Milky Way of both novæ and Wolf-Rayet stars, point to a close connection between some of the latter and temporary stars in the later stages of their history. The hypothesis that the phenomenon of a temporary star is due to a star entering a nebula is deserving of some attention, since the disappearance of the chief nebula lines is coincident with the emergence of the stars from the nebula.

THE ANTWERP "GAZETTE ASTRONOMIQUE."—It is proposed to recommence the publication of the *Gazette Astronomique* formerly issued by the Astronomical Society of Antwerp. The occupation of that town by the Germans occasioned the temporary suspension of the *Gazette*, and many of its supporters have now found hospitable homes in this country. A number of English astronomers, on the initiative of Mrs. Fiammetta Wilson, of Bexley Heath, are interesting themselves in the matter by financial assistance and the promise of literary contributions. It is intended to restart the *Gazette Astronomique* early in January in the French and English languages. The minimum subscription will be five shillings annually, but English astronomers who are able and willing to subscribe more liberally may send half-a-guinea or a guinea as a means of more effectively aiding their

unfortunate Allies in the attempt to revive their astronomical journal. It will be issued once a month unless circumstances should enable it to appear more frequently. Subscriptions and correspondence should be sent to Felix de Roy, Hon. Sec., 29 Stamford Street, London, S.E.

THE HARDENING OF METALS.

A VISITOR at the recent meeting of the Faraday Society could scarcely have failed to be struck by the fact that although the society was supposed to be discussing the hardening of metals, in reality the discussion centred almost entirely round the various theories of the hardening of steels. The reason for this was probably twofold. First, in spite of, or perhaps on account of, the considerable amount of research work that has been published on this problem it still remains the most keenly debated topic in metallurgical circles, and one on which widely different opinions have been held. Secondly, from a practical point of view it may be broadly stated that, in regard to hardening, steels are the only alloys that really matter.

Yet there can be no doubt that the council of the Faraday Society made a wise choice in the title of the topic for discussion. Even the simplest pure iron carbon steel is a complex material. Its complexity is due to the facts that (1) iron exists in at least two well-defined allotropic forms; (2) above 780° C. it is non-magnetic; below it, magnetic; and (3) carbon has a remarkable tendency to form compounds of a high degree of molecular complexity. While considerable attention has been directed to the first two aspects of the matter, the third has not yet received the attention that it deserves, and will require before a complete solution of the problem can be reached. The position, therefore, is that while steels may be the most interesting alloys to investigate it does not follow that they are most suitable. What is first of all required is a fundamental investigation of the theory of the hardening of metals from which the foregoing disturbing causes are absent. When the foundations of this have been securely laid the precise effect of the above "variables" will no doubt be elucidated by suitably chosen experiments.

This aspect of the matter was clearly seen many years ago by Dr. G. T. Beilby, who has investigated the physical mechanism of the hardening of metals such as gold, silver, and copper, which can be obtained in a high state of purity, and from which magnetic and chemical complications are absent. Until quite recently it would have been possible to say that allotropic complications were also absent, and so far as present knowledge goes they were absent in the case of gold and silver. Recent investigations by Prof. Ernst Cohen (Utrecht), however, have led him to conclude that the metals cadmium, lead, bismuth, copper, zinc, and antimony ordinarily occur as metastable systems consisting of two or more allotropic forms, so that this consideration must be kept in view. Prof. Cohen was unfortunately unable to be present at the meeting, but an important summary of his results was available and is worthy of very close study. Ordinarily the transformations from one allotropic form to another are subject to strongly marked retardations, and it is only by employing certain devices such as the addition of an electrolyte and the use of the metal in a finely divided state that the transformation velocity can be increased to such an extent that the change from the metastable to the stable form occurs within a short time. These transformations are frequently accompanied by marked volume changes leading to complete disintegration of the metal.

These recent developments do not, however, alter the fact that Dr. Beilby chose for his investigations metals of the most suitable kind from the point of view of arriving at a physical conception of the mechanism of hardening by mechanical deformation, and they enabled him to prove the existence of a thermally stable crystalline and a mechanically stable amorphous vitreous phase in each metal investigated. How far-reaching and fundamental these conclusions have proved to be is evidenced by the fact that all the papers dealing with the hardening of steels presented at the meeting incorporated and made more or less use of them. According to Mr. Humfrey, "The hard structure which can be produced in carbon steels by quenching and in certain alloy steels by normal cooling is due to the presence of a hard, amorphous solution of α iron and iron carbide." Mr. McCance's view is that the hardening is due to "interstrained" α iron, and the suppression of the carbide change. The theory of Profs. Edwards and Carpenter is that the hardness is caused by the complete suppression of the carbide change, together with the presence of amorphous layers existing at the surfaces of slip upon which copious twinning occurs when carbon steels are quenched. On this view the *final* cause of hardening by quenching is exactly the same as that of hardening by cold working, viz., the internal deformation of the crystals.

When these theories are carefully examined it is significant to note how much they have in common. All of them agree that the carbide (Ar 1) change is suppressed, a fact of very fundamental importance. The differences centre round the precise condition of the iron, and arise chiefly from differences in conclusions drawn from the magnetic condition of the alloy. They will not be adjusted until it has been settled whether iron can be magnetic in other than the α condition. Mr. McCance apparently denies that the iron in hardened steels is amorphous. It is not yet clear precisely what he means by the term "interstrain," and how it differs, if at all, from the term "internal tension," suggested many years ago by Metcalf and Langley.

Most significant of all is the fact that none of the above theories make use of β iron. This means that the controversy has essentially changed. It is no longer between the allotropists who laid chief stress on the postulated existence of a hard, stable, crystalline β iron, which was held to be primarily responsible for the hardness of quenched steel, and the carbonists, who denied this altogether, and ascribed the hardness to the action of carbon without, however, being able to explain it. The complete solution of the problem now appears to be bound up with the acquisition of a more intimate knowledge of the molecular combinations between iron and carbon in hardened steels and their variations in the hardening range of temperature. Stimulus to investigations of this character will no doubt be given by the substantial prize offered by Sir Robert Hadfield, the president of the Faraday Society, for the best research dealing with the combinations between iron and carbon. He has rendered an important service in directing attention to this difficult but neglected side of the subject.

H. C. H. CARPENTER.

AIR, CLIMATE, AND TUBERCULOSIS.[1]

IN October, 1891, Thomas George Hodgkins, of Setauket, New York, made a donation to the Smithsonian Institution the income from a part of which was to be devoted to "the increase and diffusion of more exact knowledge in regard to the nature and

[1] Smithsonian Miscellaneous Collections. Vol. lxiii., No. 1. Hodgkins Fund. "Atmospheric Air in Relation to Tuberculosis." By Dr. G. Hinsdale. Pp. x+136. (Washington: Smithsonian Institution, 1914.)

properties of atmospheric air in connection with the welfare of man." From this fund a prize of 300*l.* was offered in 1908 for the best treatise on the relation of atmospheric air to tuberculosis. Numerous essays were submitted to the adjudicators, and Dr. Guy Hinsdale, of Hot Springs, Virginia, was one of the successful competitors. His essay, enlarged and more fully illustrated, has now been printed in vol. lxiii. of the Smithsonian Miscellaneous Collections, Publication No. 2254. It is necessary to recite these details; otherwise it would be difficult to understand the *raison d'être* of such a work as that now before us, which is that of an enthusiastic specialist. It has its faults—many of them—it also has the virtues of its kind. It is an expanded essay. It contains an enormous amount of information; facts and figures abound, and anyone studying questions of climate, the effect of elevation, the condition under which moisture is precipitated, the action of sunlight and the like, will here find ample data for consideration. One cannot but feel, however, that to it might be applied with propriety the Scotsman's description of a "haggis" as "fine confused feeding." This is to be regretted, as one is constantly coming across evidence that if the author could only leave his authorities severely alone now and again and let us have the result of his own cogitations, a far more stimulating and quite as informative a book would have been the result.

Starting out from the Adirondack Forest, whither Dr. A. L. Loomis, of New York, sent patients in order that they might have the benefit of the purest and most invigorating air obtainable, and where Dr. E. L. Trudeau, who himself had benefited from the treatment, founded a cottage sanatorium in 1884, Dr. Hinsdale, after indicating the success of Dr. Trudeau's experiment, takes his institution as an example. He maintains that the condition of the atmospheric air may be of great importance in the successful treatment of tuberculosis, and that such pure air is to be obtained in the midst of an evergreen forest of more than 10,000 square miles. It was "common knowledge" in the days of Pliny that forests, especially those which abound in pitch and balsam, are beneficial to consumptives, or to those who do not gather strength after long illness, and that they are of more value than the voyage to Egypt (C. Plinii, Hist. Nat., lib. xxiv., cap. 6). Such forests are to be found in the Hartz Mountains and the Black Forest of Germany, in the Ardennes, the large American and Canadian forests, and in our own New Forest areas. Here the air is pure and moderately moist—an important feature, though one to which too little attention is paid—and the rainfall averages not too high, in order that patients may get out of doors during a considerable part of the year.

It appears that there is a slight excess of ozone in the air of forests, and this, of course, may be a factor in the treatment of consumptive patients, though it is maintained by some that ozone which, even in great dilution, irritates the lungs, the throat, and the frontal sinuses cannot be of much value in the treatment of such cases. The author ventures no opinion on this point, but quotes Lorrain Smith to the effect that oxygen which at the tension of the atmosphere stimulates the lung cells to active absorption, at a higher tension acts as an irritant and sets up inflammatory processes.

Perhaps the most important points brought out by Dr. Hinsdale in connection with forests and afforestation are that the work of raising, transplanting, and caring for trees is specially adapted to the strength of convalescent consumptives and that various forms of woodcraft, such as basket-making and the manufacture of small rustic articles, may easily be carried on under healthful conditions in the forest.

The site of a model sanatorium for consumption may, with advantage, be above the snow-line for some part, if not for the whole, of the year. Here there is less organic matter in the atmosphere, and, as demonstrated by Boycott and Haldane, it is the organic matter in the air and not an excess of carbon dioxide that gives rise to the discomfort, headache, etc., suffered in badly ventilated rooms; moreover, the anaphylactic phenomena corresponding to those noted in "horse asthma" or "stable asthma," may be avoided by changing the air even when considerable quantities of carbon dioxide are allowed to persist. It is interesting to learn that the consumptive daughter of the discoverer of oxygen, Dr. Joseph Priestley, was condemned to pass a considerable time in a cow-house in order that the diminished oxygen and increased carbon dioxide "might lower the inflammatory action associated with the disease." Dr. Beddoes, who had charge of the patient, thought that this treatment would not be acceptable to all his patients, "as it seemed to me hopeless to propose residence in a cow-house, I advised that the patient should live during the winter in a room fitted up so as to ensure the command of a steady temperature. This advice was followed. Double doors and double windows were added to the bedroom, the fireplace was bricked up round the flue of a cast-iron stove for giving out pure air." Dr. Hinsdale's comment on this note is that the doctor persisted in his plan of treatment until the patient died. Dr. Hinsdale, from his own experience, makes a further point on which sufficient attention had not been concentrated. It is not the expired air of tuberculous patients that carries infection, but the sputum and the tiny drops of moisture coughed by the patient that carry the bacilli and communicate the disease to others, but, be it remembered, that many of the bacilli carried into the nose, mouth, and upper air passages soon lose their activity or are extruded.

In his chapter on the influence of sea air the author mentions that Aretaeus, about 250 B.C., recommended sea voyages to the patient strong enough to endure them, for the cure of consumption, and that about three hundred years later Celsus prescribed a voyage from Italy to Egypt, or, failing this, that the patient should pass a large portion of his time sailing on the Tiber. Such treatment has fallen out of vogue, probably because long distances are now covered in such short periods that changes in temperature and atmospheric conditions occur far too rapidly, and the patient is unable to accommodate himself to them sufficiently rapidly. Patients who are fond of the sea and who have the opportunity of travelling in a sailing ship in roomy, well-ventilated cabins, and under medical supervision, even now receive great benefit from this treatment which, however, should not be used indiscriminately.

It would be difficult to follow the author through his disquisitions on warmth, moisture, fog, and the like, but it may be accepted that he favours quiet, bracing atmospheres, through which the sun's actinic rays can pass but little obstructed. These, he thinks, are to be found on high ground, where also expansion of the thorax almost invariably occurs, though, following our own surgeons who send their cases of surgical tuberculosis to Margate, he recommends sea air for such cases. High grounds, he maintains, are natural gymnasia where patients living out in the open air can *graduate* their exercise and form and absorb their own tuberculin. Dr. Hinsdale insists that rest is essential to the well-being of the patient during the febrile phases of phthisis, and that a patient must never *over-exercise*, as he is greatly tempted to do in clear, bracing climates. Finally, he comes to the very common-sense conclusion that when all is said and done it is the man behind the climate who is able to

treat a tuberculous patient with greatest advantage, and that even he can do little without the hearty co-operation of his patient.

Many interesting questions are raised by Dr. Hinsdale; he gives numerous excellent and interesting illustrations of shelters, of institutions, of methods of treatment, of the results of heliotherapy and immobilisation in plaster; he delineates patients before treatment, patients during treatment, in plaster jackets and in sun baths, and patients after treatment, and altogether makes us feel that the publication is what it pretends to be, a collection of data that will interest those engaged in the treatment of tubercular patients. With all this it is a constant matter for regret that the author has not put a little more of himself into his work. For what it is, however, we are grateful, and it may be anticipated that it will be very widely consulted.

THE BRITISH ASSOCIATION IN TASMANIA.

THE Tasmanian contingent of the British Association left Melbourne by the s.s. *Loongana* on Saturday, September 5, at 10.30 p.m., and arrived at Launceston about 5 p.m. on the following day. The party numbered twenty-one. Owing to an unfortunate dislocation in the boat service it was impossible to carry out the Launceston portion of the original programme, although time was found to visit the Launceston Museum on Sunday evening, under the guidance of the curator, Mr. H. H. Scott, to whose zeal and energy this excellent little museum owes so much. On the following day there was just time for a brief visit to the beautiful Cataract Gorge before leaving by rail for Hobart. Tuesday, September 8, was occupied by receptions at the Hobart Town Hall, the museum, and the university, and a luncheon at Government House, and in the evening Dr. G. T. Moody gave a lecture on some commercial aspects of education. Wednesday, September 9, was devoted to a motor excursion to Mount Wellington, the party being entertained at lunch at the Springs Hotel by the Hon. Henry Dobson, who has done so much to open up Mount Wellington as a tourist resort. Some of the party proceeded on foot from the Springs to the summit, while others devoted themselves to the collection of natural history specimens, including the remarkable "mountain shrimp," *Anaspides tasmaniae*, so characteristic of the mountain streams of the island.

On Thursday, September 10, the party divided for several excursions in the neighbourhood of Hobart, including a dredging trip to the D'Entrecasteaux Channel, which resulted in the collection of much interesting material. On the following day they left for Maria Island, on the east coast, proceeding by motor as far as Spring Bay, whence the crossing to the island was made by motor boat. Maria Island is celebrated as the scene of a former convict settlement, and afterwards of various industrial experiments of the "wild-cat" type, in which much capital appears to have been sunk. The limestone rocks, of Permo-Carboniferous age, are crowded with fossils, which may be collected in unlimited quantity both in the "Fossil Cliff" on the shore and in an extensive quarry excavated to supply the now defunct cement works. Perhaps the most conspicuous of the fossils in the cliff is the large bivalve Eurydesma, but numerous others occur in profusion. A dredging trip in the neighbourhood of the island, in about 20 to 25 fathoms of water, yielded an enormous profusion of sponges in great variety, including some very remarkable and novel Calcarea. On the island itself numerous land planarians were collected, and the botanists were delighted to find the curious Tmesipteris growing upon tree-ferns.

The party left Maria Island early on Sunday, September 13, and after crossing to Spring Bay visited the kitchen middens at Little Swan Port. These were found to consist almost entirely of immense quantities of oyster-shells, forming a deposit several feet in thickness, and extending over a good many acres. The curiously rough chipped "flints," so characteristic of the Tasmanian aborigines, were found here in abundance. After lunch at Spring Bay the party motored back to Hobart through very beautiful scenery. This concluded the main part of the programme, but the zoological visitors remained by special invitation to take part in a collecting expedition to the Great Lake. Before leaving Hobart on this trip Prof. Dendy gave an address to the Royal Society of Tasmania on progressive evolution, and Dr. W. M. Tattersall delivered a public lecture on the depths of the sea. A visit was also paid to Mrs. Roberts in Hobart, whose collection of living Tasmanian and other animals excited much interest, two "native devils" (Sarcophilus) with young ones being particularly admired.

The party for the Great Lake started from Hobart on the morning of September 16 in three motor cars, and reached their destination the same evening. It had been hoped that they would be able to obtain a good deal of marsupial and monotreme material for the committee appointed by the council of the British Association for that purpose, but these hopes were only very scantily fulfilled. No monotremes were seen, though tracks and burrows of Ornithorhynchus were found on the shore of the lake, and only a very few wallabies and rat kangaroos were obtained to represent the marsupials. The invertebrate fauna of the neighbourhood, however, yielded a large number of extremely interesting specimens. The shrimp-like Paranaspides was obtained in quantities by dredging in the lake, and under the stones along the shore were found Phreatoicus, numerous freshwater planarians (one of remarkably large size), etc.

The forest around the lake has unfortunately been ravaged by fire, but laborious turning over of the fallen timber yielded many most interesting cryptozoic animals, including the land nemertine (*Geonemertes australiensis*), which was fairly common, a number of species of land planarians, and several specimens of the rare Tasmanian Peripatus (*Ooperipatus insignis*). The visitors returned to Hobart on September 22, and some of them left Launceston for Melbourne by the s.s. *Rotomahana* on the following day.

In every respect the Tasmanian visit must be regarded as a very great success. The thanks of the visiting members are due to all who contributed so generously to this result, and especially to his Excellency the Governor of Tasmania (Sir W. Ellison-Macartney) and Lady Ellison-Macartney, to the Premier and other members of the Government, to local scientific men, such as Mr. R. M. Johnston, Mr. Rodway and Mr. May, and, above all, to Prof. T. Thomson Flynn, the able and energetic organiser of the visit.

A. D.

AUSTRALIA AND THE BRITISH ASSOCIATION.[1]

IT is just one hundred and forty-four years since the first scientific expedition from Great Britain to Australia visited Moreton Bay. The expedition consisted of his Majesty's barque *Endeavour*, a vessel which had been built for the coal trade and was chosen because she was an excellent sea-

[1] Concluding discourse delivered before the British Association at Brisbane on August 31 by Sir Edward Schäfer, F.R.S.

boat, and required a smaller complement of officers and men than a regular ship of war. It was commanded by Lieut. James Cook, and included Mr. Joseph Banks, a gentleman "possessed of considerable landed property in Lincolnshire, who although he had received the education of a scholar, had long desired to know more of nature than could be learned from books," and who afterwards, as Sir Joseph Banks, was for no fewer than forty-one years president of the Royal Society; Dr. Solander, a Swedish botanist and pupil of Linnæus, who was attached to the newly established British Museum, and who, along with two accomplished draughtsmen and a secretary accompanied the expedition at Mr. Banks's expense; Mr. Charles Green, one of the assistants of the Astronomer Royal at Greenwich; and other scientific observers. These gentlemen, in the words of one of the biographers of Captain Cook, "quitted all the gratifications of polished society and engaged in a very tedious, fatiguing, and hazardous navigation with the laudable views of acquiring knowledge in general, of promoting natural knowledge in particular, and of contributing something to the improvement and the happiness of the rude inhabitants of the earth."

I would not be so bold as to suggest that the present expedition has as high aims as those of its predecessor, nor would it be fair to press too closely the comparison between our present expedition and the certainly more famous expedition of Captain Cook, which first brought a ship-load of scientific men to this then inhospitable shore. But whether we may be lacking in quality or not as compared with the members of that expedition, at least we make up for it in quantity; and where the first expedition found nothing but rudeness and inhospitality on the part of the inhabitants, the members of our expedition have met with all the signs of an enlightened civilisation and have received the warmest and most hospitable of welcomes.

Could anyone authoritatively have foretold to Captain Cook and his companions what they were likely to find here if they were to revisit this spot, after a lapse of time which is after all measured only by the lifetime of two individuals, how great would have been their astonishment! That a fine city of nearly a hundred and fifty thousand inhabitants should be overlooking the magnificent bay which they christened "Moreton's," which is now traversed in every direction, independent of wind and tide, by huge, weird vessels, where its solitude was then only relieved by the presence of their own comparatively small sailing-ship; that some three hundred people, devoted to science, should have faced the dangers and other inconveniences of the deep in order to meet and compare notes with kindred spirits amongst the inhabitants of the opposite side of the world; and that large meetings should assemble for the discussion of scientific problems in magnificent halls, in places where the members of the first expedition found no habitations and none but the rudest of savages—these it must be admitted are facts which would be calculated to surprise the staid eighteenth-century men of science and mariners brought by the *Endeavour*, who were still in the habit of getting about quite satisfactorily to themselves with only such aids to locomotion as nature herself had provided, and who were not accustomed, as we are, to hear of a first-class scientific discovery every month or so.

Although I have spoken of the visit of Captain Cook's expedition to this spot, it is well-known that he did not actually land at Brisbane, nor did he even ascertain the existence of the Brisbane River, although we are told that it was inferred by some members of the expedition, from the appearance of the sea water, that a considerable stream must open into the bay. The wind was unfavourable for approaching the land more closely, or, as Cook tells us, he would certainly have made this the subject of a special investigation. But even although you—*i.e.* your predecessors in title—never had the chance of seeing the famous seaman in the flesh, that is no reason why his visit to your harbour should not be adequately commemorated, and I venture to suggest that the erection of a suitable memorial of so memorable an occasion as the visit to Moreton Bay in the month of May, 1770, of Captain Cook and his company will—when the present troubles are over—be an appropriate tribute to the deathless memory of the most famous navigator that our race has produced.

I have introduced the subject of Captain Cook's visit because it serves as a convenient illustration of the value to the world of the organised pursuit of any branch of science, however abstract and however removed from application to one's ordinary daily avocations it may at the time appear. For be it remembered that this expedition in the *Endeavour* was primarily intended for observing the transit of Venus at Otaheite, and was fitted out by George III.'s Government on the pressing representations of the Royal Society. Incidentally, and after the primary object had been carried out, the commander had instructions to make discoveries and surveys of the unknown parts of the South Seas; and the east coast of New Holland was visited after several months had been spent in cruising amongst the islands of the Pacific and circumnavigating and incidentally surveying the complicated coast line of New Zealand. Less than a month after leaving Moreton Bay the *Endeavour* struck a coral reef, and after being got off proved to be damaged to so serious an extent that but for a piece of rock having become broken off and embedded in one of the largest holes made in her bottom no amount of pumping could have kept her afloat. This incident of the embedded rock, and the fact that soon after she struck and whilst she was still on the rock a dead calm supervened might naturally have been regarded at the time as a special dispensation of Providence to preserve the expedition from destruction, but the historiographer of the voyage frankly admits that if Providence is to receive credit for stopping the leak it should have its share of blame for permitting the vessel to get on the rock at all.

"It will perhaps be said," says Mr. Hawkesworth, "that in particular instances evil necessarily results from that constitution of things which is best upon the whole, and that Providence occasionally interferes and supplies the defects of the constitution in these particulars; but this notion will appear not to be supported by those facts which are said to be providential; it will always be found that Providence interposes too late, and only moderates the mischief which it might have prevented. But who can suppose an extraordinary interposition of Providence to supply particular defects in the constitution of nature who sees those defects supplied but in part? It is true that when the *Endeavour* was upon the rock off the coast of New Holland the wind ceased and that otherwise she must have been beaten to pieces; but either the subsiding wind was a mere natural event or not; if it was a natural event Providence is out of the question, at least we can with no more propriety say that providentially the wind ceased, than that providentially the sun rose in the morning. If it was not a mere natural event, but produced by an extraordinary interposition, correcting the defect in the constitution of nature, tending to mischief, it would lie upon us to maintain the position; to show why an extraordinary interposition did not take place rather to prevent the

ship's striking, than to prevent her being beaten to pieces after she had struck."

But whatever part Providence may have taken in the transaction, it may be added, to give honour where honour is due, that she was materially assisted by the ingenuity of one of the midshipmen (Mr. Monkhouse), who carried out a method he had learned in the merchant service of introducing oakum and wool into the leak by rubbing a staysail with pieces of these materials loosely attached to it along the damaged bottom; so that a single pump was afterwards sufficient to keep the vessel afloat until a convenient place was found where she could be beached and repaired; although all hands that could be spared to work at three pumps were before scarcely able to keep the water down, and the men would soon have had to relinquish the attempt from sheer fatigue. One contemplates with dismay even at this distance of time the blank in geographical knowledge which would have persisted for many a long year if Captain Cook had met his fate off Cape Tribulation in 1770 instead of in Karakakoa Bay in Hawaii somewhat less than nine years later.

I am now going to ask you to make a jump with me of about sixty years and of half the circumference of the globe in order that we may be present at the birth of the British Association. This event, which was to prove of much greater importance than the founders of the Association could have conceived, occurred in the year 1831. A number of gentlemen, amongst whom are included the well-known names of Brewster, Lyell, Vernon Harcourt, Murchison, and Phillips, who were interested in science and believed in its value to the community, met in the month of September of that year in the ancient city of York. The object of the gathering was to try to spread a knowledge of the progress of science throughout the country by presenting new scientific facts, not only to other men of science, but also to the general public. These functions were already efficiently performed for London by the Royal Society and by the Royal Institution respectively, but nothing of the same nature had been hitherto provided for the provinces. With this laudable object it was decided to establish a peripatetic society which would visit provincial centres in Great Britain and Ireland in turn, and thus carry the torch of scientific enlightenment even to remote parts of the United Kingdom.

I think that if the founders of the British Association could have been told that in eighty odd years the Association would be carrying this torch to the Antipodes and would be holding a meeting of the Association at a place in New South Wales—of which Queensland was then a part—which had not even been marked on the map, their astonishment would have been nearly as great as that which I have supposed that Captain Cook and his companions would have experienced sixty years earlier could they have received similar information. That the holding of this meeting should be possible is due to the progress of the sciences which the Association was established to assist, and certainly very largely to the advances in what our American cousins call "transportation"—a term which had a somewhat more restricted meaning in the early days of this community. At the time of that memorable meeting in York—although it is true the Liverpool and Manchester Railway had been opened in the previous year—journeying by land still depended in its most advanced form upon the mail-coach, a vehicle which was regarded by our great-great-grandfathers as the *ne plus ultra* of speed and convenience, although we ourselves look back upon it as merely an interesting and picturesque phase in the evolutionary history of methods of locomotion. And it was not until seven years later that the first passenger steamer crossed the Atlantic, and the doom of the sailing ship was pronounced. Probably our own great-great-grandchildren will regard our present methods in much the same light as we do the old mail-coach and sailing ship, and wonder that we should have been so long satisfied with the servitude of land and water when the freedom of the air was to be had for the asking.

It must be admitted that this establishment of a scientific association for the provinces of the United Kingdom was a brave project at a time when four days or more were required by a coach to cover the two hundred miles intervening between London and York—a distance which now occupies an express train less than four hours, and which can be done by aeroplane in little more than half that time. York was, however, a relatively convenient centre, to which many lines of coaches converged from all parts of the country. Subsequent meetings held in Oxford, Cambridge, Edinburgh, Dublin, and Bristol must have presented greater difficulties, and for scientific men from remote parts to get across country to some of these places a month would scarcely have been too much to devote to the to-and-fro journey. Yet nowadays we think less of the voyage to and through Australia than our forefathers did of the journey from London to Edinburgh, so easy and comfortable is travelling rendered by the palatial steamers and luxurious trains which are at our disposal.

Those of us who are getting on in life remember when the Association first began to think of extending its sphere of operations beyond the confines of the United Kingdom. This was about thirty years ago, and the occasion was an invitation from Canada that we should include Montreal in our visiting list. The older and more conservative elements of the Association were up in arms at the suggestion. It was prophesied that such a change would break up the Association; that most of the regular *habitués* would not attend; that the meeting would have no scientific value, and would be little more than a sort of glorified picnic. It was also argued that if we go to Canada the Australians will be wanting us to visit their country, and this was regarded as indeed a *reductio ad absurdum*! But not only were these gloomy prognostications not fulfilled, but the dreaded sequel has come about without any manifest appearance of absurdity, and we have been in Australia for nearly a month, honoured guests of the Commonwealth, more than delighted with our reception, and hoping that we may leave behind us some elements of permanent benefit, although we cannot but feel that we shall be taking away, not only in general knowledge and experience, but also in some matters which are exclusively scientific far more than most of us have been able to bring.

These visits to the Dominions, which at one time seemed so impossible and are now so easy, exhibit the Association from a point of view which could, as I have said, never have been taken by its founders, however clearly they may have figured out the scientific benefits to be derived from its annual reunions. They furnish the most direct evidence possible of the bond which unites us into that singular body, the Empire, a body of which we are each and all inordinately proud, although it only consists of a congeries of States which are knit together by what in times of peace has sometimes seemed a perilously slender tie. The religious and political views which are prevalent in the several constituents of this inchoate body may and do differ *toto coelo*, and one might almost expect these differences to act centrifugally and tend in the direction of disintegra-

tion. In the matter of commerce and manufactures, also, there have been in the past, and still here and there survive, doubts as to whether our interests are identical. But that our scientific interests are the same is a doctrine which is received everywhere without question, and this community of scientific interests serves to bind together the constituent parts of the British Empire none the less firmly because it also helps to link us severally and collectively to the rest of the civilised world. For scientific knowledge and the benefits which accrue from it are never confined within the limits of any barrier, either of race or nationality, but are free to all people and to all nations. This fact has been long recognised, and we find in the history of Captain Cook's voyages a remarkable illustration of the principle (of community of scientific interest), in the rescript sent during his third voyage of discovery in the year 1779 by the Secretary for the Marine Department of France, with whom England was then at war, directing all captains of armed vessels who may meet "that famous navigator, Captain Cook," to treat him as a commander of a neutral and allied Power. A similar order was issued to all captains and commanders of armed ships acting by commission from Congress by the Ambassador of the United States to the Court of France, directing them to treat Captain Cook with all civility and kindness, affording him as a common friend to mankind all the assistance in their power, and assuring them that by so doing they might depend on obtaining the approbation of Congress. Franklin was, it is true, mistaken in the confidence he expressed regarding the sentiments which were likely to actuate Congress, the members of which displayed less enlightenment than their distinguished representative—but this is a commodity with which members of Parliament and Congress are not always too well provided even at the present day.

About the time of that first scientific expedition which I have ventured to use as a convenient introduction to a Brisbane audience, Watt was engaged in carrying out those improvements in the construction of machines which ushered in the age of steam and steel, and were eventually destined to enable us, within the period of our academic holidays, to hold our annual gathering at this end of the globe. Chemistry was beginning to feel its feet. Priestley had prepared carbon dioxide, and Lavoisier soon afterwards isolated oxygen. Discoveries were in the air, although the progress of science was very perceptibly checked by the long wars and general social disturbances which followed the French Revolution. After these wars ensued a period of exhaustion, during which commerce was only very gradually recovering her position, and although science was progressing, it was with relative slowness. Nevertheless, in Great Britain the important investigations of Humphry Davy into the chemical constitution of the alkalies, resulting in the discovery of several new metals, form a marked exception to this general statement; and Davy's successor, Faraday, was, in the twenties of the nineteenth century, commencing those brilliant researches which, with the previous work of Oersted and Ampère, form the basis of our knowledge of electricity and magnetism. The first publication of Faraday's discoveries of voltaic induction and the relation of electricity to magnetism took place in the year of the foundation of the Association, and the last of the more important of his papers on this subject appeared in the Philosophical Transactions of 1851.

Two or three years before the York meeting, the absolute barrier which was thought to exist between the organic and inorganic world was broken down by the discovery of Woehler that urea—until that time considered a purely animal product—could be prepared synthetically from inorganic materials. In biology matters had not moved so much. Nearly everybody still believed, in spite of the brilliant and suggestive theories of Lamarck and Laplace, that the round world and all that therein is was the result of a single act of creation which had occurred some four thousand odd years previously; and another thirty years were to elapse before that comfortable belief was shattered by the epoch-making observations and brilliant generalisation of Darwin and Wallace. The mere enumeration of everything that has grown out of the investigations and discoveries of the great men I have mentioned would much more than occupy the whole time allotted to this discourse. All the resources of modern civilisation, whether for peace or war, are indeed the direct result of the researches in physics and chemistry to which I have alluded, although many of these researches may have seemed at the time to be of purely scientific interest and to have no application to human needs. One can imagine a member of the audience at the Royal Institution asking Davy, "What can be the possible use of knowing that gases can be liquefied?" although no such question would be likely to be put to the present distinguished occupant of Davy's chair; or another member telling Faraday that his demonstration of the rotation of one coil of wire within another might make a pretty enough toy, but could never be of any practical utility.

Similar questions and remarks are still made whenever a discovery which is purely scientific is announced. Shades of Galileo and Galvani! Will the world never profit by the lessons which the history of science teaches it? Has it not again and again been shown that the establishment of a fact which at first sight seemed to furnish no possible utilitarian application has eventually far outweighed in its importance any number of discoveries which are capable of being immediately utilised in commerce or manufacture? You have, I suppose, all heard of the eminent man of science who thanked God that a discovery he had made could never, so far as he could see, be of the slightest use to any living creature! Probably he is apocryphal; but we see that there is some basis for his expression of gratitude, since it has again and again occurred that discoveries which appeared to be of no utility were pregnant with immense issues. Who could have thought it possible that Pasteur's investigation into the constitution of racemic salts would have led to a complete revolution in our knowledge of medicine and surgery, and in our methods of treatment, a revolution so complete as even to involve the use of a different kind of language to express the difference of conception of disease which characterises modern medicine as compared with that which was practised even so recently as the seventies of the last century? And although it is mainly to Lister that we owe the application of Pasteur's chemical and biological researches to surgery, we must not forget that their application to disease in general was due to the great French chemist.

It is not given to every man, as it was to Pasteur and Lister, to witness the full development of the discoveries which their experiments have initiated, or to receive during their lifetime the honour which is their due, and in most cases little or no benefit comes in the way of the actual discoverer. It is the man who applies the scientific discovery to the exigencies of manufacture or to commerce who reaps the harvest of the golden shekels. Not that we grudge it to him! But I

would none the less impress upon him and upon people in general the importance of encouraging and assisting in every possible way investigations in pure science, which of themselves bring no pecuniary reward to the investigator, but which may nevertheless prove of inestimable value to the community. The labourer is worthy of his hire—but the hire which the scientific labourer is considered worthy of is a mere pittance when compared with the colossal incomes which result from the application of his researches. It should be the aim of Governments to attract the best intellects to the pursuit of science, but few, if any, offer inducements to such to devote themselves to this study, a fact which fortunately does not always deter them from engaging in it. Virtue is, we know, her own reward, but the rewards offered by the pursuit of commerce, of law, and even of medicine are gilded with something much more tangible than the self-gratification which follows the pursuit of pure science. The first necessity of life is to be able to live, and unless a man can live, and not only live, but live comfortably and sure of freedom from pecuniary anxiety, he is not likely to produce the best work his intellect is capable of. I wonder when this will be understood. Be sure that the nation which first understands it will come to the front. Unfortunately, we find that things are in this respect no better, but rather worse, in democratic communities than in some of the supposedly effete monarchical systems of the Old World. Democracy must look to her laurels, or she will find herself left behind in the race for knowledge—and knowledge will always be power, as long as mankind continues to exist.

The remedy lies in the education of the people. It is certainly remarkable how little importance seems to be attached to scientific instruction as a part of general education. Science is, indeed, incidentally tacked on to education schemes, and a certain proportion of the coming generation are taught a little physics and chemistry, and sometimes a still smaller modicum of biology and geology; but our children, although trained in many subjects which are interesting in themselves, are, as a rule, not instructed in those which have a close relationship to the problems of their daily life. How few people know anything of the constitution and properties of things around them, things which are essential to their existence, such as air and water, and substances which serve them for food. How few know anything about themselves! If the proper study of mankind is man, how great is the neglect of that study! Surely it is more important that a man should understand how the world around him is constituted and how he himself lives and moves and has his being within it than that he should be efficient in ancient and modern languages, or in mathematics, or that his knowledge of history and geography should be as extensive and peculiar as Sam Weller's acquaintance with London! The appreciation of science by the people cannot come until the general ignorance regarding matters scientific is dispelled. And there is so much to learn, and so little time to learn it, that no child should be considered too young to be taught something about himself and his environment. Doubtless this would involve a change in the system of education which now everywhere prevails, but that it would be a change for the better and would conduce to the health and happiness of mankind cannot, I believe, be gainsaid.

We know what the past of science has produced: we have the evidence all around us. But what of the future? What is in store for our successors? Speculation regarding this is even more fascinating than the study of the past. Can we form any kind of anticipation regarding possible discoveries? In pure science I imagine not. Discoveries in this always come unexpectedly; at any rate, they are always unexpected so far as the world in general is concerned; which, indeed, only very slowly recognises them as real discoveries. Our speculations regarding the future must therefore be mainly confined to applications of what is already known, or to extensions along the lines which recent investigations have been laying down. But even so, the possibilities which are opening out to us are almost limitless. We are proud of the progress of what we Englishmen call the Victorian era, but is it not likely that this will be vastly eclipsed by the second Georgian? It took more than half a century to develop the steam engine, nor have we by any means as yet exhausted its possibilities. But the internal combustion engine has made more progress in less than half that time, and to it we already owe the supersession of animal traction on our roads, and the use of the air as the medium by which locomotion is or very soon will be effected. The applications of electricity which are already in use are dazzling in their variety, but we have scarcely touched the fringe of the applicability of the Hertzian waves, and the vast possibilities of radio-activity are still *terra incognita*. Who can reasonably doubt that we shall soon be flying safely through the air faster than the swiftest bird, and that our means of intellectual communication will be at least as much advanced as that of the transportation of our goods and bodies?

The rate of progress of chemical knowledge at the present time is no less extraordinary than that of physics. Every day shows an advance in our acquaintance with the structure of the molecules of which the elements and their compounds are built up. Our information regarding the complex molecules which compose living substance is receiving such continual additions and so much is already known about it that we cannot fail to recognise that the problems of life itself must sooner or later find their complete solution within the scope of physical chemistry. The attempts of science to solve the mysteries of the universe recognise no limitation: "thus far shalt thou go and no farther" is a command which can never be obeyed by the scientific inquirer. But to attempt to foretell coming scientific events even in the near future —merely to endeavour to guess at the kind of truths which are likely to be discovered—is a futile task. For the investigations of modern science are being extended to depths which have hitherto been regarded as unfathomable, and we can have no idea to what they will eventually lead us. Neither the infinitely great nor the infinitely small any longer presents serious difficulties to the investigator, by whom both the stars in their courses and the atoms which compose the molecules of matter—nay, even, the all-pervading and imponderable æther itself—are called to yield up their secrets.

We may be justly proud of what has been achieved, but let us not fail to remember with Newton that "the vast ocean of truth" still "lies" for the most part "undiscovered before us." However marked may be the progress of science, her individual votaries must always feel a sense of humility at the little the best of them is able to contribute towards the general result. Not that this thought need dishearten any scientific worker. For there is no other way of erecting an edifice, however stately, but by laboriously piling brick upon brick, stone upon stone, girder upon girder. And if our successors assemble here at the end of another century,

can it be doubted that the subjects which they will discuss will show as much advance in knowledge on those with which we have been dealing during this visit as the science of the present day transcends that of the beginning of the nineteenth century? I think that even if we had no other use for a future existence it would, at any rate, be interesting to our ghosts to be able to follow the progress of human knowledge and to observe how problems which during their life on earth were regarded as insoluble are ultimately solved by the *labor et ingenium* of those who come after us—an occupation which would I believe, be more congenial to most of them than those employments to which, by the general consensus of theologians, they are expected to devote their infinity of leisure. In the meantime, it is for us to lay our bricks well and truly, even although the opportunity is given to very few of us to witness a definite result of our labours. For we may be sure that every addition to scientific knowledge will help to promote the general happiness of mankind, and will tend to dissipate that ignorance which, in spite of the four intervening centuries, still remains as much "the curse of God" as ever it was in the days of Shakespeare.

Since this is the last general assemblage of the association which is to be held in Australia, it will, I trust, not be considered inappropriate for me to spend the few minutes which remain in endeavouring to formulate in the best manner I can—although the best will, I am conscious, be but imperfect—the impression which has been produced upon your visitors from the mother country by what they have seen and heard, read and learned of this antipodean country, its resources and inhabitants. To say that that impression is profound seems a commonplace, but there is no other word which can adequately express the actual fact. Your splendid organisations flooded us with information regarding the Commonwealth in general and the individual States which compose it in particular even before we started on our voyage here; and I suppose that we each and all of us have utilised some of the time which on a passenger ship is not occupied in eating and sleeping in taking in and digesting a part, at any rate, of the mass of statistics that the compilers of the volumes you have presented us with have provided. We have in our extensive journeyings had an opportunity of seeing some of the fine scenery which the country possesses. We have become familiar with your principal cities and with the magnificent streets and buildings which they contain. We have been exhaustively informed regarding the products of the country, both natural and artificial. We know, or can know if we like, the number of sheep, cattle, and horses which are annually reared; and although I have noticed that the number of rodents has nowhere been recorded in the literature with which we were provided, we may yet live to see the manufacture of coney sealskin develop into an important Australian industry. We are, or can be if we like, familiar with the output of gold and copper, of coal and opals; with the progress of the timber trade; with the development of the railway system, of telegraphs, of posts. We have made the acquaintance of your educational systems, and have had the opportunity of closely observing your universities and other institutions for advanced studies. We have seen something of the prosperity of your commerce and industries, and have been duly furnished with interesting and valued information regarding their growth and activity. We have even had dangled before our eyes statistics regarding the wages which you pay to your employees, until some of us have probably thought that it might be worth while to stay in the country and become Australian working-men, whose pay—with the possible exception of that of the San Francisco bricklayer—appears to be pitched on a higher scale than that of the same class anywhere else in the world, and in some cases to touch, if it does not even exceed, the salary of the average European professor. We shall indeed—some of us—go home knowing more about Australia than about our own country, and you may expect within a twelvemonth or so a perfect shower of books and magazine articles on Australia and the Australians; for does not every globe-trotter think he is capable of writing about the countries he has visited, even when he is not furnished with more information than is to be obtained in the average guide-book?

There is one phase of your development which cannot fail to interest not only the visitors to your shores, but the outside world in general, and that is the experiments you are making in dealing with such social problems as industrial disputes and the regulation of trade and manufacture. Many of these experiments are enough to make Adam Smith turn in his grave; but the proof of the puddin' is in the priein' o't, and if you are able to carry on your industries successfully to the contentment of employer and employed, and without the constant threat of strikes or lock-outs, you will find no lack of imitators on the other side of the globe.

A political experiment which, although not peculiar to this side of the world, may yet be said to occupy a more prominent position in it than in other parts where it has been adopted is the referendum. As you are probably aware, our politicians at home have always made a fetish of Parliament—by which they mean the House of Commons—and one of the assumptions which underlies the British constitution is that as long as a given Parliament exists—and it may exist with us for half a dozen years—it represents the settled opinion of the country, *i.e.* of a majority of the electors. But everybody knows that this opinion, so far from being settled, is often very unsettled, and in any case it need scarcely be said that questions may arise within the Parliamentary period which have never been before the electors at all. Whether for good or ill, we cannot but admit that the adoption of the referendum at home would soon settle certain vexed questions which have been, and still are, the source of a vast amount of political inquietude and even of grave social disturbance.

Although the nature and character of the inhabitants of a country is a question which is always treated prominently by travellers who are narrating their experiences, it is one which can scarcely be freely discussed in the presence of so large an assembly of the subjects of discussion. Nor has the difficulty been reduced by the extraordinary kindness with which we have been received by the inhabitants in every place at which we have stopped. But this, at any rate, can be said, viz., that—with the exception of a greater amount of warmth and spontaneity than we at home are accustomed to exhibit, combined with a certain tone of personal independence which, in the British Isles, is more common in the northern parts than elsewhere—there is no obvious difference in character between the man in the street here and the man in the street at home. Any change that has taken place is, at any rate, for the better, as is exemplified by the way in which your citizens of all classes have come forward, even in time of peace, to be trained for the defence of their country. If our responsible statesmen would imitate yours and give the lead on this vital question of citizen-service, instead of waiting to see which way the electoral cat is likely to jump, the people of Great Britain would not be long in following the example which the sense of patriotism of Australia has set them, and

they could then afford to smile at the idea of an invader setting foot within our little sea-girt land, sure in the prospect of its remaining the centre of "a greater Empire than has been."

And I think I may venture to assert that if we had adopted at home the principle of universal service for the defence of that Empire, a principle which that great man and soldier Lord Roberts has so persistently advocated, the present iniquitous war would never perhaps have been set on foot.

I suppose that, on the whole, one thing regarding the population of Australia that strikes the visitor from the Old Country more than another is the enormous disproportion between the extent of habitable country and the number of actual inhabitants. That a continent nearly as large as Europe should have far fewer inhabitants than London alone, and a density of only about one seventy-fifth that of Europe is an obvious incongruity. But it is one which will naturally tend to right itself as the years roll by; and since the necessity for a great increase of population in order to develop the country is forcing itself upon the attention of those who guide the fortunes of the several States, we shall no doubt witness, in the near future, a much more rapid rise of population than has occurred in the past. Fortunately, the increase which has taken place is of the right sort. Australia has, to its credit, long refused to be the dumping-ground for the dregs of the Old World, and is developing a race which will, in the course of a few decades, probably be more purely British, both in physique and character, than any other extensive area of population in the world, not even excepting the mother country. No nation has greater possibilities for the future. Assured of peace and of freedom from outside interference, there is nothing to impede that advance which, in her adopted motto, Australia puts before herself as her constant aim; and her invitation to us to visit her shores was, we may take it, not intended merely as an act of graceful hospitality, but also as a means of promoting within her borders that advancement of science which, as its title expresses, is the essential object of the existence of the British Association.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. T. V. Barker, fellow of Brasenose College, has been appointed University lecturer in chemical crystallography for five years from January 1, 1915; and Mr. A. G. Gibson, Christ Church, as University lecturer in morbid anatomy for five years from the same date.

SPEAKING at the annual meeting of the Sheffield University on Monday, the Vice-Chancellor, Mr. H. A. L. Fisher, said he believes that when the war is concluded it will be possible for England very largely to step into the place hitherto occupied by Germany. If our universities will only be a little more imaginative and try to reproduce some of the perfection of organisation which prevails in Germany, and has brought eternal honour to the German nation, our universities may become cosmopolitan in the sense in which Oxford was the great cosmopolitan university of the Middle Ages. It is only since the Reformation that English universities have become, in a sense, provincial. In certain regions of applied science there is no reason why in the next fifteen or twenty years Sheffield should not be the technical capital of Europe.

A COPY of the annual report of the 118th session, 1913–14, of the Royal Technical College, Glasgow, has been received. Judged by the tests now universally applied the session was one of the most successful in the history of the college. The number of day students continues to increase steadily; but the most satisfactory feature is the accession to the number of those attending full courses, resulting in a great expansion in "student-hours" of actual attendance and work. The total number of "student-hours" of the day classes was 237,908, an increase of more than 15 per cent. on the corresponding figure for the preceding session. The scheme affiliating the college to the University of Glasgow came into operation at the beginning of the session, with satisfactory results. Forty-one matriculated students were in attendance on qualifying classes within the college, and of these twenty-eight were following a full course of study. At present the scheme applies only to degrees in engineering, but the advisory joint-committee, established by the University and the college, has prepared a draft Ordinance for degrees in applied chemistry, which is now under consideration. It is hoped that this Ordinance will receive the approval of the Privy Council during the coming session, and thus give to college students in chemistry the opportunities for graduation now open to students in engineering. The report points out it is believed that more than a thousand past students have now joined H.M. Forces; the First Company of the 3rd Glasgow Battalion H.L.I. consists of college students exclusively. The Carnegie Trust for the Scottish Universities recently considered the position of the college in view of their allocation of grants for the next quinquennium. In the result, the trust made a grant to the college of 1000*l*. per annum for five years. Of this sum, 100*l*. is for the maintenance of the library, 300*l*. for provisional assistance, and 600*l*. towards a superannuation scheme. The college received during the year, among other gifts, legacies of 5000*l*. from the late Mr. William Weir, and 500*l*. from the late Mr. J. C. Alston.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 19.—Sir William Crookes, president, in the chair.—A. **Mallock**: Note on the circulation of the atmosphere.—Sir Sidney **Burrard**: The origin of the Indo-Gangetic Trough, commonly called the Himalayan Foredeep.—G. W. **Walker**: Approximately permanent electronic orbits and the origin of spectral series. In this paper an endeavour is made to find a basis of explanation of spectrum series in terms of strict electrodynamics. The illustrative system consists of a spherical nucleus radius a, with a positive electric charge E and a fixed magnetic moment μ. It is constrained to be fixed and may be regarded as corresponding to a comparatively massive atom. A single corpuscle with a negative charge e and mass m is free to move under the influence of the forces exerted on it by the nucleus. When the effect of radiation is neglected circular orbits are shown to be possible. The circumstances, stability, and range of these orbits are examined in detail, both for orbits outside and inside the nucleus. Only the inside orbits appear to have a bearing on the problem in hand. It is found that there is a class of circular orbits in each of which the angular momentum of the corpuscle has the same value. This result has already been obtained by Conway, who sought to identify the value with Planck's unit. It is here shown that these orbits occur only if the charge of the nucleus is concentrated mainly at the surface, or if the material of the nucleus has a large dielectric ratio. Another class of circular orbits exists. They lie in the equatorial plane of the nucleus, and have

different angular momenta. The formulæ, although possessing the same general features, are not so simple as those for the Conway orbits. The effect of radiation is next considered. The motion of the corpuscle gives rise to radiation disturbance inside and outside the nucleus, while the nucleus produces radiation in the manner proved by Lamb. The disturbance can be analysed into terms of electric and magnetic type. In each case a series of values of r/a are found for which the reaction on the corpuscle becomes very small, and so it is argued that the corpuscular orbit for which r/a has one of these values is comparatively stable and gives a spectral line. Following Lamb in supposing that the dielectric ratio is great, we find that from the Conway orbits with magnetic type of disturbance we get the recognised Balmer formula, while with the electric type of disturbance we get a series closely resembling the Rydberg formula. In addition to these series we ought to get Lamb's series from the nucleus, but quite consistently with the theory they may be in the infra-red or the ultra-violet. In order to fit the formula of Balmer type with the hydrogen series, and taking $e/m=1{\cdot}7\times10^7$, $\mu=1{\cdot}8\times10^{-21}$, the radius of the nucleus required is about 2×10^{-10} cm.—W. **Jevons**: Spectroscopic investigations in connection with the active modification of nitrogen. IV.—A band spectrum of boron nitride. (1) The interaction of active nitrogen and boron trichloride or methyl borate develops a band spectrum extending from λ 6371 to at least λ 2140, with well-defined heads degrading throughout towards the red. (2) The new spectrum consists mainly of two distinct systems, in the less refrangible of which each band consists of four heads forming two close doublets. The more refrangible system has single heads, and thus resembles the silicon nitride spectrum described in a previous paper. (3) The wave-lengths of the heads have been measured, and the wave-numbers in each system have been classified and represented by formulæ in the usual manner. (4) Chemical and spectroscopic evidence has established that the origin of the spectrum is boron nitride. Boron, carbon, and silicon compounds are thus alike in developing nitride spectra in the nitrogen afterglow. (5) The boron nitride bands, like those of cyanogen, are produced in the electric arc spectrum where they occur, together with bands of the oxide.—Prof. E. **Wilson**: An additional note on the production of high permeability in iron. It has been shown that if stalloy in laminated ring form is subjected to a magnetising force due to a direct current whilst it is cooling through the temperature at which it regains its magnetic properties, and is at the same time shielded from the influence of the earth's magnetism, the permeability recovered at atmospheric temperature has a maximum value of more than 10,000 when the magnetic induction was of the order 6000 C.G.S. units. It had been shown previously that high values of the permeability can be obtained without the use of a special magnetic shield when iron has impressed upon it a magnetising force, due to an alternating current, during the time that it cools through the temperature at which it regains its magnetic properties. As, however, in the last-mentioned case, an iron tube was used to enclose the specimen and became heated with the specimen, it was thought desirable to discover whether the high value of the permeability can be obtained when there is no question of magnetic shielding. In the present experiments the specimen of stalloy in ring form was allowed to cool inside a sealed fire-clay crucible, when subjected to a magnetising force of 13 C.G.S. units, and at atmospheric temperature a permeability of more than 10,000 was again obtained. Further experiments have been made with stalloy in the form of straight strips. The specimen which consisted of a number of strips side by side was wound with a magnetising coil and then placed inside an iron tube. On allowing it to cool through the temperature at which magnetic quality is regained, when subjected to a magnetising force due to a direct current, the improvement in maximum permeability, when at atmospheric temperature, was small, and had apparently disappeared when re-tested at the maker's works.

Royal Anthropological Institute, November 17.—Prof. A. Keith, president, in the chair.—The Hon. John **Abercromby**: The prehistoric pottery of the Canary Islands and its makers. In the museums of the Grand Canary, Teneriffe, and Palma a considerable number of prehistoric vessels are preserved. Anthropologists are agreed that the natives of the archipelago at the time of its conquest in the fifteenth century were a composite people made up of at least three stocks: a Cro-Magnon type, a Hamitic or Berber type, and a brachycephalic type. These natives were in a Neolithic stage of civilisation. Their arms were slings, clubs, and spears. Most of the people went naked, except for a girdle round the loins, and there was no intercommunication between the islands. Their stone implements were of obsidian or of basalt. Only four polished axes are known from the Grand Canary and one from Goméra. The axes are of chloromelanite, and of a type contemporary with megalithic structures in France. The first colonists probably brought the knowledge of making pottery with them, but each island developed an individuality of its own. Even the painted ware of the Grand Canary appears to be of local origin and not due to external influence. Although undoubted Lybian inscriptions in the Grand Canary and lava querns of Iron age type prove that the archipelago was visited before its conquest by the Spaniards without affecting the general civilisation of its inhabitants.—Major E. R. **Collins**: Stone implements discovered in South Africa during the Boer war. The paper dealt mainly with finds in or on the terrace-gravels, the principal sites being Burghersdorp, in Cape Colony, Spytfontein in the Orange Free State, and Vereeniging, Meyerton, Panfontein, Klerksdorp, and Vlekfontein, in the Transvaal. A few palæoliths from undisturbed South African gravels have been recorded, but several more were brought to light in digging shelter-trenches, and certain finds on the surface confirm the view that the early Cave-period of Europe is also represented in South Africa, quite apart from the supposed Bushman series.

Geological Society, November 18.—Dr. A. Smith Woodward, president, in the chair.—A. **Dunlop**: A raised beach on the southern coast of Jersey. The raised beach is on the eastern slope of the ridge between Le Hocq and Pontac. The section, facing northwards, shows the following succession of beds from above downwards:—

	Thickness in feet	inches
(1) Earthy loam, with a layer of rubble ...	4	0
(2) Stiff brownish-red clay	1	0
(3) Yellow loamy clay, containing water-worn pebbles and angular fragments	3	4
(4) Coarse brown sand	3	6
(5) Water-worn pebbles, closely packed in a matrix of coarse brown sand ...	4	6

The rock beneath is fine red granite. The section is terminated at its western end by sloping rock. The base of the section is about 50 ft. above mean sea-level. The pebbles are of the red granite of the locality, but some are of diabase and of quartzite, as well as a few of flint. Flint pebbles have also been found in two low-level raised beaches, and flint-pebbles and fragments have been noticed in the yellow clay. A raised beach was recently pointed out in the railway

cutting near the eastern railway station. Its base is about 55 ft. above mean sea-level, and it is covered by a thick bed of yellow loamy clay.—Prof. S. J. **Shand**: Tachylyte veins and assimilation phenomena in the granite of Parijs (Orange Free State). The district is the neighbourhood of Parijs township, situated on the Vaal River, and lies upon the northern portion of the Vredefort granite-mass. The so-called "granite" near Parijs is a red and grey streaky gneiss, often traversed by veins of red pegmatite; these are of a later period of consolidation than the rest of the rock. The grey facies of the gneiss results from assimilation of the country-rock by an ascending magma; while the red facies represents the residual portion of the same magma. The tachylytic veins everywhere intersect the granitic rocks. These veins range from a fraction of an inch to 2 ft. in thickness, but in the thicker veins there are numerous inclusions of the country-rock. They are irregular in form, thickness, and direction, and are due to the intrusion of a basic magma which underlay the district. The author brings forward evidence to prove that the position occupied by the tachylyte is independent of tectonic features, but follows directly from solution and corrosion of the granitic rocks by the basic magma.

Linnean Society, November 19.—Prof. E. B. Poulton, president, in the chair.—A. J. **Wilmott**: Discovery of *Hydrilla verticillata*, Casp., in Esthwaite Water. This is a small lake to the west of Windermere; and the discovery was made by Mr. Pearsall.—C. H. **Wright**: The Mosses and Hepaticæ of West Falkland Islands, from the collections of Mrs. Elinor Vallentin. Having made a collection of phanerogams and ferns, which formed the basis of a paper published in the Journal of this society, (Botany, vol. xxxix., 313–39), Mrs. Vallentin returned to the Falkland Islands and made collections of the lower Cryptogams. The present paper contains the determinations of this collection and attempts to bring together the information previously published on other collections. The genera represented are either terrestrial or aquatic, and the species much resemble those from the northern hemisphere. Many are capable of resisting cold and drought, such as they are exposed to in these wind-swept islands. Very little affinity is shown with the flora of New Zealand and the subarctic islands to the south of it.—R. S. **Bagnall**: Thysanoptera of the West Indies.

CAMBRIDGE.

Philosophical Society, November 9.—Prof. Newall, president, in the chair.—Sir J. J. **Thomson**: Experiments with slow kathode rays.—Prof. J. **Zeleny**: The conditions of instability of electrified drops, with applications to the electrical discharge from liquid surfaces. Experiments on the electrical discharge from liquid drops formed at the ends of small tubes, show that under some conditions the surface of the liquid is subject to more or less agitation. When the surface is examined under the instantaneous illumination of a spark, small masses of liquid are seen to be pulled away. This behaviour is shown to have no direct connection with the electrical discharge but is explained by the surface becoming unstable under the action of the electric forces, the observed electrical current being carried across the gas gap by minute electrified drops. The square of the potential at which the instability begins is directly proportional to the radius of the drop and to its surface tension, a relation which has been verified by experiment. Whether an electrical discharge, from a given surface, may begin before the surface becomes unstable depends upon the gas used and its pressure, since these quantities determine the starting potential for the electrical discharge.

MANCHESTER.

Literary and Philosophical Society, November 3.—Mr. F. Nicholson, president, in the chair.—W. C. **Jenkins**: Note on the aerolite which fell at Upholland, near Wigan, on October 13.—H. **Day**: Variation in a Carboniferous brachiopod. The species chosen for investigation was *Reticularia elliptica*, as a common and typical representative of the "*Spirifer glaber*" group, regarding which considerable doubt has existed as to the distinction of species and genera. This type is readily distinguished by its fine, reticulate ornament, but great variation is shown by individuals in respect of relative length, breadth, and thickness. The length, breadth, and thickness of each of 1000 specimens, collected from one spot, were accurately measured, and the ratios L/B and L/T were then determined. Each of these ratios was found to vary according to a symmetrical simple variation curve, leaving no doubt as to the specific unity of the assemblage. It was further ascertained that variation in respect of either ratio was nearly independent of that in respect of the other. There is, however, a slight tendency for breadth and thickness to vary together in relation to length, in such a way that both ratios on the average diminish as the individual increases in size.

November 17.—Mr. R. L. Taylor, secretary, in the chair.—F. W. **Atack**: The salt-formation of oximes. After outlining the current theory of oxime-isomerism, due to Hantzsch and Werner, the author pointed out that there is a notable discrepancy between the formulæ first deduced by Hantzsch and Werner in support of their theory and those in agreement with the Beckmann change, and this discrepancy has never been explained. Tschugaev's statement that only the so-called α-dioximes form characteristic salts with metals of the eighth group of the periodic system is incorrect, the author having obtained similar salts with the so-called γ-dioximes. It has been found that in case an "oxime" group forms a hydrochloride, it does not form such salts. New methods for the purification of oximes were outlined.

DUBLIN.

Royal Dublin Society, November 24.—Dr. J. H. Pollok, in the chair.—Prof. W. **Brown**: The fatigue of nickel and iron wires when subjected to the influence of alternating magnetic fields of frequency 50 per second. The results of some experiments showed that it takes about three times longer to fatigue an iron wire than a nickel one when tested under the same conditions.—Nigel G. **Ball**: The action of pectase. The action of the pectase of *Syringa vulgaris* on a solution of pectin was investigated by determining the change in viscosity of the mixture. In the presence of electrolytes the viscosity rose to a maximum and then decreased.—W. R. G. **Atkins** and G. O. **Sherrard**: The pigments of fruits in relation to some genetic experiments on *Capsicum annuum*. In Capsicum fruits red is dominant to yellow, chocolate, and orange. The reds and chocolates have oily pigments in plastids. These are distinguished from lycopin, carotin and xanythophyll by their ready solubility in cold alcohol and in petroleum ether.—W. R. G. **Atkins**: Oxidases and their inhibitors in plant tissues. Part iv. Peroxidase reactions of related species of Iris are similar, even though distribution of anthocyanin may be different. Alterations in peroxydase due to removal from light are not rapid enough to vitiate this conclusion. Anthocyanin is frequently present where there is no peroxydase. Well-marked inhibition patches are found in some species. Toluene water is as effective in removing inhibitor as is cyanide.

PARIS.

Academy of Sciences, November 16.—M. P. Appell in the chair.—H. **Deslandres**: Observation of the total eclipse of August 21, 1914, by the expedition from the Meudon Observatory. The expedition organised by the Observatory of Meudon made observations at Strömsund, in Sweden. Photographs were taken with two spectrographs, a brief description of which is given (see p. 373).—A. **Chauveau**: The question of the diminished resistance of enfeebled organisms to the destructive action of the tubercle bacillus. The author has previously published the view that healthy subjects, living in close contact with tuberculous patients, are as liable to contract tuberculosis as enfeebled subjects. They are all, strong and weak, equally liable to receive and cultivate the specific germs of the disease if these germs succeed in penetrating in the living state by the two usual modes of infection (respiratory or digestive). The author discusses from the public health point of view the opposite view more commonly held, and protests against erroneous interpretations of his views.—André **Blondel**: The most general enunciation of the laws of induction. Experiments are described showing that the enunciation of the laws of induction in some well-known text-books is too general.—M. **Courty**: Observation of the transit of Mercury made at the Observatory of Bordeaux, November 7, 1914.—P. **Gaubert**: Artificial macles of tin.—Marcel **Baudouin**: Discovery of a menhir remaining upright under a dune on the coasts of Vendée. The stone was found in modern Quaternary deposits and was indisputably of human workmanship.—Maurice **Lugeon**: The presence of crystalline plates in the Prealps and their signification.—H. **Colin**: The saccharogen in the beetroot.—P. **Hariot**: The marine flora of the island of Tatihou and of Saint-Vaast-la-Hougue.

CALCUTTA.

Asiatic Society of Bengal, November 4.—J. J. **Kieffer**: Chironomides du Lac de Tibériade. Six new species are described and one already known from Europe and North Africa (*Pelopia monilis*) recorded from the Lake of Tiberias.—H. **Sāstri**: Recent additions to our knowledge of the copper age antiquities of the Indian Empire. The note brings up to date the information about the copper or bronze antiquities of India by noticing some fresh material that has come to light since Mr. V. A. Smith wrote on the subject in the *Indian Antiquary*, and makes some corrections in the descriptions by Mr. Smith.

BOOKS RECEIVED.

Inaugural Address of the President, W. A. Evans, to the Members of the Leicester Literary and Philosophical Society, October 5: Wheat and its Relation to the Present Crisis. Pp. 20. (Leicester: W. Thornley and Son.)

Atti della Fondazione Scientifica Cagnola dalla sua Instituzione in Poi. Vol. xxiii. Anni 1908–12. (Milano: Tipo. Lit. Rebeschini de Turati E. C.)

The Museum of the Brooklyn Institute of Arts and Sciences. Science Bulletin. Vol. ii. No. 4: A Report on the South Georgia Expedition. Edited by R. C. Murphy. Pp. 43–101. (Brooklyn: The Museum of the Institute.)

Memorie del R. Istituto Lombardo di Scienze e Lettere. Vol. xxiii.–xiv. della Serie III. Fasc. I. Saggio di un Indice Lessicale Etrusco. By E. Lattes. Pp. 66. (Milano: U. Hoepli.)

RELATIVITY.

The Theory of Relativity. By Dr. L. Silberstein. Pp. viii+295. (London: Macmillan and Co., Ltd., 1914.) Price 10*s.* net.

THE appearance of a connected account of the Principle of Relativity in our own language will be welcomed by many as an opportunity of acquainting themselves in more detail with the ins and outs of a controversial subject. The note of controversy is, however, almost completely absent from this book. There is scarcely a reference to the longings of the physicist for an objective æther, save the sentence, "Lorentz had not the heart to abandon the æther which he confessedly 'cannot but regard as endowed with a certain degree of substantiality.'" The readiness to "abandon" well-worn concepts and old-established theory is becoming a marked feature of the thought of physicists to-day. We are witnessing at this moment a revolutionary movement in the 'quantum theory' which at times seems to forget entirely the classical electrical theory, and all the wealth of experimental evidence out of which it grew. In the same way the exponents of the principle of relativity have found delight in pouring contempt on the æther as the basis of electromagnetic influence, while in their turn the more conservative of physicists, failing to see how natural was the transition from Lorentz' theory of optical and electromagnetic phenomena in moving bodies to the novel point of view of Einstein, seized upon the somewhat artificial system of clocks by which the latter sought to make his meaning clear, and found in it a laughing-stock.

It is strange that there has been so much difficulty in making the fundamental point of view of this theory clear to those whose interests are experimental rather than theoretical. Many will read Dr. Silberstein's careful and detailed introduction to it, consider his illustrations, and follow his logic, and yet feel there is something lacking. The 'argument from need' for an æther is not dealt with. The reluctance that Lorentz had to abandon the æther remains. The seeker after a deeper understanding of the physical is apt to fight shy of a principle which cannot be expressed in terms of concepts to which he can give some 'degree of substantiality.' A systematic exposition of the principle of relativity necessarily consists very largely in the demonstration of invariant properties of certain mathematical relations. Hence it is almost bound to appear a little uninteresting to the experimentalist. Dr. Silberstein compresses the purely mathematical discussion, and judiciously separates it from the general and descriptive account as far as possible. He shows how many of the invariant relations fall simply and naturally into quaternionic form. But little is done to remove the unfortunate impression that relativity is a fad of the mathematician, and not a thing for the every-day physicist. It is to be feared that many will turn to this book full of hope, and come away from it feeling that the subject is barren for the future. For the universe is not compact of quaternions or matrices. As a physical principle, the principle of relativity needs to be placed in its relation to other great generalisations, such as the conservation of energy and momentum, and the status of the fundamental concepts of space and time in mathematical physics needs to be clearly realised.

The present book gives an adequate supply of material for meeting these needs; the account of the developments which led up to Einstein's work is useful and clear; but the reader will need imagination and sympathy if he is to find here an answer to the many difficulties which the subject raises.

PRACTICAL CHEMISTRY.

(1) *The Elements of Qualitative Chemical Analysis.* By Prof. Julius Stieglitz. Vol. i.; Fundamental Principles and their Application. Pp. xi+312. Vol. ii.: Laboratory Manual. Pp. viii+153. (London: G. Bell and Sons, Ltd., 1914.) Price 6*s.* net each volume.

(2) *Introduction to Modern Inorganic Chemistry.* By Dr. J. W. Mellor. Pp. xvi+684. (London: Longmans, Green and Co., 1914.) Price 4*s.* 6*d.*

(3) *Allen's Commercial Organic Analysis.* Vol. viii. Fourth edition. Entirely re-written. Edited by W. A. Davis and S. S. Sadtler. Pp. x+696. (London: J. and A. Churchill, 1914.) Price 21*s.* net.

(4) *Handbuch der Arbeitsmethoden in der anorganischen Chemie.* Herausgegeben von Dr. Arthur Stahler. Dritter Band. Erste Hälfte. Pp. x+692. (Leipzig: Veit and Co., 1913.) Price 22 marks.

(5) *Quantitative Analysis by Electrolysis.* By A. Classen. With the co-operation of H. Cloeren. Translated from the thoroughly revised fifth German edition by Prof. W. T. Hall. Pp. xiv+308. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1913.) Price 10*s.* 6*d.* net.

(6) *Anleitung zur Darstellung Phytochemischer*

Uebungspräparate. By Dr. D. H. Wester. Pp. xi+129. (Berlin: Julius Springer, 1913.) Price 3.60 marks.

(1) QUALITATIVE analysis still forms the beginning of all instruction in chemistry, but in its modern form it no longer takes the guise of the familiar tables, supported by the test-tube rack and the shelf of reagents. Indeed, at the hands of the more advanced apostles of physical chemistry it has been altered beyond all recognition, and it is from this point of view that we must criticise the new contribution of Prof. Stieglitz to the literature. The method of instruction advocated by him aims at developing the critical searching mind of the professional productive chemist. The students taking his course are supposed to have been prepared in general chemistry on physico-chemical lines.

In part i. of the new work the student is started off on fundamental principles, and he is involved at once in the consideration of osmotic pressure, theories of solution, ionisation, chemical and physical equilibria, as a preliminary to undertaking the systematic analysis described in part ii. For those few students who can stand it the treatment is admirable, but it demands teaching of the very highest class to make it at all successful, as well as very great concentration on the part of the student.

The second volume is entirely a laboratory manual devoted to the study of reactions and systematic analysis. The text, which is interleaved with blank pages, consists of a series of instructions of the usual type with the variation that the "ionic phraseology" is used throughout.

From the point of view of those who follow the new school the book is one of the best of its kind —whether it will help to produce another Hoffmann or Faraday, or what is as important, a Mond or a Muspratt, is more open to question.

(2) Dr. Mellor's "Modern Inorganic Chemistry" has already won a place on the shelves of most chemists, so that his new introduction, written from a more elementary point of view, should need no external recommendation. The author's statements as to what a student may expect from a general course of chemistry are worth quoting even at a risk of repetition, as too many of the modern text-books have already the opposite tendency. They are:—(1) Skill in observation and experiment; (2) memory and knowledge of relevant facts; (3) ability to reason and think in a logical, systematic way; (4) cultivation of the imagination; (5) development of a critical and impartial judgment.

The finished student with these attributes would not seek long for a lucrative position.

(3) The volume under notice completes the new edition of this well-known work, though we understand that a supplemental volume bringing the whole work up to date is in course of preparation. The articles on the analytical examination of the proteins are written by eleven authors whose names are sufficient guarantee of the completeness of the sections. It would be easy to quote small details where errors or omissions had been made, but it is fairer to comment on the vast mass of information which the volume contains and to praise the industry which has gone to its making, the more especially as such work is well known to be largely a labour of love. The new edition of Allen's work will more than maintain the reputation won by its forerunners.

(4) Dr. Stahler's work is an example of the modern omnibus type of German dictionary, full of every possible detail, and no doubt of the utmost value. The facts that it is very costly, so large as to make search in it a matter of difficulty, that it is published spasmodically in any sort of order, and contains a great amount of padding, all militate against it being found outside a few large university libraries. Furthermore, like so many recent German works, it tends to ignore much of the work done outside Germany, and so sacrifices any claim to completeness.

(5) It will be generally admitted that not the least of the advantages derived from the modern advances in electro-chemistry are the many valuable methods of analysis which have been based on them. In particular many of the methods are in use in those cases where speed is essential.

Prof. Classen's German text, which was published originally as long ago as 1882, is very widely known, and has passed through several editions. Prof. Hall has done a considerable service in bringing the English edition again up to date. The table of contents illustrates sufficiently how widely electro-analytical methods are applicable both to the more simple operations, such as the separation of metals from one another, and also to more special technical analysis, such as that of commercial copper, zinc, lead, and their ores. All the more recent new methods are included, and the apparatus required is fully described and figured.

(6) The danger of extreme specialisation has been emphasised often enough, but so exaggerated is this now becoming that we are offered from Germany a special course of phytochemical preparations picked out for the would-be botanist. A selection of organic compounds which are in some way connected with plants is made, and the manner of their preparation described in some

detail, so that the student can make them in the laboratory and gain an idea of their individual properties.

There will be no difference of opinion amongst teachers as to the futility of such a plan. The student can get no proper idea of chemistry as a subject, or of its theories and application. He will regard it merely as a series of manipulations, and his text-books as akin to cookery books.

At a time when the teaching of chemistry to medical students is steadily improving it is disconcerting to notice a tendency in the reverse direction in the case of biological students, which unhappily is not confined to the Continent.

MATHEMATICAL BOOKS: ELEMENTARY AND ADVANCED.

(1) *Arithmetic.* By H. Freeman. Pp. viii + 231 + xxxi. (London: G. Bell and Sons, Ltd., 1914.) Price 2*s.* 6*d.*

(2) *The School Algebra.* By A. G. Cracknell. Pp. viii + 568 + lxxvii. (London: University Tutorial Press, Ltd., 1914.) Price 5*s.*

(3) *Statics.* By R. C. Fawdry. Part i. Pp. vii + 165. (London: G. Bell and Sons, Ltd., 1914.) Price 2*s.* 6*d.*

(4) *A First Schol Calculus.* By R. Wyke Bayliss. Pp. xii + 288. (London: E. Arnold, n.d.) Price 4*s.* 6*d.*

(5) *A Treatise on Differential Equations.* By Prof. A. R. Forsyth. Fourth edition. Pp. xviii + 584. (London: Macmillan and Co., Ltd., 1914.) Price 14*s.* net.

(6) *Linear Algebras.* By Prof. L. E. Dickson. Pp. viii + 73. (Cambridge University Press, 1914.) Price 3*s.* net. Cambridge Tracts in Mathematics and Mathematical Physics, No. 16.

(7) *The Elements of Non-Euclidean Geometry.* By Dr. D. M. Y. Sommerville. Pp. xvi + 274. (London: G. Bell and Sons, Ltd., 1914.) Price 5*s.*

(8) *A New Analysis of Plane Geometry, Finite and Differential, with numerous examples.* By A. W. H. Thompson. Pp. xvi + 120. (Cambridge University Press, 1914.) Price 7*s.* net.

(1) THIS book consists mainly of examples, and there is said to be "just sufficient bookwork to be of use to a pupil when in difficulty." We do not think that, for example, any difficulty a pupil may feel about negative numbers can be dispelled by a complete absence of "bookwork" about them (p. 7).

(2) The aim of this book is to bring the teaching of elementary algebra into closer touch with "intelligible" calculations, and also to give a clear account of the elements of algebraic theory. The author warns us that "a rigorous logical account of the fundamental laws of algebra is very difficult, and would be quite out of place in a book of this description." Accordingly, we find, on p. 172, that "*the* negative unit" is defined as "*a* unit which cancels a positive unit" (the italics are ours). In this confusion between definite and indefinite articles, there seems to be some departure from the author's intention to give a clear account of things. The author seems to recognise that such things as the law of signs does present difficulties, but his treatment is not satisfactory. The book is not without merits.

(3) This pleasant little book shows the very healthy influence that the work of Mach has exerted on the teaching of mechanics. It deals with the subject on an experimental basis, and contains many examples, mostly numerical.

(4) This is an attempt to introduce the calculus by means of simple questions based upon matters familiar to the student either from his every-day experience or from his work in the laboratory. It is said to be "planned upon the latest educational theories," but this ought not to prejudice us against a very sound book which contains none of the subtlety that is required in higher walks of mathematics. For example, on p. 153, under the stimulating heading of "The Borderland of Discovery," the introduction of new functions by integration is treated apparently on the principle that any combination of symbols whatever must mean something. This is rather a natural supposition for most budding mathematicians to make, but it would be as well to warn them of possible dangers.

(5) The third edition of this well-known and solid work was published in 1903. This fourth edition is larger, but the general scope of the book is unaltered. Prof. Forsyth's object is to produce a working text-book, and the general theory is scarcely touched upon. Thus, such subjects as theorems of existence are noticed only by a reference to the author's "Theory of Differential Equations." There is an advantage, says the author, "even if only of conciseness," in assuming some results of the theory. Some parts of the book have been re-written, particularly the early part of the chapter on the hypergeometric series, and parts of the chapters on partial differential equations. A number of short additions has been made: on ordinary linear equations with some of their integrals of the type called "regular"; on total differential equations; and on partial equations. The only misprint—if, indeed, it is a misprint—that we have been able to find is a reference in the index to Abel on a page where algebraic functions are spoken of, and not Abel. It is perhaps almost inevitable that a text-book on

differential equations should not excite a learner's vivid interest unless it so departs from the logical order as to be historical. Often a modified logical order seems the easiest and most natural order. But the problem of education seems to be rather a problem of awakening interest, and not of choosing "natural" paths. Difficulties cease to matter if one's interest is aroused.

(6) Prof. Dickson's introduction to the general theory of linear algebras, including also non-associative algebras, shows in many places the influence of the German "Encyklopädie." The exposition of the main theorems of the general theory follows Cartan and, to some extent, Wedderburn, and is a most useful introduction to the subject.

(7) Here is an excellent text-book for all students of geometry. As seems to be always the case with this subject, the treatment is, to a great extent, historical, but the analytical treatment begun by Riemann occupies a rather minor position. A very welcome feature is that, throughout this book, Euclidean geometry is exhibited as a particular case of non-Euclidean geometry, and the apparent want of symmetry and the occasional failure of the principle of duality are explained. It seems rather confusing to assume tacitly, as the author does on p. 30, that through any point there are in hyperbolic geometry two, and only two, parallels to a given straight line.

(8) This book claims, rather magisterially, to be original. It seems to us more interesting than strikingly original. The equation of a line, $y=mx+c$, may be regarded as having the coördinates m and c. By using the word "measure" to denote a concept including both the distance of two points from one another, the perpendicular distance from a point to a line, and the angle between two lines, it is possible to state shortly what co-ordinate geometry does. This is the reduction of a set of joins and intersections of points and lines to functions of the measures of the elements. This idea is developed by the author and applied also in differential geometry.

ϕ

OUR BOOKSHELF.

Quain's Elements of Anatomy. Eleventh edition. Vol. ii., part ii., Splanchnology. By J. Symington. Pp. x+392. (London: Longmans, Green and Co., 1914.) Price 10*s*. 6*d*. net.

IN this further contribution to the eleventh edition of Quain's "Elements of Anatomy" Prof. Symington describes the following systems of the human body:—Digestive, Respiratory, and Urogenital. Two minor sections are devoted to the ductless glands and peritoneum, the latter being written by Dr. P. T. Crymble. During the eighteen years which have elapsed since the tenth edition appeared—under the joint editorship of Sir Edward Schäfer and Prof. Symington—anatomists, physiologists, and particularly surgeons have altered our conception of the splanchnology of the human body in many and important details. These changes are reflected in the text and illustrations of the new edition of "Quain."

No one is better qualified to edit this standard work on human anatomy than Prof. Symington. We feel, however, that in giving the Belfast school its full due, Prof. Symington has done less than justice to those who live and work outside the limits of Belfast. One example will suffice. About twelve years ago a series of observations were made by Keith, Barclay Smith, and T. R. Elliott, which served to show that the contents of the small and great intestine were separated, not by a mechanical valvular apparatus as was formerly supposed, but by a muscular mechanism, similar in the manner of its action to a sphincter. Sir William MacEwen and Dr. A. F. Hertz have demonstrated the existence of an ileo-cæcal sphincteric mechanism in the living human body, and emphasised its functional and clinical significance. Yet in the text of this edition no mention is made of these observations, and the erroneous and antiquated description of a mechanical valve is reproduced. This is the more surprising because the illustrations of the ileo-cæcal junction, reproduced from the former edition, bear out the non-mechanical nature of the ileo-cæcal orifice.

(1) *The Great Ball on which we Live*. Pp. 249. (2) *Our Good Slave Electricity*. Pp. 246. By C. R. Gibson. (London: Seeley, Service and Co., Ltd., 1915.) Price each volume, 3*s*. 6*d*.

MR. GIBSON has attempted with considerable success the solution of the old problem—how to interest children and at the same time instruct them. In the first volume he tells the story of the earth, and invites his readers to accompany him on imaginary visits to our planet before man's appearance on it. The fact that at one place a jelly-fish tells the story of what happened in the sea, and at another a worm records its experiences underground, will indicate the style of treatment adopted.

The second book describes in a similar simple manner some of the achievements of electrical science, and young readers will probably be led by these chapters to take up serious study later.

If it is possible to form sound elementary ideas of experimental and observational science merely by reading, it would be difficult to find more attractive introductions than Mr. Gibson has prepared.

Brown's Marine Electrician: for Sea-going Engineers. By A. E. and A. H. Larkman. Pp. xv+244. (Glasgow: James Brown and Son. Second edition, 1914.) Price 5*s*. net.

IN this book "the authors seek to give practical information on such matters as the installation, repair, and use of electric lighting, heating, and

other appliances suitable for use in ships." Apparently the reader is expected to acquire that information from illustrations which seldom show more than the outside appearance of the apparatus, and often show nothing at all but a cast-iron case! There are some more detailed diagrams, but too many of them refer to machines or apparatus which could only now be purchased in the electrical equivalent of the old clothes shop.

The book will certainly enable the sea-going engineer to distinguish between a search-light and a telephone, or between a dynamo and a switch, but we fear he would be very much at sea when anything went wrong if his knowledge was not a great deal deeper than that in the book.

It may be the printer's fault that a very ordinary Welsh name is given as that of one of the celebrated builders of high-speed engines, and that Mr. Marconi's has been associated with his great rivals. But these errors sufficiently well typify much of the contents of the book.

DAVID ROBERTSON.

Die Insekten Mitteleuropas insbesondere Deutschlands. Edited by Prof. C. Schröder. Band iii. Hymenopteren (Dritter Teil) Die Gallwespen (Cynipidæ). By Prof. J. J. Kieffer. Die Blatt- und Holzwespen (Tenthredinoidea). By Dr. E. Enslin. Pp. xiii+213+viii plates. (Stuttgart: Franckh, 1914.) Price 7.20 marks.

THE third part of the third volume of the "Insects of Central Europe," so ably edited by Prof. Chr. Schröder, of Berlin, contains an account of the gall-wasps (Cynipidæ) by Dr. J. J. Kieffer, and of the saw-flies and wood-wasps (Tenthredinidæ) by Dr. E. Enslin. In both cases the systematic description is preceded by an effective introduction dealing with structure, life-histories, and ecology. Thus we find a very clear account of the various theories of gall-formation by Cynipidæ and of parthenogenesis in Tenthredinidæ. The volume is very well illustrated, both as regards the text figures and the coloured plates.

Bartholomew's Orographical Map of Central Europe, showing Political Frontiers. Scale: 31·5 English miles to 1 in. Price 2*s*. 6*d*. net. *Bartholomew's War Map of Europe and the Mediterranean.* Scale: 86 miles to 1 in. Price 1*s*. net. (Edinburgh: John Bartholomew and Co., 1914.)

NOTHING assists an intelligent appreciation of the details of military campaigns more than good maps of the areas concerned. The maps before us are excellent. The first enables the reader of war news to realise the intimate interdependence of strategy and land relief; and the second depicts boldly the present extent of the European territories of the nations at war. Both maps are produced in the workmanlike manner for which the Edinburgh Geographical Institute has long been well known.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Soldiers as Anthropologists.

IN NATURE of December 3 (p. 383) there appeared a brief abstract of a paper communicated by Mr. Reginald A. Smith to the Royal Anthropological Institute on behalf of its author, Major E. R. Collins, D.S.O., now a wounded prisoner of war in Germany. The paper is not only an important contribution to our knowledge of the prehistoric stone implements of South Africa, but is evidence that a brave and capable soldier may, while helping to shape the history of his own time, give material assistance in unravelling the past history of the country through which he may be campaigning.

Major Collins collected the material for his paper while engaged on trenching operations during the late Boer war. These operations extended over a large part of South Africa—from Cape Colony to the Transvaal. The trenches were usually cut to a depth of 5 ft., and often crossed terrace deposits, which are presumably of Pleistocene age. It was whilst engaged on these operations that Major Collins made his collection of the stone industries of the ancient inhabitants of South Africa, keeping systematic records of the deposits in which the implements occurred, and the levels at which the various types were found. That Major Collins's interest in anthropology did not interfere with his military duties may be inferred from the fact that he earned the Distinguished Service Order.

Mr. Reginald Smith has directed my attention to an earlier instance of a soldier utilising military operations for the progress of anthropology. In the Journal of the Anthropological Institute for 1884 (vol. xiii., p. 163) there is a paper, also on South African implements, contributed by Major H. W. Feilden, which was described by the late Mr. Hyde Clarke, vice-president of the institute, as "remarkable for the circumstances under which the information was obtained—on the march, in the battlefield, and through the perils and vicissitudes of war." Major Feilden made his observations during the campaigns in Natal, 1881–82. I have little doubt that some of our French colleagues, amidst all the dangers and anxieties which attend the present war, will avail themselves of the opportunities presented by the extensive trenching operations in northern France to extend further our knowledge of prehistoric times.

I have headed this note "Soldiers as Anthropologists," but I may be pardoned if, at the present time, I direct attention to another side of the matter, "The Anthropologist as Soldier." In a letter I had lately the honour to receive from Prof. Manouvrier, secretary to the Society of Anthropology of Paris, I was grieved to learn that "Nous avons perdu en France un anthropologiste archéologue des plus estimés, M. Déchelette, capitaine de territoriale, tué dans une charge à la tête de sa Compagnie." M. Déchelette was author of a standard work, "Manuel d'Archéologie préhistorique Celtique et Gallo-Romaine," the third volume of which appeared during last year. M. Déchelette did not allow either his past or present services to science, his family ties, or his age—he was fifty-nine—to stand between him and what he considered his duty to his country. Although a great number of its members—including many of the most eminent anthropologists in Europe—are on active service—some have fallen, some wounded, and

others decorated for bravery in the field—the Société d'Anthropologie still continues its meetings. I was able to inform Prof. Manouvrier that the sister society in London, in common with other English scientific societies, also continued its meetings, that many of its members—including the honorary secretary and assistant-secretary, had volunteered for active service, and that a member of the council (Major S. L. Cummins) had been decorated with the Legion of Honour.

"Pour moi," writes Prof. Manouvrier, in concluding his letter, "je ne puis plus qu'un vétéran—un ancien volontaire de 1870. Je fus ainsi un très obscur compagnon d'armes de notre aimé Lord Kitchener."

Royal College of Surgeons, Lincoln's Inn Fields, W.C. ARTHUR KEITH.

A Central Thought of Vector Analysis as used in Physics.

VECTOR analysis is now recognised fully as furnishing standard modes of expression for many ranges of mathematical and physical thought; and meanwhile, the atmosphere of the physical thought especially is continually reacting upon the newer analytic method, and adapting it with preciser discrimination to the needs of actual use. Thus the dichotomous arrangement of quantities as scalar or vector has been supplemented by the tensor-triplet as a *tertium quid,* vectors are habitually grouped as free or localised, pseudo-scalars have been set off from pure scalars. Something has been done, too, through the influence of ascertained physical connections, toward unifying discrete formal results by appreciating real underlying articulation. Such advances as are made deserve immediate incorporation in the accepted text, as likely to render the methods more widely available; and the serving of that end has suggested presenting the notes that follow.

Most of the orthodox lines of development leave scalar product and vector product isolated from one another, each sharply differentiated by its own special definition. And an impression is then ordinarily felt that the novel characteristics of vector analysis in cutting through the rules of algebra centre upon the vector product. What there may be of exaggeration in this impression can be corrected by very simple and accessible considerations. First we may observe that an axial vector and a vector product are essentially two aspects of the same conception, the former being potentially resolvable into two factors determining an oriented area that is at the same time the geometrical basis of the vector product. But the projection of areas and their graphic representation by their measured normals are familiar elementary notions; while the assignment of "circulation" round the perimeter to an area, being necessary in order to complete the plan of conventional representation, must be expected to appear also in the equivalent vector product. In fact, the rule for sequence of the factors there and the change of sign upon reversal of that sequence are only assignment of circulation scarcely disguised. To establish the connection is to restore the emphasis of Grassmaun's thought where it may have been neglected.

At another point current procedure is apt to dislocate the vector product from its natural or original setting, and encourage a misleading effect of antithesis where there is in reality more nearly a complementary relation. When a scalar product and its corresponding vector product are introduced separately and held apart by exclusive stress upon their divergence of type, an instructive link uniting them is lost sight of or ignored. At their source they are linked in that completer combination of two vectors according to the fundamental idea of multiplication of which they are partial aspects. Again it is Grassmaun who more than hints at this very point of view, presented also in a somewhat different dress by the quaternion and the dyad. For purposes of elementary introduction the relation in question comes, perhaps, most clearly into prominence if the vector factors to be combined are from the outset of this particular development written each as a "semi-cartesian" trinomial, yielding thus nine terms for the presentation of the completed combination. On inspection three of these terms are obviously scalar; they constitute the "scalar product" (or expressed more fully the "scalar side of the product"). The remaining six terms are just as obviously to be accepted as vectors in their nature; together they constitute the "vector product" (or the complementary "vector side of the product"). These mutual complements make up the complete expression into which they enter, though they cannot coalesce, very much as a complex quantity contains a real term and a detachable imaginary term.

The value of the more inclusive statement is to be rated still higher in its justifiable extension to the combination of Hamilton's operator with a field-vector, which is also expressible formally as the expanded product of two trinomials, the nine terms of which, here too distinguishable as scalar and vector to unstrained interpretation, are presently grouped under the headings "divergence" and "curl." For the complete combination that might be written (∇V) is intended to place in our hands by its results a means of specifying with all reasonably attainable detail the local peculiarities of distribution for the field-vector. And here the usual partition of the specification into apparently quite disconnected divergence and curl seems plainly artificial at first sight, and becomes yet more so as we trace out the intimately complementary character of the two items in the description. It will always be helpful to emancipate ourselves from the formal constraints of our algebra, which here, for example, in a degree forbid the association of scalar and vector parts, and aim on the contrary, through the choice of orthogonal components, at a segregation at once complete and reduced to simplest terms. We remember with profit that one main office of the vector analysis is to do away with those mechanical features of algebra which contribute nothing or little to the progress of thought.. FREDERICK SLATE.

University of California.

Science and National Needs.

IN a recent issue of NATURE (October 29, p. 222) the remark occurs:—

"In this hour of national emergency there is no time to be lost. We cannot all be soldiers, but we can all help, we men of science, in securing victory for the allied armies. Every day lost means the destruction of a number of our fellow-countrymen and of our allies, and the sooner we co-operate for the good of the nation the sooner will the war be over."

Acting upon the suggestion, and bearing in mind the manner in which the dew-ponds on Salisbury Plain suffered during the drought of 1911, I immediately offered my services to the War Office, to advise as to the digging of dew-ponds and the choice of sites for them.

I find that there is not now so great a necessity for them there as formerly, as water has been laid on to many of the camps, but should the necessity arise anywhere that camps are placed, the War Office has my offer before them.

I write this in order to encourage others to do what in them lies. EDWARD A. MARTIN.

285 Holmesdale Road, South Norwood, S.E.

THE SUPPLY OF PITWOOD.

ATTENTION has already been directed in NATURE to the great diminution in the normal supply of pitwood since the beginning of the war. This tends at the moment to raise the cost of coal, and would, if continued, ultimately reduce the output. The official returns[1] show a great decrease in the import of pitwood from foreign countries, but this need cause no alarm so long as the command of the seas is retained. Ample supplies are available in Canada and Newfoundland, and a considerable amount of home-grown timber suitable for use in the mines can be felled during the coming winter.

FIG. 1.—A' Cruach before planting. Note the rocky face. From the Transactions of the Royal Scottish Arboricultural Society.

Timber is necessary in coal mines for supporting the roofs of galleries and main roads, for sleepers on the haulage lines, etc. Steel, concrete, and masonry are used in various ways as substitutes, but timber remains the cheapest and most easily handled material.

The great bulk of timber used in coal-mining consists of poles $2\frac{1}{2}$ to 7 inches in diameter at the small end, which are cut into convenient lengths for use as pit props. Such poles are readily procured, either as thinnings or as the smaller-sized trees in woods which are clear felled, and are sold at a cheap rate, being of little value except for utilisation as pit props, firewood, or pulpwood. Both home-grown and foreign timber are used, but the former, of which no statistics are available, scarcely exceeds one-tenth of the total amount consumed. In 1912, a normal year, 260,000,000 tons of coal were raised in the United Kingdom, valued at 118,000,000*l.*, or 9*s.* 1*d.* per ton. During the same year the import from abroad of pit timber was 2,925,000 loads, equivalent to 117,000,000 cubic feet, valued at 3,660,000*l.* In other words, to raise each ton of coal about $\frac{1}{2}$ cubic foot of foreign timber, costing $3\frac{1}{3}d.$ is required. The expenditure on pit props is about 3 per cent. of the price of coal. It is evident that a considerable increase in the price of pit timber could be borne before the cost of coal would rise to a ruinous figure.

There are two classes[2] of foreign pit-timber, the statistics of the import of which in 1912 were:—

	Loads		£
1. Spruce and common pine from Russia, Sweden, and Norway; nearly all from Baltic ports	1,170,000	...	2,580,000
2. Maritime pine from France, Portugal, and Spain ...	1,189,000	...	1,039,000

[1] Import of pitwood from foreign countries, 193,002 loads in September, 1914, against 479,341 loads in September, 1913. The figures for the nine months ending September 30, 1914, are 1,920,000 loads; for the same period in 1913 as much as 2,585,459 loads

[2] A small quantity, 26,000 loads, from Germany and other countries is not included in the above figures.

As soon as war was declared, the supply from the Baltic practically ceased, as pit-timber was declared contraband by Germany, and its exportation prohibited by Russia. The supply from France, Portugal, and Spain, though hindered by scarcity of labour while mobilisation was going on in the Landes, appears to be now normal, as the price at Cardiff, which was 20*s.* per ton in July before the war, after rising to the panic figure of 35*s.* in August, dropped to 21*s.* on October 10. These pit-props of maritime pine are cheap in price, as the vessels which convey coal from Wales to Bordeaux, Lisbon, Oporto, etc., carry back the timber to Cardiff and Swansea as ballast at a nominal freight-charge, often as low as 4*s.* 6*d.* per ton. The Welsh collieries will probably continue to receive regular supplies from France, Spain, and Portugal, but these countries will have no surplus timber to send to other colliery districts in England and Scotland.

It is well known that an abundance of timber suitable for pit-props is available in the vast forests of Canada and Newfoundland. Representatives of the Board of Trade, who were conferring on October 1 with the Dominion Minister of Trade at Ottawa, ascertained that the only difficulty is the question of price. It is not possible to obtain Canadian pit-props at as cheap a rate as the Baltic product, on account of the longer sea-voyage, higher cost of labour, etc. As soon as an equitable price is fixed,[3] we may expect adequate supplies of mining timber to arrive from Montreal, Quebec, Halifax, etc. In case of need, further supplies are doubtless available from British Columbia.

Home-grown mining timber consists chiefly of larch, spruce, and Scots pine, either grown in districts near the collieries, or obtained from the Highlands of Scotland and Ireland, the latter country sending last year about 50,000 tons of larch, a good deal of which is used in the pits of Lancashire. A small quantity of inferior timber, in the form of branch wood, coppice, etc., of broad-leaved species, like elm, sycamore, and beech, is also used from local sources; but it is disliked by miners, who prefer to handle coniferous poles, which are light in weight and smooth on the surface, besides being very strong. Oak, on account of its great strength and durability, is used in mines for special purposes, but in no great quantity.

In the present urgent necessity, the supply of native pit-timber can be greatly increased for one or two years at any rate. Once the price offered reaches a certain point it will be advisable for

FIG. 2.—A' Cruach 32 years after planting with Douglas fir. (Altitude 54–1000 ft. above sea-level.) From the Transactions of the Royal Scottish Arboricultural Society.

[3] To encourage shipment of pit-timber, vessels from Canada are now allowed by the Board of Trade, as an emergency regulation, to carry unrestricted deck-loads of timber.

owners of coniferous plantations to execute moderate thinnings that will yield pit-props of useful sizes. The present time also affords an excellent opportunity for the clear-felling of unprofitable woods, that is, of all those which are not in a thriving state, or which are insufficiently stocked, or which are over-ripe, and no longer increasing in volume at an appreciable rate. A considerable area of coppice, which has been nearly worthless for some years past, owing to the constantly declining prices of all kinds of small timber, should also be cleared, and be converted into conifer plantations. All such clearances would provide a good deal of timber useful in the present crisis, which was formerly impossible to sell, owing to the abundant supply at a cheap price of the same kind of timber from the Baltic. After the trees are felled, re-planting with fast-growing conifers (as a general rule) should be proceeded with at once. All these operations, felling, planting, etc., would give rise to much employment of labour in country districts during the coming winter, and help to check the migration of the unemployed into the large cities.

Reasonable schemes of State afforestation have hitherto been regarded unfavourably by those in authority, but this view may change after the war is over. Meanwhile, during the present time of national danger, a great deal of useful work can be done by private owners of woodlands on the lines suggested above. There is little doubt that plantations, which can be made out of the proceeds of the sale of pit-timber besides increasing the employment of labour, will prove a safe investment.

What is possible in the way of afforestation in Scotland is the chief subject discussed in Transactions of the Royal Scottish Arboricultural Society (vol. xxviii., part 2), which has recently appeared. This part, besides some useful articles and notes on Douglas fir, Sitka spruce, acetone, etc., gives an account of a tour of inspection of the woods and afforestable lands of the Highlands, made during last July, to which foreign[4] and colonial representative foresters were invited. The splendid results obtained by modern methods of forestry in Perthshire, Deeside, and Strathspey were much admired. The enormous area of land suitable for afforestation was the main feature noticed in Inverness-shire and Argyllshire.

As an example of what can be done in a short period of years, the Benmore plantations on the Clyde are most remarkable. Here 2000 acres were planted thirty-four years ago, mostly on steep and rocky hill-sides, from sea-level to 1200 ft. altitude, the soil being a poor sandy peat covered with heather.

The species cultivated are mainly Douglas fir, larch, Thuya gigantea, Scots pine, and spruce; and the average volume per acre is about 3400 cubic feet, *i.e.*, an annual yield of 100 cubic feet of timber. One detached small plantation of Douglas fir and Thuya, situated at a low level, under 130 ft. altitude, was blown down in 1912, when it was thirty-five years old, and yielded the enormous volume of 7430 cubic feet of timber per acre, which was actually sold for 130*l.* The cost of planting, loss of grazing (5*s.* per acre), rates, taxes, expenses of management, with compound interest at 3 per cent. added, amounted to 61*l.*, so that this plantation gave a net profit of 69*l.* per acre at the end of thirty-five years. The owner of the estate, Mr. H. G. Younger, stated that the whole glen, if afforested in the same way, which could easily be done, would support an extra 1000 families by the employment that would necessarily arise. Fig. 1 shows the mountain of A'Cruach at Benmore with its bare rocky face before planting was done, and Fig. 2 shows it covered with forest trees. Both illustrations are from the Transactions of the Royal Scottish Arboricultural Society, and are here reproduced by the courtesy of the Society.

A. H.

[4] Dr. P. E. Müller, the great authority on Forest Soils, was the delegate from Denmark. His views concerning the succession of soils and of species of trees in the Danish forests form the subject of an article in the Transactions, p. 241, which is of interest to plant ecologists as well as foresters.

WOOKEY HOLE.[1]

WOOKEY HOLE is situated in a narrow ravine on the south side of the Mendips, two miles from the cathedral city of Wells. Those familiar with the labours of the pioneers who discovered the presence of man in Pleistocene deposits of British caves need no introduction to this ravine in the Mendips, for the hyæna den, where Prof. Boyd Dawkins, the doyen of British "cave-hunters," commenced his labours fifty-five years ago, is situated on its eastern side, within stone-throw of the main series of caves which open on the ivy-covered crags at the northern or blind end of the ravine.

At the time when Prof. Boyd Dawkins (in partnership with the late Rev. T. Williamson) was commencing his early exploration of the hyæna den (1859), Pengelly and Falconer were bringing their exploration of the cave at Brixham to a close and were in a position to prove that the earlier discoveries made by the Rev. J. MacEnery at Kent's cavern and by Schmerling in the caves along the Meuse were true—namely, that man had been a contemporary of extinct animals such as the mammoth and woolly rhinoceros. Prof. Boyd Dawkins's explorations in the hyæna den at Wookey Hole clinched the matter; man had been living in England in the Pleistocene period. It is also worthy of remark that at the very time Prof. Boyd Dawkins was at work at Wookey Hole, Lartet was exposing, in the strata and hearths of the cave at Aurignac, human bones mingled with the charred remains of extinct animals and certain types of human implements—now recognised as characteristic of a period of Pleistocene culture.

In 1887, Mr. Henry Balch, the author of the work now under review, one to which artist, engraver, printer, and bookbinder have given of their best, began to make further explorations in

[1] "Wookey Hole: Its Caves and Cave Dwellers." By H. E. Balch. Pp. xiv + 268. (London: Humphrey Milford, Oxford University Press, 1914.) Price 25*s.* net.

the hyæna den, and afterwards transferred his labours to the main caverns which open at the head of the Wookey Hole ravine. In the vestibule or passage leading to the first of the three great caverns (see Fig. 1) he found a deposit on the floor amounting in thickness to nearly six feet. The main part of this work is an account of the exploration of this deposit. It is clear from the author's account that the vestibule or entrance had been used as a habitation by man during two periods. The more superficial or recent layers contained pottery and implements belonging to the period of the Roman occupation; the deeper strata were marked by objects belonging to a pre-Roman period—one which reaches back, in Mr. Balch's opinion, to ancient Bretons. He elaborates a tragic short story of a goat-herd to explain the discovery of part of a human skeleton, the skulls of two goats, an earthenware pot, a tethering stake, and a deposit of goat manure in the strata and recesses of the cave floor (see Fig. 2).

Mr. Balch suspects the cave-dwellers of cannibalism (1) because stray human bones were found in the strata of the cave, mixed with animal bones, and (2) because some early writers have alleged that the ancient British were cannibals. None of the bones showed the least mark of human workmanship—of knife or of saw; the fractures which Mr. Balch figures are those which may be seen in human bones dug from modern graves—fractures produced by the grave digger's spade. If

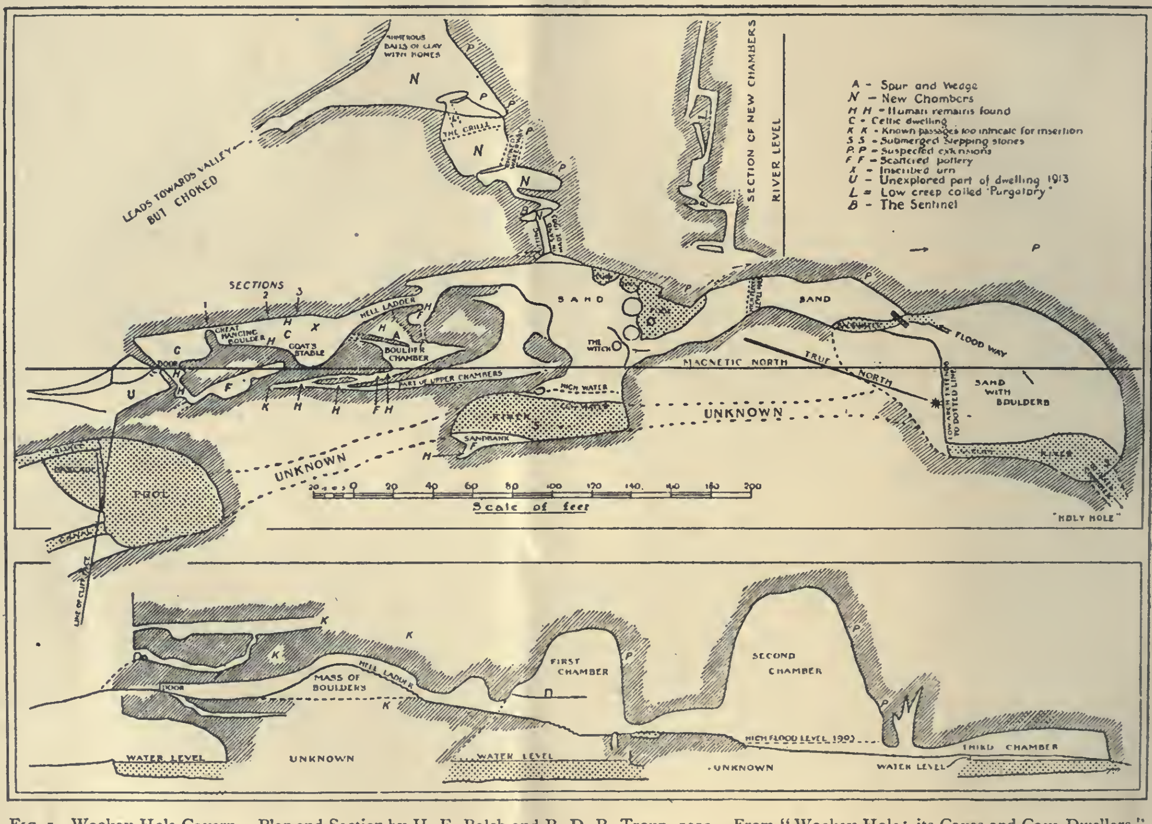

FIG. 1—Wookey Hole Cavern. Plan and Section by H. E. Balch and R. D. R. Troup, 1912. From "Wookey Hole: its Caves and Cave Dwellers."

about 400 B.C. The pottery, implements, ornaments, and objects of culture, found in the deeper strata are identical with those revealed by the investigations at Glastonbury. It is evident that the cave was used as a habitation when the neighbouring lake-village of Glastonbury was in existence.

Mr. Balch describes and figures in full detail all the traces left by these ancient pre-Roman inhabitants of Somerset. He has brought his imagination to bear on all the details and sought to reconstruct the home life of the cave-dwellers—ably seconded by the pencil and brush of Mr. John Hassall. He pictures the arrival of these cave-dwellers from Brittany, in order to explain the similarity of their cave pottery to that of the human bones are found scattered in the floor-strata of a British cave there is no need to suspect our ancestors of cannibalism. Nothing is better known than that Neolithic people used caves as sepulchres. We know, too, that rabbits and all sorts of animals which frequent caves, scatter the bones of skeletons embedded in the floor. Mr. Balch himself discovered a small cave in the heights above the Wookey Hole ravine; he relates how the human remains on the floor of that cave had been dismembered and spread by the animals frequenting the cave. No; Mr. Balch must bring more convincing evidence to convict the cave-dwellers of Wookey Hole of cannibalism.

Mr. Balch, with justice, dedicates his book to

Prof. Boyd Dawkins, who contributes an introductory chapter, in which he fights gallantly for opinions and conclusions put forward fifty years ago. In the opinion of the veteran geologist of Manchester we have not yet discovered a specimen of the people who lived in the caves of the Mendips during the Pleistocene period. The human skeleton discovered in Gough's cave at Cheddar he regards as an interment of the Neolithic period—whereas those who have investigated the evidence relating to the antiquity of the Cheddar man have formed an entirely opposite opinion—namely, that he represents a race which inhabited Somerset during Pleistocene time. Through the kindness of Prof. Fawcett of Bristol the writer of this note had an opportunity of examining two human

FIG. 2.—Relics of the Goat Head. From "Woo and Cave Dwellers."

skulls dug from the cave earth beneath the stalagmite of one of the Mendip caves. All the circumstances attending their discovery show that they are Pleistocene in age. What is more to the point is that they are exactly of the same form and show the same characteristics as the Cheddar skull. More interesting still, those ancient cave men are apparently of the same race as the early Neolithic people of England. Those who are following closely the progress of our knowledge of the ancient inhabitants of Britain expect much from the caves of the Mendips, and from hints dropped by Mr. Balch in this work, we have every reason to expect that these hopes will be realised.

A. KEITH.

NOTES.

DR. C. S. SHERRINGTON has been elected Fullerian professor of physiology at the Royal Institution for a term of three years, the appointment to date from January 13, 1915.

WE regret to see the announcement of the death, at eighty-nine years of age, of the Rev. Sir John F. Twisden, formerly professor of mathematics at the Staff College, and also for forty years one of the professional examiners in mechanics to the Department of Science and Art, and afterwards to the Board of Education.

IT is reported from Paris that Prof. A. Calmette, director of the Pasteur Institute at Lille, who resumed service at the beginning of the war in the capacity of Medical Inspector of Colonial Troops, is a prisoner at Munster, in Westphalia. Should any readers of NATURE have news of other men of science who are interned or prisoners on account of the war, perhaps they will send it to us for publication.

THE European war has unexpectedly checked scientific exploration in South America. Dr. W. C. Farabee, the leader of the University of Pennsylvania's expedition up the Amazon, has sent home word that he has had to cut short his journey owing to the fact that "the lack of funds, due to the uneasiness over the European war, made transportation difficult." The party had, however, already travelled about 4000 miles, and made some valuable anthropological collections.

THE eleventh award of the Reuben Harvey Memorial triennial prize will be made on July 1 next. The prize will be awarded to the writer of the best essay, on a subject to be selected by the candidate, showing original research in animal physiology or pathology, the essay to be illustrated by drawings or preparations. The competition is open to all students of the various recognised schools of medicine in Dublin, and to graduates or licentiates of the medical licensing bodies in Ireland of not more than three years' standing. The essays must be sent on or before June 1 next to the registrar of the Royal College of Physicians of Ireland, Dublin.

THE next meeting of the American Association for the Advancement of Science and of the affiliated scientific societies will be held in Philadelphia, and will begin on December 28. The retiring president, Dr. E. B. Wilson, of Columbia University, will introduce the president of the meeting, Dr. C. W. Eliot, of Harvard University, and will give the annual address on some aspects of progress in modern zoology. An interesting event of the meeting will be the first assembly of the newly established section of agriculture, which will meet on December 30. The address of the vice-president of the section, Dr. L. H. Bailey, late director of the College of Agriculture at Cornell University, will deal with "The Place of Research and of Publicity in the Forthcoming Country Life Development." A symposium on the general subject of "The Field of Rural Economics" has also been arranged.

THE following are among the lecture arrangements at the Royal Institution, before Easter:—Prof. C. V. Boys, a course of six experimentally illustrated lectures, adapted to juvenile auditory, on science in the home; Prof. W. J. Pope, two lectures on colour photography; Sir J. G. Frazer, two lectures on the belief in immortality among the Polynesians; Dr. H. G. Plimmer, three lectures on modern theories and methods in medicine; Dr. Chalmers Mitchell, three lectures on zoological studies: war and evolution; Dr. Aubrey Strahan, two lectures on London geology; Dr. R. T. Glazebrook, two lectures on aerial navigation—scientific principles; Sir J. J. Thomson, six lectures on recent researches on atoms and ions. The Friday evening meetings will commence on January 22, when Sir James Dewar will deliver a discourse on problems of hydrogen and the rare gases. Succeeding discourses will probably be given by Dr. Dugald Clerk, Prof. A. W. Crossley, Dr. W. S. Bruce, Prof. E. B. Poulton, Rev. A. L. Cortie, Sir Rickman John Godlee, Prof. G. H. Bryan, Sir J. J. Thomson, and other gentlemen.

THE death is announced, at fifty-seven years of age, of Dr. A. Celli, professor of hygiene in the University of Rome. The *British Medical Journal* gives the following account of his career and scientific work:—When still quite young Prof. Celli was appointed to the chair of hygiene at Palermo, from which, twelve months later, he was transferred to Rome. There he continued to work—teaching, investigating, and promoting social legislation—till last May. To his persevering efforts were largely due the sanitary improvements that have been made in the Campagna, and the organised campaign for the suppression of malaria. His scientific work covered a vast extent of ground, including research on the parasites which cause malaria, on cholera, on pellagra, on cerebro-spinal meningitis, on dysentery, on flies as transmitters of disease, on rabies, and many other subjects. He was an untiring worker in the cause of social reform through the spread of scientific knowledge.

THE death is reported, in his sixty-second year, of Dr. John Nisbet, Forestry Adviser to the Scottish Board of Agriculture. Dr. Nisbet was educated at the Edinburgh Institution and University, passing into the Indian Forest Service in 1875. He studied forestry at Munich, taking the degree of Doctor in National Economy. In Burma Nisbet proved himself a sound forester and a brilliant writer. He rose to the grade of Conservator of Forests, retiring in 1900. In 1903 he was decorated with the Kaiser-i-Hind gold medal for public service. His "Burma under British Rule," published in 1901, received high commendation. Dr. Nisbet spent his periods of furlough in studying British forestry and in making extensive tours in Continental woods. He thus proved a valuable coadjutor in the early 'nineties to Sir William Schlich in the campaign the latter inaugurated to arouse in these islands an interest in the forestry problem. Among the most important of Dr. Nisbet's publications of this period are "British Forest Trees" (1893), "Protection of Woodlands" (1893), "Essays on Sylviculture" (1893), "Studies in Forestry" (1894). After retiring from India Dr. Nisbet was appointed lecturer in forestry at the West of Scotland Agricultural College, relinquishing this post in 1912 when he was appointed to the Board of Agriculture. In these posts he devoted himself and his whole energies with an ardour which has not improbably shortened his life. He proved himself, with his wide and ripe experience, gained in many countries, a most valuable adviser and interesting lecturer, and his loss will be severely felt in Scotland by his Department, by the Scottish Arboricultural Society, the Transactions of which he edited at one time, and by many who sought his advice. His later publications included "The Forester" (1905), "Our Forests and Woodlands" (1908), and "The Elements of British Forestry" (1911).

THE death of Emeritus Prof. Campbell Fraser, of the University of Edinburgh, at the advanced age of ninety-five years, removes one who knew the city almost as Scott knew it. Dr. Fraser became professor of logic in the New College, Edinburgh, in 1846, and ten years later he succeeded Sir William Hamilton in the chair of logic and metaphysics in the University of Edinburgh. To the active duties of his chair he added very soon those of the dean of the faculty of arts, and continued to act as dean until his retirement from academic labours in 1891. In the early 'fifties he also edited the *North British Review*, and came into touch with many of the most distinguished essayists and philosophers of the day. He lectured in a simple, clear, unimpassioned style, which did not appeal strongly to the ordinary student, but to those who had philosophical tastes he proved an admirable guide, and retained their affection to the end. Some twenty of his students have occupied chairs of philosophy in Great Britain and the Colonies, and if we include professors in theological colleges the number may be substantially increased. His literary output was considerable, the editions of Locke and Berkeley being of especial value; and no scientific man aiming at a philosophic understanding of the principles of science can afford to neglect Berkeley. As Gifford lecturer in Edinburgh in 1894–5 Campbell Fraser developed a philosophy of theism, based on traditional Scottish lines, but worked out in the broad spirit of the nineteenth century. His interest in science was shown by his becoming, early in his professorial career, a fellow of the Royal Society of Edinburgh, serving as a member of council for a term of years. Long after his retirement he appeared with great regularity at the annual graduation functions of the University, a tall though slightly stooping figure, with lofty head and flowing beard, the typical calm philosopher.

WE regret to learn of the death of Dr. G. B. Guccia, whose work will always be regarded as one of the outstanding elements in the development of recent Italian mathematical science. Living in Palermo, where he was connected with the business of a printer and publisher, it occurred to Guccia in 1884 to start a local mathematical society, and to publish printed accounts of its proceedings. Thus sprang into existence the Circolo matematico di Palermo, with twenty-seven original members, which number

steadily increased; the total in 1908 was 570. By that time the Circolo had completely lost its local character, 319 of the members being non-Italian in nationality. These included 68 from Germany, 41 from France, 14 British, 25 Austro-Hungarians, and 92 from the United States. In 1894 Dr. Guccia was elected professor of geometry at the University of Palermo, and he was also a member of the International Council on the bibliography of mathematics, besides being president of the Italian section. When the International Congress of Mathematicians met in Rome in 1908 a "Guccia medal" was offered for the best essay on the theory of algebraic gauche curves, or, failing that, for some contribution to our knowledge of algebraic surfaces or other varieties. The commissioners, consisting of M. Noether (Erlangen), H. Poincaré (Paris), and C. Segre, recorder (Turin), awarded this medal to Prof. Francesco Severi. While the Palermo Society differs from any similar English institution in the fact of having received frequent grants from the Minister of Public Instruction and from the municipality of Palermo—these grants amounting in many cases to nearly 30*l.* and 20*l.* per annum respectively, still larger subsidies have been given by the founder himself. That the local society initiated thirty years ago should have now risen to the status of an international mathematical society of the first rank is a fitting tribute to the energy and enterprise of Dr. Guccia.

THE editor and publisher of the *Animals' Friend* are to be heartily congratulated on the success of their efforts to provide pads for the withers of cavalry horses at the front. Testimony to the value of these pads is afforded in letters of thanks from four yeomanry officers at the front published in the December number. Equal credit is due to "Our Dumb Friends' League," as reported in the same issue, for their successful effort to raise a fund for the purpose of affording assistance to wounded horses on the field of battle.

ACCORDING to a report in the December number of *British Birds*, bird-marking, under the superintendence of the editor, has been attended with conspicuous success during the past season, one operator having distinguished himself by ringing no fewer than 2521 nestlings. It is true, indeed, that the total number of ringed birds was much more than a thousand short of that in 1913, but this is more than accounted for by the decision to discontinue marking black-headed gulls. The most noticeable case of the recapture of a marked bird is perhaps that of a Sandwich tern ringed in the Farne Islands in July, 1913, and taken on the Ivory Coast in February of the following year.

ACCORDING to an article by Miss D. I. Griffin, the director, in the December number of the *Museums Journal*, the Children's Museum at Boston, U.S.A., has proved a complete success, the daily average of visitors being about two hundred, while on Sundays the attendance has sometimes reached a thousand. Temporary exhibits supplement week by week the permanent collections, and lectures (sometimes taking the shape of a stroll in the grounds) and lantern-slides form part of the programme. Labels are considered an essential feature of the museum, those devoted in the nesting season to temporary exhibits indicating the materials of which nests are composed, the adaptations of these structures to their surroundings, etc. The advisability of labels in children's museums is, however, by no means universally admitted, for in a discussion on a children's room at the Salford Museum, reported in the same issue, two museum officials declared them to be unnecessary, and liable to weary juvenile visitors. It was also questioned whether the chamber at Salford has any right to its title, a strong point being made by one speaker to the effect that the height of exhibition-cases could not possibly be made to suit both adults and children.

THE latest issue of the Bulletin of Entomological Research (vol. v., part 2, 1914) contains, in addition to several valuable systematic papers, a discussion by Mr. R. W. Jack, the Government entomologist in South Rhodesia, on the relation between tsetse-flies and "big game" in that part of Africa. Reviewing the evidence, Mr. Jack is inclined to support the opinion that the tsetse either increases or decreases in numbers, as the large ungulates are allowed either to increase under protective administration, or are freely shot or driven away. The restricted distribution of the species of Glossina suggests that these insects are "very delicately poised in the balance of nature," so that a considerable reduction in the available food supply—such as would be brought about by the disappearance of "big game"—might retard the rate of multiplication; for there is a "great expenditure of substance of the female in the comparatively slow process of reproduction." Were this reduction carried far enough, the tsetse might be unable to maintain its racial survival.

IN the last number of the *Journal of Genetics* (vol. iv., No. 2, 1914) Dr. C. Dobell publishes an interesting "Commentary on the Genetics of the Ciliate Protozoa." Students who are not specialists in the Infusoria can gather from this summary how far the results obtained by Woodruff and other recent investigators have modified the conclusions drawn from the famous researches of Maupas. Dr. Dobell's general conclusions at the end of his commentary will stimulate thought and provoke controversy. He objects strongly to the application of the term "cell" to an infusorian, which he insists should be compared with a whole metazoan, as it is "non-cellular" rather than "unicellular." Study of the Ciliates has convinced him of "the formidable complexity of all biological problems as presented by the Protozoa. . . . No new light has been thrown on the great problems of organic evolution. . . . The facts so far determined could indeed be used with far greater force to support the doctrine of the fixity of species." Biological thought just at present seems deeply shadowed by an oppressive scepticism.

IN a paper on the geology of Bermuda (*Amer. Journ. Sci.*, vol. xxxviii., 1914, p. 189) Prof. L. V. Pirsson concludes that the island is an ancient lava-cone that has been converted into a platform by marine erosion,

the oxidised products of decay being washed seaward as an accumulation over the unaltered lavas. The calcareous deposits added later to the platform go back to Lower Oligocene times. The igneous rocks are described in the same volume, p. 331.

IN the Proceedings of the Liverpool Geological Society, vol. xii (1914), p. 1, C. B. Travis provides an interesting account of the plains of denudation of various ages in Great Britain. Special attention is given to the Cainozoic peneplains of south-west England, and the author believes that the features that have been ascribed in this district to marine erosion result from submergence, subsequent to a general planing down of the surface by subaerial agents. The references to literature are valuable.

A SUMMARY of the weather has been given by the Meteorological Office for the autumn season as comprised in the weekly weather reports for the period of thirteen weeks ending November 28. The mean temperature for the period was generally in excess of the average, but the difference was not more than 0·8° in any district of the United Kingdom, and there was a very slight deficiency in the south-east and south-west of England. The rainfall was deficient over the entire kingdom, the greatest deficiency being 4·60 in. in the north of Scotland, and the least 0·67 in. in the Channel Islands. The largest absolute measurement was 10·70 in. in the north of Scotland and the least 5·42 in. in the east of England. In the Channel Islands 93 per cent. of the average rain fell and the next highest percentage was 85 in the north-west of England and 82 in the midland counties, which was followed by 81 in the south of Ireland and 80 per cent. in the south-east of England. The west of Scotland had the lowest percentage of the average, 63, which was followed by 65 per cent. in the north of Ireland and 67 per cent. in the north of Scotland. The rainy days were everywhere below the normal, the least number being forty in the midland counties, and the greatest fifty-nine in the north of Scotland. The duration of bright sunshine was mostly in excess of the normal; the greatest excess occurred in the south-east of England, where it amounted to about one-fifth of the average.

UNDER the title, "The Ice Storms of New England," Mr. C. F. Brooks has contributed to the Annals of the Astronomical Observatory of Harvard College (vol. lxxiii., 1914) a valuable paper on the theory and conditions of occurrence of the phenomenon known as "glazed frost," or coating of ice formed on trees and other objects by rain congealing as it falls, or by other causes. The data quoted refer more especially to occurrences at the Blue Hill Observatory, Mass. (formerly established by Prof. A. L. Rotch) during the years 1886–1914, together with records from a valley station at Readville and a few kite observations. The conditions which may produce ice storms are arranged in a tabular form; the combinations show that theoretically such storms are possible with the surface air temperature above 0° C., although no considerable storm under that condition was noted at Blue Hill. Several of the cases are carefully discussed, and the author states that a study of some of the details shows that storms may occur with a temperature as low as −13° C.; that it may rain hard or lightly; that the wind may come from any direction; and that the temperature may rise, fall, or remain stationary. Ice storms may be much more local than snowstorms, and their prediction in New England is very uncertain, and, at the same time, scarcely necessary.

THE latest volume of the Proceedings of the Edinburgh Mathematical Society (vol. xxxii., session 1913–14) contains a variety of interesting papers (sixteen in all), among which may be noted one on integral equations by M. Pierre Humbert; one on attractions of spherical and ellipsoidal shells by Prof. A. Gray; notes by Messrs. Taylor and Marr upon an elegant geometrical theorem, apparently first discovered by Prof. F. Morley; and papers by Prof. Whittaker and Mr. A. W. Young on Mathieu's differential equation. Prof. Gibson contributes an appreciative notice of that brilliant geometrician, J. S. Mackay.

IN illustration of a paper on the uses of mathematics by Dr. Samuel G. Barton, in *Science* for November 13, the author has worked through the eleventh edition of the "Encyclopædia Britannica," and has compiled a list of the subjects which have required the use of the symbols of the infinitesimal calculus in their treatment. The result of this inquiry is remarkable. The list contains 104 headings, of which perhaps a quarter refer to pure mathematics. The remainder deal with almost every branch of physics, chemistry, engineering, and meteorology, and as the author remarks, the appearance of "clock" and "sky" and many other entries may surprise even mathematicians. The author invites notice of omissions. Curiously none of the entries quoted appear to cover the important applications of the calculus to modern aeronautical problems. Is this Dr. Barton's oversight, or is the encyclopædia itself defective? Had the author selected a lower branch of mathematics than the calculus, such as trigonometry, the list would have been far greater. It would be interesting to estimate the percentage of articles containing some algebraic formula or equation.

Science for November 20 reproduces the address delivered by Prof. Carl Barus to the American Mathematical Society on the occasion of the one hundred and fiftieth anniversary of Brown University. Under the title, "The Mathematician in Modern Physics," it deals with the changes in the fundamental ideas of physics which have taken place since the author's student days, when Weber's theory of electromagnetic action at a distance was still regarded as a wonderful achievement, although Maxwell's ideas were slowly displacing it. Attempts to extend Maxwell's equations to moving electrical systems started a new epoch, and Michelson's light observations led in turn to the Lorentz-FitzGerald hypothesis of the contraction of a body along its line of motion, and to Einstein's theory of relativity, to which the late Minkowski gave so elegant a mathematical form. In another field Boltzmann shed new light by his definition of entropy, Wien then discovered the "displacement

law," and we now have Planck's atom of energy, which seems destined to play an important part in all future advance, while matter itself—the indestructible matter of Lavoisier—recedes into the background to consort with such shades as velocity and acceleration.

IN a "Sketch of a Generalised Theory of Relativity and a Theory of Gravitation" (B. G. Teubner, 1913; pp. 38) Prof. Einstein, in collaboration with Dr. Grossmann, gives a preliminary account of their attempts to base the whole structure of theoretical physics upon the assumption of an exact proportionality between heavy and inert mass, and consequently upon what Einstein calls "the hypothesis of equivalence." The meaning of the latter is: an observer enclosed in a box cannot decide whether the box rests in a statical gravitational field or is endowed with accelerated motion in a space free of gravitation. This leads to the requirement of universal invariance of a quadratic form in dx, dy, dz, dt with variable coefficients (which determine the gravitational field), instead of the very simple Lorentz-invariant of the "ordinary theory of relativity." Electromagnetic phenomena become entangled with gravitation; constancy of light-velocity is given up, of course; the Maxwell-Lorentz equations for a vacuum assume a generalised and more complicated form. Similar investigations are to be found in Kottler's paper of 1912 (*Wien. Berichte*, vol. cxxi.). There are many other striking consequences of the new theory, which obviously cannot be entered upon here. The "physical part" of the paper is written by Einstein, the "mathematical" part by Grossmann. Their theory, apart from undesirable complications, is far from being complete, since, as the authors themselves confess, they have not been able to find the general group of substitutions for their gravitational equations. We may remark here that, fortunately, there is thus far no urgent need of such generalisations, especially as Nordström's theory of gravitation based upon the "old" principle of relativity satisfies all reasonable requirements.

THE Journal of the Institution of Electrical Engineers for December 1 contains an account of some interesting experiments made at the National Physical Laboratory by Messrs. S. W. Melsom and H. C. Booth on the temperature rise in twin flexible wires such as are employed in ordinary electric light installations for pendant lamps with shades. It was found that, with lamps consuming 55 watts and upwards the temperature rise at the cord grip was in many cases 24° C. or more, that is to say, twice that allowed by the wiring rules of the institution, and high enough to destroy gradually the rubber insulation on the wire and to weaken the silk covering. This was due to heat from the lamp, and was irrespective of any heating of the wire itself due to the current passing. Similar observations were made in the case of flexible wires leading to electric irons, hot plates, etc. The temperature observations were in all cases made by means of minute thermo-junctions placed at the points tested. The results of the investigation emphasise the desirability of periodically renewing these flexible wires without waiting for them to show outward signs of deterioration.

OUR ASTRONOMICAL COLUMN.

DISTRIBUTION OF ELEMENTS IN THE SOLAR ATMOSPHERE.—No. 88 of the Contributions from the Mount Wilson Observatory contains the results of an investigation on the distribution of the elements in the solar atmosphere as given by flash spectra, contributed by Mr. Charles E. St. John. The spectrum used in this research was that which was obtained by Prof. Mitchell during the 1905 eclipse, and the results of the reduction of this spectrum, which have already been published, are here employed as the basis of the statistical discussion here described. The general scheme in this research has been to form numerous groups of lines on a simple plan, each element being considered by itself, and the lines of like solar intensity assigned to it forming the ultimate group. The results of the investigation are considered in relation to the author's previous conclusions regarding the distribution of the elements as deduced from the radial motion in sunspots, and he draws a series of general conclusions founded on the salient facts shown by flash spectra and displacements in the penumbræ of sun-spots based upon mean values. These are too numerous to be given here, but the author points out that "these facts are all harmonised by the consideration that the vapours of the elements ascend in detectable amounts to different heights, that the lines of any one element originate at depths increasing with decrease of solar intensity, that the enhanced lines are higher than unenhanced lines of equal solar intensity, and that we see into the sun to greater depth at the red end of the spectrum than at the violet." A general summary states that "the resulting distribution shows that H_3 and K_3 lines of calcium are the lines of highest level, followed by the $H\alpha$ line of hydrogen, and that, in the main, the heavy and rare elements occur in detectable amounts only in the lower portions of the solar atmosphere."

PHOTOGRAPHS OF HALLEY'S COMET AND COMETS OF THE YEAR 1911.—In the *Annalen der k.k. Universitäts-Sternwarte in Wien* (vol. xxiii., No. 1) Dr. Joseph Rheden publishes a valuable memoir containing details about the photographs which he secured of Halley's comet in 1910 and other comets in 1911. Several instruments (on one equatorial mounting) were employed, such as an objective of 325 mm. aperture and 3·4 m. focal length, a Voigtländer portrait anastigmat of $f/4·5$, with focal lengths of 450 or 225 mm., and, lastly, a Zeiss-Planar $f/3·6$ of 110 mm. focal length, and another of $f/3·5$ of 100 mm. focal length. The memoir contains a brief description of the details of each of the photographs taken and numerous excellently reproduced plates illustrate the general forms of the various comets photographed. Besides Halley's comet, those of Kiess (*b*), Brooks (*c*), Quénisset (*f*) and Beljawsky (*g*), are discussed. It is interesting to note that attempts were made with two different instruments to record the transit of Halley's comet across the solar disc on May 19, but the weather was not very favourable, and the results not of a satisfactory nature.

STRANGE OBJECTS TRANSITING THE SUN'S DISC.—In scanning the solar surface observers have often remarked that they have seen bright objects passing across the sun's surface, and have concluded that they were meteors in the absence of any other plausible explanation. Attention may be directed to two interesting letters dealing with this subject which are communicated to the *Observatory* for November by Prof. Barnard and Mr. Denning. They put before the reader a large number of instances when such objects were observed, and decide conclusively that these daytime showers are not meteors. Mr. Denning

in a series of conclusions, sums up the reasons why the objects seen were nothing like telescopic meteors, and these are as follows:—They require a longer focus than the sun; they did not move in parallel directions; their general direction agreed with the direction of the prevailing wind; they were objects of irregular shape and light filamentous material; their vagaries of motion while in sight were greatly dissimilar to that of true telescopic meteors seen at night; and, finally, on one occasion Mr. Denning followed them on several successive days and a change occurred in the directions. These showers, they state, are purely local terrestrial events. In most cases they are seeds or the down of various plants carried by the wind at high elevations. In some cases snowflakes are the cause of the phenomenon, whilst insect-swarms, gossamer-threads, etc., are sometimes observed. Prof. Barnard states that at certain seasons of the year they can be seen in abundance when the telescope is pointed within a few degrees of the sun, giving the greatest angle of reflection, and if moving slowly appear like minute stars.

STARS HAVING PECULIAR SPECTRA.—In Circular No. 184 of the Harvard College Observatory Prof. E. C. Pickering publishes an additional list of stars having spectra with bright lines or other peculiarities found by Miss Cannon since the publication of Circular 178, which contained a list of peculiar objects in the course of the work on the new Draper Catalogue. The first table in the new circular gives a list of fourteen stars, six of which are described as new variables. In Table II. a list of thirty-one stars having composite spectra, including twenty-four new double stars, is given, and this brings the number of stars with composite spectra found on the Harvard photographs up to 100. The stars in this table range from magnitude 5·32 to 10·6, and the class of spectrum of the brighter and fainter components, as they have been determined from the general appearance of the blended spectra, are given in each case. In both tables the stars are arranged in order of Right Ascension, with the corresponding Durchmusterung numbers.

EFFECTS OF THE WAR ON SCIENTIFIC UNDERTAKINGS.

SEVERAL international or otherwise co-operative investigations of a scientific kind which were in progress at the opening of the war have necessarily been affected by the naval and military operations and the limitation of usual channels of communication. It is not opportune to state the position of some of these undertakings at the present moment, but various negotiations are proceeding, and it is hoped that a means will be found of carrying on work already well begun. The incalculable loss which scientific research must bear in the suspension of the international fishery investigations was referred to in an article in NATURE of October 22 (p. 201). Reference has also been made (NATURE, October 15, p. 183) to the need for a central bureau for the distribution of astronomical telegrams, as was done before the war by the Zentralstelle at Kiel. A few weeks after that note appeared Prof. Elis Strömgren, director of the University Observatory at Copenhagen, announced that by an agreement made between Prof. Kobold, of Kiel, as publisher of the *Astronomische Nachrichten*, and himself, the management of the Zentralstelle für astronomische Telegramme during the present war has been passed over to Prof. Strömgren. Consequently, all communications for the Zentralstelle should be addressed to him until further notice at the Observatory, Copenhagen.

The work of the Tropical Diseases Bureau in London has diminished since the outbreak of the war owing to the non-receipt of French and German journals; for the bureau exists primarily for the collection of information, chiefly from medical journals, on the diseases of tropical and subtropical climates, and its collation and dissemination within the pages of a journal, the *Tropical Diseases Bulletin*. There is little doubt that such investigations are being hampered in Africa by operations of war, and that they will be seriously interfered with in the future owing to lack of funds now derived both from the home Government and the tropical dependencies of Great Britain.

As to the future of the International Catalogue of Scientific Literature, the report of the council of the Royal Society states that the responsibilities of the society in relation to this undertaking have been a source of anxious consideration since the outbreak of the war. Apart from the question of continuance, the society is faced with serious liabilities in respect of this undertaking as it stands at the present moment. Should the annual amount of the subscriptions from Germany, Austria, Hungary, Belgium, and Poland not be available, as seems certain, at any rate until after the close of the war, this would mean an annual loss of about 1060*l.* in income in respect of each issue, or a total loss of about 4000*l.* on the issues of 1911, 1912, and 1913, after taking into account reduction of expenditure and in sales of trade copies and back numbers. This loss will fall, at any rate in the first instance, on the Royal Society.

Daily Weather Maps.—The Quarterly Journal of the Royal Meteorological Society (October, 1914) prints the subjoined note on the effect of the war on the issue of daily weather maps:—The sudden outbreak of war has a very marked effect upon the compilation and publication of the various daily weather maps. The *Daily Weather Report* issued by the Meteorological Office contained the usual information until July 31, but after that date some of the observations began to be missing, while from August 6 no data have been received from central Europe, and the wireless reports from the Atlantic were altogether discontinued. For several weeks the reports from Scandinavia and Spitsbergen were missing, but these were resumed in September, though reports from Iceland are still absent. The difficulties of preparing the usual forecasts and storm-warnings have consequently been much increased. The publication of the daily synoptic weather maps of Europe, the North Atlantic, and a large portion of North America, which has formed part of the *Weekly Weather Report*, has been suspended from August 2, until the necessary data have been received.

It has been the practice of the *Times* newspaper since 1876 to print each day the previous 6 p.m. weather map. This was continued until August 4, but after that date no further map appeared—no doubt owing to all the available space in the newspaper being urgently required for war information. For the same reason the table of observations from health resorts was discontinued from August 3.

On August 6 the Chief of the U.S. Weather Bureau announced that "owing to the state of war involving the great nations of Europe, the meteorological observations from regions in Europe and Asia, heretofore employed by the Weather Bureau in the construction of its weather map of the northern hemisphere, are no longer received, and the issue of this map will be suspended from this date until such time as the reports can be resumed."

Investigations of the Upper Air.—The effect of the war upon investigations of the upper air so far has only been indirect in the British Isles, but several independent causes have led to the fact that the present year has not been as fruitful of results as

previous years, and the difficulty of getting rubber balloons of really good quality has been greatly intensified by the war. During both 1912 and 1913 between fifty and sixty satisfactory balloon ascents were obtained, but the average maximum height in 1913 showed a distinct falling off compared with previous years. This was due to the balloons, of which the quality and workmanship are of the utmost importance. During the present year, although fresh sources of supply have been tried, the quality of the balloons has still further deteriorated, with the result that in many cases a premature bursting of the balloon has occurred and a maximum height of some five only instead of some fifteen kilometres has been attained. Since the details of the ascents have remained the same, the poor heights reached must be due to defective balloons.

There is an old proverb that misfortunes never come singly. The ascents at Manchester have ceased since the beginning of this year, and a run of persistent ill-luck in the finding and return of the instruments has been experienced; also the station of the Meteorological Office at Pyrton Hill, Watlington, ceased to be available in the spring. The present station is at Benson, about six miles W.S.W. of Pyrton Hill, a place equally suitable, but the compulsory removal of the station dislocated the regular routine work of the investigation during the first half of the year. From these various causes the number of successful balloon ascents this year in the British Isles can scarcely reach twenty-five, since the war has, for the time being, cut off the supply of balloons, and the very poor returns from the first half of the year cannot be made up by an extra number of ascents in the latter part.

It has been an unsatisfactory state of affairs that balloons should have been obtained from foreign firms, but cheaper and better balloons were so obtainable. It is hoped that arrangements may shortly be made for the supply from an English firm.

There is another way in which the investigation may be influenced by the war. In England compressed hydrogen can be obtained cheaply and conveniently in steel cylinders, but in some of our colonies these cylinders cannot be obtained. Failing this source of supply hydrogen is most easily produced from calcium hydride, the free lift of the hydrogen in air being equal to the weight of hydride used. Apparently the calcium hydride can only be obtained in Germany.

There is no information about what is occurring on the Continent. The international days are fixed until the end of the year, but after December, if ascents continue in Germany and Austria, it does not seem likely that we shall know the dates. Also the meeting of the International Committee which was to have been held in England next year can scarcely now take place.

In the investigation of the upper air the value of the individual observations is decidedly increased by a well-planned system of co-operation, but happily there are many problems which may be attacked without such co-operation, and we may hope that the work may go on with equal vigour as in the past, excepting that the necessary funds are not likely to be increased by the heavy expenses due to the war.

International Seismological Association.—The fifth meeting of the International Seismological Association was to have been held early last September at Petrograd, under the presidency of Prince Galitzin. Soon after war was declared, it was announced that the meeting was postponed, and, indeed, with the president a Russian, the secretary a Hungarian, and a committee including Germans, Englishmen and Japanese, no other result could be expected. The formal meeting of the association once every two or three years is not, however, the most useful work carried out under its auspices. The permanent committee of the association, with its headquarters at Strassburg, was engaged in collecting materials that could not fail to be of the greatest service. The compilation of the annual catalogues of perceptible earthquakes and of those registered at distant stations would alone justify the existence of the Association. To all this useful work, there must for the present be an end, and, even if the threads of the organisation are ultimately resumed, there will be a long delay in the issue of the next catalogues, and there will be many imperfections in the lists of perceptible shocks. In the registers of seismological observatories, the effect of the war will probably be less serious, for the network of stations established in the British Colonies and in allied and neutral countries is practically world-wide. The late Prof. Milne's decision to maintain the organisation which he created outside the control of the International Association is thus likely to have most beneficial results.

THE NATURAL HISTORY MUSEUM IN THEORY AND PRACTICE.[1]

DR. GUSTAVE GILSON, director of the Royal Belgian Museum of Natural History, has recently given to the scientific world his views on the general theory of a natural history museum in a magnificent quarto volume. The following is a brief abstract of his conclusions.

A universal museum being obviously impracticable, a regional museum is all that can be attempted, and the "region" must be limited according to circumstances. The collections of the museum must be acquired by systematic observations conducted by one or more officials (*chefs d'exploration*) specially trained for this particular work, and the exploration must include the acquisition not merely of individual specimens, but also of such material, drawings, plans, photographs, and records as are needed to give a full account of the environment. "The museum ought only to accept with suspicion a specimen that has not been collected by its own officials and furnished with data written down at the moment of its discovery."

The museum is not primarily an institution for the dissemination of scientific information among the populace, but a progressve institution dedicated to the advancement of knowledge, free from all pedagogic trammels and from every preoccupation alien to the investigation of nature, and thus playing an important part in the humanitarian mission of the development of natural history: "le musée renseigne, mais n'enseigne pas." Nevertheless, the museum may without being false to its ideals, expound to the people many of the results of its work, and become a valuable teacher in a line, and by methods different from those of the schoolmaster.

The regional museum must preserve collections on a generous scale, but these must be properly kept in suitable storehouses (*conservatoires*) under the constant supervision of trained curators (*conservateurs*). Dr. Gilson makes some strong remarks on the failure of many museums to take due care of their treasures. Besides the main collections there should be others, such as the "comparative" department, containing examples of similar objects from other places for study in connection with those of the region. These specimens may, of course, be acquired by gift or purchase. There should also be a public collection of examples judiciously selected; "here everything useless is harm-

[1] "Le Musée d'Histoire Naturelle Moderne—sa mission, son organisation, ses droits." Extrait des Mémoires du Musée royal d'Histoire naturelle de Belgique. By G. Gilson. Pp. xii+256. (Bruxelles: l'Académie Royale de Belgique, 1914.)

ful." Every object must be accompanied by an explanation setting forth its most interesting characteristics, and addressed, not to the unlettered, but to the man of education, who is not a specialist. "Exhibition without explanation is vain and profitless, and causes a justifiable feeling of irritation in every serious intelligent visitor." The colonial museum is another institution which may form a suitable annexe to the regional museum, and should be the result of, and an incentive to, the carrying out of the principle that "exploration should precede exploitation," and, as the author aptly remarks, "the more thoroughly and scientifically the former is done the more profitable will be the latter."

The relations, which should exist between the metropolitan museum and local museums are thus defined. "Certain species represented by only one specimen should be sent to the central museum, in view of the paramount necessity of centralisation. The central museum should, however, only receive these on deposit, and should carefully indicate that they are the property of the local museum. Furthermore, a cast or reproduction of such specimens should be placed in the latter with the label, 'The original is deposited in the national museum.'"

Royal Belgian Museum of Natural History, Brussels. The portion to the right is the old building; to the left is the new south wing; a north wing parallel to it was contemplated, as well as a new central connecting member parallel with the old building on the side remote from the spectator.

The regional museum must of necessity be a State institution, but the relations of the museum with the administrative departments of the State should be as simple and restricted as possible. The actual work of the museum should be controlled by an individual not a committee. "Under the autonomy of a personal head the institution utilises the powers of its direction to the full. If mistakes are made they are temporary; the error is in the personality which is short-lived. On the other hand, under the rule of a committee the work, impersonal in its nature, will be mediocre and sluggish, and the institution will vegetate exposed to the gravest perils; the error is perpetual because it is inherent in the system."

The remainder of the volume is devoted to an account of the Royal Belgian Museum of Natural History at Brussels, its origin, present condition, and future. Its history has been one not unusual in the case of similar institutions: progress impeded by official ignorance, coupled with apathy or opposition; the situation improved on the advent of a strong and enlightened personality who knew how to secure more generous treatment. At present the building consists of an old centre and a new south wing. It was proposed to add a similar north wing and a frontage parallel with the old building, but in present circumstances there does not seem much likelihood of these additions being carried out in the near future.

There are numerous well-printed illustrations, which represent a great variety of specimens and all departments of museum work, and it is a singular fact that, though they bear very directly on the text, they are scarcely ever referred to in it.

BACTERIAL DISEASES OF PLANTS.[1]

THE third volume of Dr. E. F. Smith's work on "Bacteria in Relation to Plant Diseases" deals exclusively with "vascular diseases"—that is, those in which the causal organism advances along the vascular tissues of the plant, completely blocking up the zylem vessels. When compared with the account by Russell under the same title, written in 1892, the present work shows markedly the immense progress made since that date in this branch of botanical study. It is a compilation representing indefatigable labour, and forms, with the preceding volumes, a comprehensive summary of all that is known under the head of bacterial diseases of plants. A feature of the work is the care taken to collect a complete biblography, and the author's extraordinarily wide knowledge of the subject and the extent of his own observations and research render his critical review of all investigations bearing upon the etiology of the disease of extreme value to other workers in this field. Moreover, the full abstracting of original papers, which are brought quite up to date, and lengthy excerpts concerning methods, technique, and results, fulfil the purpose of enabling the reader to form his own conclusions and emphasise the essential character of the publication as a book of reference.

Each disease described is treated in an exhaustive manner, the same plan having been followed throughout the series. The geographical distribution, history, signs of disease, the etiology and morbid anatomy are all fully considered, as well as the morphological and cultural characters of the parasite, to which great attention is given as a means of identification of the specific organism. A discussion of treatment is usefully included, and a general computation of pecuniary losses is attempted.

The present volume deals almost entirely with

[1] "Bacteria in Relation to Plant Diseases." By Dr. E. F. Smith. Vol. iii., Vascular Diseases (continued). (Carnegie Institution of Washington, 1914.)

diseases affecting tropical or subtropical plants, such as the sugar-cane, banana, sweet-corn, etc., which are of no economic importance in this country. If, however, the cultivation of tobacco is to have any great development in Great Britain, a reference to these pages is indispensable as a guide to the destructive

FIG. 1.—Tobacco-leaf from the hothouse, showing the typical red-brown shrivelled spots of the Granville tobacco wilt. The remainder of the leaf was green. *Bacterium solanacearum* abundant in vascular system of the midrib and in many side veins. Plant inoculated in stem, by needle-pricks, on September 23, 1905, using a pure culture of the North Carolina tobacco organism. Photographed February 20, 1906.

attacks to which this crop is subject, and the conditions which influence its successful growth. It seems also to be substantially proved by the author's own examinations and the weight of evidence which he has been able to accumulate, that the various forms of tobacco wilt, including those described by the Dutch

FIG. 2.—*Bacterium vascularum* in stem of sugar-cane received in 1902 from New South Wales. The figure represents a bundle in cross-section. The ground tissue, endodermal sheath, and phloem are still free, also a part of the xylem, including the two big pitted vessels. Sectioned from paraffin and stained with Flemming's triple stain, the contrast being not exaggerated.

and Japanese writers, are due to the same organism, *Bacterium solanacearum,* Smith, which causes the well-known rot of potatoes, tomatoes, and other solanaceous plants. This parasitic disease of tobacco has been known for the last twenty-five years in Japan, and the damage caused is widespread in all countries where tobacco is cultivated; the loss has often been enormous, and many planters have been driven to harvest their crop while unripe and half-grown, in order to save some portion of it.

The specific communicable disease of the sugar-cane, caused by a one-flagellate schizomycete, *B. vascularum,* Cobb, is, so far as is known, confined to this one host plant. It is responsible for a considerable reduction of sugar-content, and is apt to give trouble in the sugar factory, gumming the machinery, and interfering with proper clarification and crystallisation. The disease is most prevalent in the southern hemisphere, and it is satisfactory to learn that it has not been reported from the British West Indies or Porto Rico. It is, however, specially liable to be transmitted in cane cuttings, and planters in these islands are warned to be careful to guard against its introduction. The question of the origin and nature of the "gum," which is such a typical feature accompanying vascular bacterial diseases, is extremely interesting, and it is disappointing to find that nothing has been done on this point since Greig-Smith's work in 1904. His researches, undertaken upon the lines of qualitative chemistry, are entirely confirmatory of the bacterial origin of the "gummosis," as he concludes from tests of the chemical reactions that the "gum" and the bacterial slime from pure cultures on agar are identical. Apparently the mucilaginous substance blocking up the vessels is a bacterial zooglea, but its exact composition has not yet been determined, and remains one of the many unsolved problems of biochemistry. It would seem that these plant-gums are derived by the bacteria from the saccharine contents of the cell-sap, and are clearly not a degeneration product of the cell-wall, as was formerly supposed.

The book is profusely illustrated with excellent photographs and drawings showing all stages of the diseases cited and innumerable inoculation experiments. M. C. P.

ZOOLOGY AT THE BRITISH ASSOCIATION.

SECTION D held its meetings in the lecture theatres of the Universities of Melbourne and Sydney, and presented a full and varied series of papers. It will be noticed from the subjoined summary that about one-half the time of the section was devoted to the consideration of researches on Australian material.

Recent Work in Antarctica.

A discussion on the past and present relations of Antarctica was arranged by Section D, in conjunction with the Sections of Geology, Botany, and Geography. An account of the contributions of the geologists and geographers to this discussion appeared in NATURE of October 19 (p. 241), so that it is only necessary to refer here to the observations made by Mr. Hedley and Prof. Seward on the biological relations of Antarctica.

Mr. C. Hedley stated that naturalists have deduced the age, climate, contour, fauna, and flora of Tertiary Antarctica from the nature of Antarctic refugees now living in southern lands. For instance—(1) the monotremes, once perhaps numerous, are represented by two widely different types which survive in Australia, Tasmania, and Papua; the bones of other monotremes occur in South American deposits; (2) the Thylacines are recent in Tasmania, and fossil in South America and Australia. Either we must consider that these groups arose independently in each hemisphere, or that they spread from the one to the other. In the latter case a south polar land offered the most direct

path. The simplest explanation of the distribution of marsupials, past and present, is that they originated in South America, spread by way of Archihelenis to western Europe, by way of the West Indies to North America, and by way of Antarctica to Australasia. Turning to the Amphibia, Mr. Hedley pointed out that the families Hylidæ and Cystignathidæ have their chief seat in South America, and both families extend to Australasia, where they are best developed in the south-east and gradually vanish before reaching the Moluccas. In these cases also the most direct route between the two centres lies across Antarctica, and by cumulative evidence from plants and animals of many and varied kinds the conclusion is reached that this was the way they went.

Prof. Seward gave a brief account of some of the fossil plants collected by members of Captain Scott's second expedition, with special reference to Dr. Wilson's discovery of Glossopteris in 85° S. Fragments of well-preserved leaves of *Glossopteris indica* found in the rocks of Buckley Island, a nunatak on the Beardmore Glacier, afford important evidence, both as to the age of the Beacon Sandstone formation and as to a former connection between Antarctica and Gondwana Land. The geological distribution of Glossopteris in other parts of the world suggests that the strata of the Buckley nunatak must be assigned to the Permo-Carboniferous period. A large piece of wood obtained by Mr. Priestley from a sandstone boulder on the Priestley Glacier in 74° S. proved to be a gymnospermous stem of considerable botanical interest; the wood shows well-marked rings of growth and exhibits Araucarian characteristics, but in view of certain peculiar features has been referred to a new genus—Antarcticoxylon. Associated with this was found a winged pollen-grain, described as Pityosporites, which bears a striking resemblance to the pollen of recent Abietineæ. In conclusion, Prof. Seward referred to the bearing of these important discoveries on climatic considerations, and pointed out that while there is clear evidence of a considerable change in climatic conditions since the period when Glossopteris flourished on the Antarctic continent, there is no adequate reason to assume any change in the position of the earth's axis. Meagre as it is, the material collected by the polar party calls up a picture of an Antarctic land on which it is reasonable to believe were evolved the elements of a new flora that spread in diverging lines over a Palæozoic continent, the *disjuncta membra* of which have long been added to other land-masses where are preserved both the relics of the southern flora and of that which had its birth in the north.

Plankton.

Prof. Herdman gave an account of some recent plankton investigations in European seas (especially in the Irish Sea and off the west coast of Scotland), and of the apparatus used and the difficulties met with. He exhibited photographs of different samples of hauls showing that the diatoms attain their maximum in spring and are at a minimum in summer, while the copepods are few in spring but numerous in summer. He pointed out the necessity for taking samples simultaneously with vertical and horizontal nets, and for using coarse and fine nets in order to gain a true picture of the total plankton, and referred to the irregularity in distribution of plankton organisms, swarms of organisms being sometimes present in restricted areas, hence it was necessary to be careful in drawing conclusions from the samples taken in a single haul. He briefly discussed the application of plankton investigations to fishery problems, pointing out that diatoms are the ultimate food of marine animals, and therefore the starting-point of the problems.

The Abrolhos Islands.

Prof. W. J. Dakin gave a summary of some of the results of recent work by himself and Mr. W. B. Alexander on the Abrolhos Islands. These are situated in lat. 28° 40′ S., about fifty miles off the west coast of Australia, and near the edge of the continental shelf. The depth of water between the islands and the mainland averages about 25 fathoms, while a few miles west the depth is some hundreds of fathoms. The islands are composed entirely of coral, all the rock above sea-level (the highest point in any of the islands is 50 ft.) being uplifted coral rock or sand. There are distinct traces of a very recent uplift of about 8 ft., but at an earlier date—quite recent geologically—a much greater uplift put the islands in connection with the mainland. As a consequence of this former land connection certain of the islands are now inhabited by large numbers of wallabies, several species of amphibia, and many species of reptiles. There is thus a combination of the features of coral islands and the continental terrestrial fauna. There is evidence that a warm tropical current flows southwards and reaches the Abrolhos, and possibly accounts for certain tropical characters of the fauna of the islands. The neighbouring mainland is bathed by cooler waters, probably of southern origin. Prof. Dakin recorded from the islands a considerable number of interesting animals, including a new species of Ptychodera allied to *P. flava.*

The Development of Trypanosomes in the Invertebrate Host.

Prof. E. A. Minchin showed that if an analysis and comparison be made of those instances in which it can be claimed that the development of a given species of trypanosome in its invertebrate host is known, it is seen that in every such instance there is a part of the developmental cycle which is constant in occurrence and uniform in character, and another part which is of inconstant occurrence and variable in character.

In the constant part of the cycle the parasite always assumes the crithidial type of structure and multiplies incessantly in this form to produce a lasting stock of the parasite, certain individuals of which change sporadically from the crithidial into the trypaniform type and so become the final, propagative form of the development, destined to pass back into the vertebrate host and establish the infection in it. During hunger-periods the crithidial forms may pass temporarily, in some cases (*e.g.* the trypanosome of the skate in the leech Pontobdella), into the resting, non-flagellated leishmanial form, until food is again abundant, when they form a new flagellum and revert to the crithidial type of structure.

The inconstant part of the cycle, when it occurs, is intercalated at the very beginning of the development in the invertebrate, and lasts but a relatively short time; it is derived directly from the trypanosomes taken up by the invertebrate from the vertebrate host, and takes the form of an active multiplication of the parasites in either the trypaniform (*e.g. Trypanosoma gambiense* in the tsetse-fly) or leishmanial (*e.g. T. cruzi* in the bug Conorhinus) condition. In the cases where this early multiplicative phase is wanting altogether, the trypanosomes taken up by the invertebrate host pass at once into the crithidial phase (*e.g. T. vivax* in tsetse-fly).

When a further comparison is made between the development of trypanosomes in the invertebrate host and the development of the closely allied species of

Crithidia (*e.g. C. melophagia* in the sheep-ked) and Leptomonas, which have no alternation of hosts or generations, but are confined during their entire life-history to particular species of invertebrate hosts, it is seen at once that the life-cycles of these parasites of invertebrates are similar in all essential points to the crithidial phases of trypanosomes in their invertebrate hosts. It is evident, therefore, that the crithidial phase in the development of a trypanosome is to be interpreted as a reversion to, or recapitulation of, the type of development that occurred in the ancestral form which was originally a parasite of the invertebrate alone, before it had obtained a footing in the vertebrate host or had acquired the trypanosome-like type of structure; while the multiplicative phases of variable character preceding the crithidial phase in trypanosome-development are to be regarded as having been intercalated secondarily into the life-cycle and of no phylogenetic significance.

Australian Haematozoa.

Dr. J. Burton Cleland remarked that, owing to the geographical isolation of Australia, the study of the blood-parasites of the vertebrates, especially of such as have no easy means of passing over stretches of ocean, is of considerable interest. In some cases, *e.g.* the marsupials, speculation arises as to whether the hæmogregarines found in them reached Australia (1) with the marsupials when these originally came; (2) as parasites of the invertebrate host by a separate arrival; or (3) whether their appearance represented the adaptation in Australia of a parasite, at one time confined to an invertebrate host, to a habitat partly in a vertebrate and partly in an invertebrate host. Dr. Cleland considered the first of these suggestions to be the most reasonable. He directed attention to the records of the principal protozoon parasites of the blood of Australian vertebrates. Plasmodium seems to be rare in birds, while Halteridium is common. Trypanosomes have been found in several species of birds, and often in the same infected birds are large parasites, apparently the intracorpuscular form of the trypanosome.

Australian Trematodes and Cestodes.

Dr. S. J. Johnston passed in review the principal Australian Trematodes and Cestodes, and stated that the entozoan fauna of the host-animals belonging to any particular class of vertebrate might be separated into two divisions: (1) those which have been parasitic in these hosts for a very long time, practically from the first appearance of the host-animals; and (2) those which represent more recent acquirements. The members of the former division may be readily recognised by the fact that they have near relatives parasitic in other branches of the same stock, while members of the latter division generally have not. The members of each genus (or sometimes of several closely related genera) in the former division, in many cases scattered all over the world, constitute a natural group, and must be regarded as derived from common ancestors. These ancestors were parasites of the progenitors of the host-animals in the very early days when the group was much more restricted in its distribution than it is at the present time. A study of the relationships and distribution of the parasites affords some circumstantial evidence of the past movements and paths of dispersal of the host-animals. Dr. Johnston instanced the entozoan fauna of marsupials in Australia, which comprises a number of Cestodes (*e.g.* Linstowia) and Trematodes (*e.g.* Harmostomum), the nearest relatives of which are found in species of the same genera which live parasitic in South American marsupials.

Parasitic Worms of Queensland.

Dr. Wm. Nicoll stated that the hook-worms, Ankylostoma and Necator, are the most common human parasites in Queensland, but these worms are not more common there than in temperate regions. Hydatids are much rarer in Queensland than in other parts of Australia. Dr. Nicoll gave a brief general account of the more important parasites observed in animals in Queensland, and referred in particular to *Onchocerca gibsoni*, the round-worm which causes nodular disease in cattle. The life-history of this worm still remains unknown, but a considerable amount of experimental work has been carried out thereon. It has been suggested that infection is either direct (taking place in young animals) or by the agency of some biting insect. Dr. Breinl's experiments indicate the possibility of infection by means of water, for he was able to induce larvæ of Onchocerca to pass out through the unbroken skin, and to emerge into water where, however, they lived only a short time. Attempts to infect various aquatic animals with the larvæ were unsuccessful. Larvæ ingested by the stable-fly (Stomoxys) were able to live therein for several days, but Dr. Cleland could not detect any development in these larvæ. Dr. Nicoll applied sterile water on a calico pad, or in a glass vessel, to the skin of a cow over an Onchocerca nodule, but did not obtain larvæ. Experiments on excised nodules placed in water showed that the larvæ can, and do, make their escape through the capsule enveloping the worm-nodule, and therefore may be found close to the surface of the body in such positions that they can be readily ingested by a biting insect.

Studies on Echinoderm Larvae.

Dr. T. Mortensen gave an account of his recent work at Misaki (Japan), undertaken with the object of studying the inter-relationships between larval and adult forms of Echinoderms, and of testing the view that within the different families the larvæ have certain structural features in common, for if this prove to be a general rule larval characters may be of considerable importance in helping to settle doubtful cases in Echinoderm classification. Dr. Mortensen reared more or less completely sixteen species. Among these were three Temnopleurids, the larvæ of which have been hitherto unknown. This family has a special form of larva characterised by peculiarities of its skeleton. Four species of Clypeastroids—*Clypeaster japonicus*, Mellita sp., *Laganum fudsiyama*, and *L. decagonale*—were reared; their larvæ all proved to be of the type characteristic of other Clypeastroids. *L. fudsiyama* is a deep-water species (200–1000 mètres), and this is the first time that the larva of a deep-water Echinoderm has been reared. The larva is pelagic and of typical Clypeastroid structure. *L. decagonale* has large eggs, rich in yolk, and in correlation with this the development is shortened, the whole metamorphosis being completed in three to four days. The larva takes no food, the mouth being rudimentary; there is no ciliated band, but a strong general ciliation. The larval skeleton is rudimentary, but of the usual Clypeastroid form; only four larval processes at most are developed, but generally only two, sometimes one, three, or none. *Asterina pectinifera* was found to have a pelagic larva, while the two other species, the development of which is known, take care of the brood and have non-pelagic larvæ. The larva of this species has a Brachiolaria stage, thus proving the correctness of the view that the larval appendages in the young *A. gibbosa* are homologous with the brachiolarian processes of free-swimming larvæ.

Sheep-maggot Flies.

Mr. W. W. Froggatt exhibited specimens of four species of Diptera, the larvæ of which have been found on sheep in New South Wales. The common blow-fly (*Calliphora villosa*) is a serious pest to wool-growers, as it "blows" the soiled wool on the backs of living sheep, and the resulting maggots feed upon the wool-substances, and when full grown fall out and pupate on the ground. This fly will also "blow" meat or any kind of animal matter. Two other species of Calliphora (*oceaniae* and *rufifacies*) also attack sheep and all kinds of animal matter. The fourth fly—*Lucilia sericata*, the green-bottle fly—is the common sheep-maggot fly in Britain, but although found at times breeding in living wool in Australia, is not common in living wool, but is found about Sydney commonly living on all kinds of animal and vegetable matter, and congregating on plants and shrubs. Although it will "blow" meat placed outside, it seldom enters houses as do the common blow-flies. *C. rufifacies* had not been recognised as a sheep-fly as late as 1910, and had not up to that date been bred from the maggots found in soiled wool, though in the west of New South Wales the fly was plentiful about killing yards, freshly skinned sheep, and dead animals. This fly seems to have recently adopted the habit of "blowing" the wool owing to the presence of soiled and "smelly" wool, and in the north and west of the state this is now the common sheep-maggot fly, while the two other species do comparatively little damage in those areas. Mr. Froggatt also exhibited a Chalcid (*Nasonia brevicornis*) which was found to infest the larvæ and pupæ of *C. rufifacies*, and remarked that the discovery of this parasite was important and might possibly lead to new methods of control of the sheep-maggot flies.

The Emergence of the Nymph of ANAX PAPUENSIS.

Mr. R. J. Tillyard described the emergence of the nymph of this insect (order Odonata). During the three days previous to hatching, the beats of the dorsal vessel increase in number from about 30 to nearly 100 per minute, and just before hatching a cephalic heart appears in the posterior head region which drives blood forward into the head. The pressure thus caused forces off the cap of the egg and the nymph emerges quickly, swathed in an outer sheath (the "amniotic covering," Balfour Browne), which is found to be a non-cellular chitinous cuticle, not related in any way to the amnion, but representing the first moult of the larva. The swathed stage, which may be termed the pro-nymph, lasts only a few seconds. The cephalic heart increases enormously and consists of two large chambers which pulsate regularly and drive blood into the head. The latter quickly swells to twice its original size, and thus the pro-nymphal sheath is split dorsally and the young nymph emerges, freeing itself from the sheath by a few convulsive struggles. The cephalic heart quickly subsides in the free nymph. Meanwhile a rectal pulsating organ pumps water into the rectum, the branchial basket there being thus distended, and the whole tracheal system of the nymph becomes gradually filled with air. It is suggested that the rupture and atrophy of the amnion, described by Brandt in the embryology of Odonata, is due to the formation of the pro-nymphal sheath, which forms a close-fitting and far more efficient protection to the embryo.

Scent-distributing Apparatus in Lepidoptera.

Dr. F. A. Dixey pointed out that certain specialised scales found in various situations on the wings, bodies, and limbs of Lepidoptera are well known to be concerned in the distribution of a scent, which is in many cases characteristic of the species. These scales may occur in both sexes, but certain forms of them, *e.g.* the plume-scales of Pierines and Nymphalines, have been found only in males. The Pierine plume-scale often affords a ready means of identifying the species, and is frequently of service in throwing light on questions of affinity.

In some cases a special adaptation exists with the object of economising the scent until it is required for purposes of sexual recognition or attraction; for instance, the costal folds of the fore wing in many Hesperids, and the collection (seen in many Pierines and in some Satyrines and Nymphalines) of the scent-distributing scales into a patch, situated on that portion of the fore or hind wing which is covered in the position of rest.

Mimicry.

Prof. Poulton, after remarking that Australia is the most isolated of all the inhabited continental tracts, considered how far this is reflected in the insect-models and their mimics, and stated that although the subject had hitherto been little studied in Australian material, there were already conclusions of much interest.

Perhaps the most widely spread models in the world are the black, yellow-banded, stinging Hymenoptera. The central members of these powerful combinations are wasps (Diploptera), around which are ranged sand-wasps (Fossores), and, in far smaller numbers, bees (Anthophila), followed by mimetic species of the phytophagous Hymenoptera, and of other orders—Diptera, Coleoptera, Lepidoptera, etc. Throughout this dominant combination of models and mimics the sub-cylindrical body is black, encircled by many bright yellow bands; although widespread over the world, it is especially powerful in the north temperate zone. In Australia, however, its place is taken by a combination with a distinct pattern; the bands are deep-brownish orange (instead of yellow), and are few and broad (instead of many and narrow). This pattern runs through a large and complex set of models and mimics. Prof. Poulton remarked that it was very convincing to compare such a mimetic Asilid fly as the European *Asilus crabroniformis* with the Australian species, and to observe how their very different patterns resemble those of the respective Aculeate models, and that an equally significant comparison may be drawn between the mimetic Longicorn beetles of these two parts of the world.

A question as to whether insects in different geographical areas resembled each other in colour and pattern was answered by Dr. Dixey, who stated that such cases did occur, but were very exceptional, and should, in his opinion, be regarded as mere coincidences. There were no such coincidences known where complex patterns were involved, but when a simple pattern is concerned it may occur more commonly in widely different parts of the world.

Experiments on Silkworms.

Prof. Otto Maas gave an account of his experiments on the feeding of silkworms on different foods, *e.g.* mulberry and Scorzonera. When both parents were fed on Scorzonera the capacity of fertilisation is much inferior to normal, the number of eggs deposited is much fewer, and of the eggs fertilised fewer hatch. In the case where only one parent is fed on Scorzonera the mating may be as fertile as a normal one. A cross between a Scorzonera-fed and a mulberry-fed strain seemed to be superior in strength to one fed only on mulberry.

Species of Victorian Lampreys.

Dr. J. A. Leach stated that examination of 46 lampreys in the National Museum and the University Museum, Melbourne, showed a remarkable amount of

variation in almost every character used by systematists to distinguish different species. In six specimens of *Geotria chilensis* taken alive at the same time, the length of the interspace between the two dorsal fins varied from 0·6 of the length of the dorsal fin to 1·3 times that length. Dr. Leach divides the 24 specimens of Geotria examined into three species, and the 22 specimens of Mordacia into two species. The remarkable, large pouch of *Geotria australis* is not a secondary sexual character, for it is present in females as well as in males; its use is not known.

Notes on Australian Frogs.

Mr. J. Booth commenced work on the Australian frogs in the hope of finding some method of identification without resort to the dissection necessary to examine the sternal apparatus and the sacral vertebræ, but found that description and measurement of the external features could not replace observations on the skeletal girdles, the characters of which are of paramount significance, while the external configuration is more related to the mode of life of the animals and largely corresponds with the classification into swimming, climbing, burrowing frogs. The frogs found in Australia belong almost entirely to the three families of the Arcifera—Cystignathidæ, Hylidæ, and Bufonidæ. To these must be added the family Ranidæ (of the Firmisternia) on account of the occurrence of *Rana papua* in New Guinea, and on account of the recent record of three species of the genus Austrochaperina. Mr. Booth remarked on certain varieties of interest and on the occurrence of abnormal examples, the significance of which was suggested.

Migration of Birds.

Prof. C. J. Patten referred to some features in the diurnal migration of pipits, wagtails, and swallows as observed at Tuskar Rock Light-station (Co. Wexford). In certain periods of spring and autumn a procession of migrants passes this station daily, but owing to the barren nature of the rock comparatively few birds alight. Most birds fly towards the land, even those presumably on emigration. Pipits and wagtails were estimated to travel at about 20 miles per hour, swallows and martins at about 90 miles per hour. On account of the very limited area of the rock, and the considerable altitude at which many of the birds fly, the descending flight for the purpose of alighting, when attempted, is almost perpendicular.

Photographs of Narwhal and Beluga.

Prof. H. F. E. Jungersen exhibited photographs taken at Umanak in Western Greenland by a Danish physician. The first series was of full-grown male narwhals, and showed clearly that the tusk pierces the skin of the left side of the snout above and outside the mouth-opening. Prof. Jungersen remarked that neither text-books nor original descriptions by authors who have examined the narwhal in the flesh give clear statements of the exact relation of the tusk. There is, however, one exception: J. Anderson (1746) states definitely that in a narwhal captured in the Elbe the tusk pierces the left upper lip. The photographs of the Beluga prove that the front end of the snout, under the rounded forehead, forms a short but distinct beak. Most descriptions deny the existence of a "beak," or do not mention it, but in some of the better figures (*e.g.* by Scoresby and Flower) a "beak" is clearly shown.

The Sizes of the Red Blood Cells of Some Vertebrates.

Dr. J. Burton Cleland summarised a series of systematic measurements of the red blood corpuscles of various Australian vertebrates, and stated that the figures seem to indicate that with specialisation has come eventually, both in fishes and birds, a diminution in size of the red cells. The relationships of the various classes of animals to each other is clearly shown in the size of the red cells; those of Elasmobranchs approximate more nearly in size to those of Batrachians and Reptiles than do the red cells of Teleostean fishes. The enormous red cells of the Dipnoi, those of Ceratodus being $39 \times 25\,\mu$, approach those of the Urodela (the red cells of Proteus are said to be $58 \times 35\,\mu$, and those of Amphiuma $77 \times 46\,\mu$). In the frogs and reptiles the size of the red cells has decreased, and in birds the "oldest" forms show distinctly a tendency to larger cells than the more specialised ones, the smallest red cells (10 to 12×5 to $7\,\mu$) being met with in some families of Passerine birds, while the largest ($16 \times 9\,\mu$) are found in the emu.

The Heredity of Some Emotional Traits.

Prof. C. B. Davenport observed that while sociologists, who place great stress on the importance of conditions in determining human traits, have been forced to admit the hereditary basis of feeblemindedness, they still hold, for the most part, to the view that in the moral field heredity plays little part. To test this view, inquiry was undertaken into the inheritance of traits of persons of the criminalistic type, the base of the study being the family history of 165 wayward girls in State institutions of the United States. About 20 traits were considered in some detail; many did not yield any clear-cut results, but in a least five the hereditary factor was clear, and evidently determined the behaviour. (1) The tendency to tantrums or violent outbursts of temper is inherited in adults as a dominent trait, *i.e.*, does not skip generations. In several instances it was possible to trace back the tendency three, four, and even five generations. (2) Violent eroticism was similarly traced back; half of the offspring of a highly erotic parent show similar impulses. (3) Impulsions to suicide are accompanied by depressions, and it appears that this depression is inherited as a recessive or negative character. It ordinarily skips generations, but the tendency is generally found on both sides of the parentage of the affected individual. (4, 5) Two other traits—dipsomania and nomadism—appear to be sex-linked characters transmitted through mothers to some or all of their sons. They appear in daughters typically only when shown by the father and when the tendency is also carried by the mother. If both parents show the trait, all the children have the tendency to develop the trait in due time.

The Hormone Theory of Heredity.

Dr. J. T. Cunningham held that Mendelism throws no direct light on the origin of characters; it deals merely with their transmission. It is inferred, however, by Mendelians that characters transmitted as units arose as units. From the evidence of Mendelian researches it is reasonable to conclude that non-adaptive specific and other diagnostic characters arose in the course of gametogenesis and conjugation, but the doctrine of Mendelism or mutation was, in Dr. Cunningham's opinion, not applicable to the phenomena of adaptation. He cited in support (1) Animals such as the frog, flat-fish, and caterpillar, which exhibit adaptation to two quite different sets of conditions in the individual life, and he held that it was impossible to believe that such transformation was due to mutations not caused by the external conditions, for there is no evidence that the necessary gradual changes could occur unless the conditions produced them. (2) The phenomena of secondary sexual characters, of which one of the most impressive and fully

investigated is that of the antlers of the stag. The Mendelians regard such characters merely as mutations which are coupled with primary sex; but primary sex is determined at fertilisation, and such secondary characters have been shown to be dependent on the presence and function of the gonads. Characters which are determined in the gametes are not generally affected by amputations of the gonads or any part of the body in after life. It has been shown that the effects of castration on the development of secondary sexual characters are due to the stimulus of chemical substances produced by the gonads, especially in their functional activity.

The hormone theory explains how somatic modifications may be transmitted to the gametes, the hypertrophied tissue giving off chemical substances or hormones which stimulate the determinants in the gametes. A special application of this principle is necessary in the case of the functional secondary sexual characters to explain how it is that their development is so closely dependent on the functional activity of the gonads. This special part of the theory assumes that the original modification was produced in the presence of the hormone from the sexual organs, and consequently the inherited modification cannot develop in the soma except in the presence of this hormone.

The following communications were also made to the section, but in the absence of the specimens and diagrams used in illustration they do not lend themselves to the purposes of a summary.—Prof. Poulton gave an account of Dr. Perkins's researches on the colour-groups of Hawaiian wasps, Prof. Jungersen described the anatomy of Pegasus, which he showed to be an Acanthopterygian, and to require at least a suborder of its own, for it is distinguished by several structural peculiarities from all known fishes; Mr. T. Steel exhibited beautifully preserved examples of several species of Peripatus and of Australian land planarians, and added observations on their special features and habits; and Mr. E. de Hamel gave a general account of the ringing of birds and some of the observed results.

J. H. ASHWORTH.

THE SUPPLY OF CHEMICALS TO BRITAIN AND HER DEPENDENCIES.[1]

AFTER showing that the foundations of theoretical chemistry were laid almost exclusively by the chemists of England, France, and Sweden, the speaker proceeded to discuss the position of industrial chemistry. The "Report on Chemical and Pharmaceutical Products and Processes" in the International Exhibition of 1862, from the pen of A. W. Hofmann, then professor of chemistry in the Royal College of Chemistry and Royal School of Mines, London, contains the following passage (p. 3):—"The contributions of the United Kingdom, and in particular the splendid chemical display in the Eastern Annexe, prove the British not only to have maintained their pre-eminence among the chemical manufacturers of the world, but to have outdone their own admitted superiority on the corresponding occasion of 1851."

Statistics in relation to the development of the alkali trade show how rapidly the production of what are called "heavy chemicals" was proceeding at this period. Figures derived from returns collected by Mr. Christian Allhusen from 81 per cent. of the manufacturers in the United Kingdom, immediately after the first Great Exhibition, are shown below. These may be compared with statistics prepared by Mr. W. Gossage for the year 1861 immediately before the exhibition of 1862[2]:—

	1852 Tons	1851 Tons
Soda ash	71,193 ...	156,000
Soda crystals	61,044 ...	104,000
Bicarbonate	5,762 ...	13,000
Bleaching powder ...	13,100 ...	20,000

The value of these products for 1852 was estimated at about $1\frac{1}{4}$ million pounds, while the value of the products of 1861 was calculated by Mr. Gossage at upwards of two millions sterling.

The Board of Trade has recently issued a bulletin concerning German competition in the United Kingdom market, and on p. 2 we find the statement that the soda compounds, excluding chromates and bleaching powder, produced in the United Kingdom in the year 1907, are valued at 3,390,000*l.* The imports from Germany in 1912 are valued at only 8700*l.* As to bleaching materials, the product of the United Kingdom for 1907 is estimated at 527,000*l.*, while the import from Germany for 1912 was 44,600*l.*

From these figures the easy deduction is made that "the imports of these chemicals into the United Kingdom from Germany are relatively insignificant when compared with the output of the same articles in this country. It is clear that in these particular lines British manufacturers have no need to fear German competition in the home market."

Similar remarks apply to aluminous compounds, coal-tar products not dyes, the cyanides, sulphuric acid, and other acids for which the bulletin may be consulted. It thus appears that the British manufacturers of sulphuric acid and soda, from the early times of a century ago, have been able, up to the present, to hold their own against foreign competition, and have thus added substantially to the revenues and well-being of their country.

Now leaving to the department of "heavy chemicals" all such things as agricultural and horticultural washes, coarse disinfectants, and artificial manures, the question arises, How do we in England stand in regard to the supply of drugs, dyes, photographic chemicals, agents for research, and perfumes at a time when many of these things are very urgently needed?

It may be safely asserted that the sources of supply of all these materials in the United Kingdom are seriously inadequate. And, further, we may point to the acknowledged fact that many of the dyes, nearly all the synthetic drugs, and photographic materials have been systematically imported from Germany.

The annual statement of the Board of Trade (p. 108) shows that in 1913 we imported from Germany:—

	£
Alizarin and anthracene dyes ...	271,119
Aniline and naphthalene dyes ...	1,382,478
Synthetic indigo	76,681
	£1,730,278

Under the head of "Drugs, unenumerated, including Medicinal Preparations" (p. 107), out of a total of imports from foreign countries and from British possessions amounting to 1,302,860*l.*, more than one-fourth, or to the value of 332,464*l.*, was in 1913 received from Germany. From this is to be deducted the inconsiderable amount of dyes and other chemicals from coal-tar, valued at 24,691*l.*, exported in 1913 to Germany (p. 300). According to the Final Report on the First Census of Production of the United Kingdom for 1907 (p. 547), this country made 139,000 cwt. of coal-tar dyes, valued at 373,000*l.*, of which practically the whole was consumed at home.

[1] Abstract of a paper read before the Royal Society of Arts on November 25 by Sir William A. Tilden, F.R.S.

[2] Gossage's "History of the Soda Manufacture."

As to fine chemicals for analysis and for research, there are no figures available, but it may safely be said that there has been no appreciable production of these things in this country.

If we are ever to be in a position to supply ourselves and our Dependencies with the dyes, the drugs, and the rest of the fine chemicals required in our work, it will only be achieved after a careful review of the circumstances which led to the removal of the industries from this the country in which many of them originated, together with a determination to take to heart the lessons of the past.

After a review of these circumstances in which it is shown that it has not been due to inactivity on the part of scientific chemists, but to the ignorance and neglect of British manufacturers down to quite recent times, the author considered what ought to be done and what it is possible to do in this country to remove reproach from British chemical industry, and to render the Empire independent of supplies from foreign sources.

We need many first-rate chemists, a few engineers, plenty of capital, and some good men of business. A combination of these elements in due proportion is certain of success, and the time, though so unhappy for the world, is favourable for this enterprise.

Inasmuch as the functions of each and the best way of combining them have already been settled in practice on the Continent, is to be hoped that the ancient precept about being taught by the enemy—*fas est et ab hoste doceri*—will not be forgotten. For there can be no doubt that the principle acted on in all German chemical factories, namely, the employment of the best available scientific skill and the constant appeal to scientific research, has been the secret of their success.

In conclusion, two remarks only require to be made. The establishment of what will be practically a new industry in this country will require consideration and assistance from the State, if it is to survive the period of fierce competition which will follow the conclusion of the war. Encouragement is already promised to the dye industry, in the form of definite financial aid to be given by Government. But remembering that the colour-maker is dependent on the production of many chemicals, which represent intermediate stages in the processes which lead from the raw materials to the finished product, and that the production of these chemicals is naturally associated with other chemical manufactures, it is to be hoped that the temporary protection will be extended beyond the immediate field of the colour-maker.

The other remark may raise a smile on the part of those business men who are moved only by commercial considerations. There will be a great temptation when the war is over to resume former business relations with the enemy. The German chemical manufacturers have a powerful organisation and many years of experience behind them. Let them keep any markets they can retain outside the British Empire, but every man who cares for his country will surely demand that business at home shall be limited to British goods.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

EDINBURGH.—The chair of medicine and clinical medicine in the University has become vacant through the retirement of Prof. John Wyllie. With the exception of the years 1866 to 1868, when he was house physician to the General Hospital in Birmingham, Prof. Wyllie has lived his professional life in Edinburgh, where he filled many important positions as a physician, and attained a high reputation in medical circles. In addition to contributions to medical journals, he is known as the author of a book on "The Disorders of Speech," published in 1894.

As in all other universities the war has seriously depleted the classes in Edinburgh. The diminution is observable in all the faculties, but is particularly noticeable in the later years of the medical curriculum, in the third year of engineering science, and in the law classes. A considerable number of the junior staff of lecturers are also with the colours. To encourage students to offer themselves for service the University authorities have granted important privileges, so that when the war is over the studies may be resumed without serious loss of time. The great majority of the men who are attending classes are being drilled several times a week, and are receiving military instruction. The Indian students are being trained as an ambulance corps.

LONDON.—A course of nine advanced lectures on certain aspects of British ecology will be given at University College, with the exception of lecture 5, which will be given at the Botany Building, Imperial College of Science, Prince Consort Road, South Kensington, S.W., at 5 p.m. on the following dates:—December 10, Dr. E. J. Salisbury, "Woodlands"; December 17, Dr. W. G. Smith, "Grasslands"; January 14, Dr. C. E. Moss, "Unsolved Problems relating to Calcareous Vegetation"; January 21, Miss M. C. Rayner, "Some Aspects of Heath Vegetation"; January 28, Prof. J. B. Farmer, "Alpines"; February 4, Dr. E. J. Salisbury, "Determining Factors in Aquatic Distribution"; February 12, Prof. R. H. Yapp, "Fen Vegetation"; February 18, Prof. G. S. West, "The Occurrence and Distribution of Fresh-water Algæ"; February 25, Mr. A. D. Cotton, "The Algal Vegetation of the Salt-marsh and Seashore." The lectures are addressed to students of the University and to others interested in the subject. Admission is free, without ticket.

SHEFFIELD.—Dr. W. MacAdam has been appointed to the post of demonstrator in public health, and Mr. T. Chetwood to the post of lecturer on hygiene in the training department.

MR. G. S. YUILL, of Yuills, Ltd., a graduate of Aberdeen University, has made a gift of 4000*l.* to the University, the interest upon this amount to be applied in furthering the study of chemistry.

IT is announced in *Science* that the United States General Education Board has granted 50,000*l.* to Goucher College, Baltimore, conditionally upon 150,000*l.* being raised by April 1, 1917. From the same source we learn that a fund of 12,000*l.* has been turned over to Amherst College by the alumni council. The disposal of the income from this sum is to be determined by the trustees and the council.

WE learn from *Science* that on November 19 the honorary degree of doctor of science was conferred by Brown University upon Prof. W. H. Bragg, of the University of Leeds, before the corporation and faculty of the University in special Convocation. Following the conferring of the degree Prof. Bragg delivered the last of four lectures on X-rays and crystals, which he has been giving as the first of the anniversary lectures to celebrate the one hundred and fiftieth anniversary of Brown University.

NOTICE is given by the Institution of Naval Architects that a scholarship, to be known as the "Institution of Naval Architects Scholarship in Naval Architecture," will be offered for competition among students of the institution in 1915. The scholarship, which is of the annual value of 100*l.*, and tenable for

three years, will be awarded in connection with the competitive examinations for scholarships, studentships, etc., to be held by the Board of Education in May, 1915, in naval architecture, pure mathematics, applied mechanics (materials and structures), and either applied mechanics (machines and hydraulics), or heat engines. Applications must reach the secretary of the Institution of Naval Architects on or before January 15.

AT the last meeting of the governors of the South-Eastern Agricultural College, Wye, the principal, Mr. M. J. R. Dunstan, reported that 110 students and thirteen members of the teaching staff, besides college servants, farm and garden employees, had joined the colours. The new college buildings have been completed at a cost of 12,500*l.*, towards which the Board of Agriculture has given 6000*l.*, whilst two grants, each of 500*l.*, have been made by a generous anonymous benefactor towards the completion of the research equipment, and these gifts have been met by equivalent grants from the Board of Agriculture. The probable financial position of the college, owing to the reduction in the number of students, was considered, and it was decided to bring the matter before the Government educational and agricultural departments before taking any definite steps to curtail the teaching or research work. A vacuum drying plant for experimenting on the drying of fruit and vegetables has been installed by means of a grant from the Board of Agriculture, and it is hoped that assistance may be forthcoming to continue the investigations into the economical feeding of dairy cows of which a third report has just been issued. Results which may prove to be of considerable practical value have been obtained from the hop-breeding experimental work.

THE report of the Commissioner of Education of the United States Bureau of Education for the year ended on June 30, 1913, has been received from Washington. It consists of two bulky volumes running to 931 and 700 pages respectively, and every department of American education is dealt with exhaustively. For the academic year with which the report deals, the bureau received reports from 596 universities, colleges, and technological schools in the United States. Ninety-four of these institutions are controlled by States or municipalities, and 502 are administered by private corporations. The number of collegiate and resident graduate students in these institutions of higher education was during the year 128,644 men and 73,587 women, as compared with 125,750 and 72,703 in the preceding year. These numbers show on analysis an increased attendance of 2·35 per cent. of college students in graduate and undergraduate courses, and a decrease of 11 per cent. in the number of preparatory students. The Commissioner points out in his introduction that in most instances high-school work can be done better and at less cost in the regular high schools than in the preparatory classes of colleges. The decrease in the number of students in the preparatory classes of colleges is due to some extent also to the more liberal practice of the colleges in accepting for admission work in subjects other than those heretofore required.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 3.—Sir William Crookes, president, in the chair.—M. de **Lange**: The thermophone—a new form of telephone.—Dr. G. S. **Walpole**: Hermann's phenomenon. At the boundary between two solutions of unequal specific conductivity a change of reaction is developed if a difference of potential be maintained between them. Alkali is liberated if the current passes from the better conducting solution to that not conducting so well; acid, if the current passes in the opposite direction. The amounts may be calculated from the potential gradients in the solutions on each side of the boundary, the time for which the difference of potential is maintained, the resistance constant of the vessel employed, the dissociation constant of water, and the known migration velocities of hydrogen and hydroxyl ions.

Zoological Society, November 24.—Prof. E. A. Minchin, vice-president, in the chair.—D. M. S. **Watson**: (1) Description of a new reptile from the Permian of the Cape Province, South Africa. Mr. Watson regards this as derived from a Cotylosaurian ancestor and as perhaps related to Aræoscelis and the modern lizards. A new genus is founded for the reception of the so-called *Proterosaurus huxleyi*. (2) The origin of the Chelonia. A number of reasons is given for supposing that they may be descended from some such form as *Eunotosaurus africanus*, Seeley. (3) The skulls of Bauria, Microgomphodon, and Sesamodon. The relation of the group with the Cynognathids is discussed, and a new skull of Lycosuchus, in which both the prevomers and vomer are present, is described.—F. A. **Potts**: Polychæta from the N.E. Pacific: the Chætopteridæ. With an account of the phenomenon of asexual reproduction in Phyllochætopterus and the description of two new species of Chætopteridæ from the Atlantic. The new species of Phyllochætopterus was found in branched tubes, each usually containing several individuals. The origin of these colonies each from a single individual is suggested by the frequent occurrence of worms in various stages of regeneration. An examination of these shows that autotomy first occurs in the middle region of the animal's body, and a complete animal is regenerated from each of the two parts. This phenomenon appears to be characteristic also of another new species of this genus from Plymouth, which lives in small colonies in branched tubes. Several points in the morphology of the Chætopteridæ are also discussed.—E. **Heron-Allen** and A. **Earland**: Evidence of purpose and intelligence on the part of Foraminifera.

EDINBURGH.

Royal Society, November 16.—Prof. F. O. Bower, vice-president, in the chair.—Dr. D. **Ellis**: Fossil micro-organisms from the Jurassic and Cretaceous rocks of Great Britain. The paper contained a study of fossil moulds from four localities—the Frodingham Ironstone of Lincolnshire, the Secondary rocks in the Island of Raasay (N.W. Scotland), the Dunliath ferruginous Limestone, and the Gault, near Folkestone. These supplied in order a fossil mould belonging to the Phycomycetæ, with abundant examples of hyphæ, sporangia, and spores; a fossil mould provisionally named Palæomyces α; a fossil Actinomyces; and three members of Bacteria, two Bacilli, and one Micrococcus. Evidence was given that these were genuine micro-organisms, and reasons were discussed why the organism in its lifetime had a chemiotactic affinity for iron.—J. M'Lean **Thompson**: The anatomy and affinity of *Deparia moorei*. The paper dealt with the anatomical features of the axis, leaf, and sorus. Comparison with *Deparia prolifera* showed an advanced type of leaf trace, the expansive lamina being possessed of a few pinnæ and a reticulate venation—suggesting an adaptation for life in moist shade. The sori were of normally marginal origin, but occasionally truly superficial sori appeared on the upper leaf surface in *D. moorei*. This in no way invalided the conclusion that it belonged to the series Marginales. The consensus of characters justified the rejection of

an alliance with Athyrium or Aspidium, but rather assigned the plant to a place in the Davallioid series of forms.—Dr. T. **Muir**: Properties of the determinant of an orthogonal substitution.

PARIS.

Academy of Sciences, November 23.—M. Ed. Perrier in the chair.—A. **Chauveau**: Physiological weakness and tuberculosis in armies in the field. The debility caused by exposure to the hardships of a campaign in no way favours the introduction of the tubercle bacillus into the body. But, once the body is attacked by the organism, the reduced power of resistance to the ravages of the bacillus caused by privation and insanitary conditions may have a marked effect on the rapidity of development of the disease.—E. L. **Bouvier**: The carcinological fauna of Maurice Island. A description of some specimens collected by M. Carié during the last four years.—Haton de la **Goupillière**: A property of arithmetical progressions.—M. **Gonnessiat**: Observation of the transit of Mercury across the sun, November 6–7, at the Algiers Observatory. The transit was observed under excellent atmospheric conditions. The times of the four contacts are given and compared with the calculated data.—Henri **Chrétien**: The transit of Mercury across the sun of November 7, 1914. Details of observations made at Nice.—Comas **Solá**: Photographic observations of a small planet, apparently new. The photographs were obtained on November 15 at the Fabra Observatory, Barcelona.—C. Le **Morvan**: Photographic positions of comet 1913*f* (Delavan) obtained with the photographic equatorial at the Paris Observatory. Positions are given for September 5 and 6, October 7, 8, and 9.—Charles **Rabut**: The La Balme bridge.—André **Kling** and H. **Copaux**: The preserved meat of the Paris camp. A reply to a recent criticism of M. Balland.—Marcel **Rostaing**: A type of military under-garment.

NEW SOUTH WALES.

Linnean Society, September 30.—Mr. W. S. Dun, president, in the chair.—Dr. C. **Hall**: The evolution of the Eucalypts in relation to the cotyledons and seedlings. In regard to the form of the embryo in the Eucalypts, the cotyledons in the *E. corymbosa* group closely resemble those of Angophora, and are entire and reniform. With reference to the cotyledon-leaves of Eucalyptus, these may be divided into two great classes, entire and emarginate; and each of these into groups, according to size and shape. A study of the cotyledons supports the view that the *E. corymbosa* group is the most primitive type, while the Stringybarks have cotyledons of similar form. In response to the xerophytic conditions of Australia, the Eucalpyts have reduced the size of their cotyledons—first, by a general reduction in size, while retaining the entire, reniform shape; secondly, by the introduction of emargination, which, at last, becomes so extreme that Y-shaped cotyledons come to prevail in many of the dry-country species. The first pairs of leaves tend rapidly to assume the typical form of the juvenile foliage of the species, except in the Corymbosas, where, for a few pairs, the peltate form is adopted. Seedlings of about 150 species are figured.—Dr. R. **Greig-Smith**: Note on the bacteriotoxic action of water. When *B. prodigiosus* is used as a test-bacterium, and seeded into filtered tap-water, it generally increases. In boiled water, the rate of multiplication is lessened. Under the same conditions, *B. typhi* always decreases, and, in boiled water, the diminution is increased to such an extent that from three to six cells, out of 1000 added, remain after twenty hours.—Dr. R. **Greig-Smith**: Note on the destruction of paraffin by *B. prodigiosus* and soil-organisms. When *B. prodigiosus* is grown in the presence of paraffin, it attacks the hydrocarbon. Losses varying from 5 per cent. to 14 per cent. were obtained. Mixed soil-organisms, under the same conditions, destroyed from 11 per cent. to 49 per cent.

CAPE TOWN.

Royal Society of South Africa, October 21.—Dr. L. Péringuey, president, in the chair.—J. B. **Pole-Evans**: Some new South African aloes. The paper describes six new aloes from the Transvaal.—Th. **Wassenaar**: Optical illusions.—E. J. **Goddard** and C. S. **Grobbelaar**: A new genus of fresh-water Oligochætes (of uncertain position).—J. S. v. d. **Lingen**: The space-lattice of liquid crystals. The theory of the identity of molecules which cause the different forms of crystals of the same substance was discussed briefly. Experiments on the magnetic nature of certain liquid crystals were then described. The principal axis of the molecules lies parallel to the lines of magnetic force when the molecules are not influenced by other forces. As regards the optical properties of liquid crystals, the pseudo-isotropic layers behave like uniaxial crystals cut perpendicular to the axis. Vorlaender's experiments on such layers in convergent light show the well-known rings and crosses of uniaxial crystals. He believes that the pseudo-isotropic layers have space-lattices. When Röntgen rays are passed through such layers no interference phenomenon is obtained, hence there is no space-lattice. This indicates that: (1) the molecule itself is a small crystal possessing magnetic axes; (2) a change in the structure of the molecule itself causes a change in the form of the crystals of the same substance.

THE ROYAL SOCIETY OF ARTS.

A History of the Royal Society of Arts. By Sir Henry Trueman Wood. Pp. xvii+558. (London: John Murray, 1913.) Price 15*s*. net.

TO many who have attended meetings and lectures at the Royal Society of Arts during the last quarter of a century, or have been connected with its management, it will seem exceedingly appropriate that this history of the society since its inception in 1754 should have been written by Sir Henry Trueman Wood, its secretary since 1879, who, during all these latter years has been so intimately associated with all its activities that the society can scarcely be thought of by anyone without his well-known, tall, and spare figure appearing simultaneously to the mental eye.

To a large number of the public, and perhaps also to not a few members of the society itself, much of the information contained in this book will be something of a revelation. Few can know the early history of the society and the large amount of work that it performed during the latter half of the eighteenth century, while but a small number of its present-day members can be aware of its remarkable membership in early times. This included, among numerous and distinguished members of the peerage, a perfect medley of famous personages in various walks of life. For instance, we find among them Edward Gibbon, the historian of "The Decline and Fall"; Thomas Chippendale, of furniture fame; Benjamin Franklin, the distinguished American natural philosopher and politician; David Garrick, the actor; Oliver Goldsmith, the poet; Dr. Johnson, of dictionary fame; William Hogarth, the painter; Robert Adam, one of the two brothers who were the eminent architects who built the existing somewhat quaint and old-fashioned building in which the society still has its offices and holds its meetings; Sir Joshua Reynolds, first president of the Royal Academy; William Pitt, afterwards Earl of Chatham; and the notorious John Wilkes, to mention only a very few of those who are best known.

The society included in its membership all sorts and conditions of men, and interested itself in an extraordinary variety and multiplicity of matters. There does not seem to be much connection between mangold-wurzels, which the society appears to have introduced, harpoons, motive power, steel and gem engraving, naval construction, leadless glazes, medicinal plants, chimney sweeping or fire escapes, to mention just a few subjects taken at random from the long list that has been dealt with by the society at various times. Evidently the society, like Francis Bacon before it, took all knowledge for its province.

Especially interesting is the account of the large part played by the Society of Arts in the foundation of the great exhibitions of 1851 and 1862, and through these, as the author states, "of that long series of international exhibitions which have had such far-reaching influence on the arts, as well as on industry and trade."

Of great interest, also, is the chapter devoted to the society's medals, many of which are well illustrated, and, having been designed by Flaxman, the two Wyons, and other celebrated artists, are in themselves objects of beauty.

Some of the facts brought out as to various inventions are somewhat astonishing, as, for instance, that, until invented by Sturgeon—to whom the society granted in 1825 both a medal and a premium—the electromagnet, which to-day is so enormously employed in telegraphy and telephony and in almost every description of electrical plant, was unknown. Without this instrument practically no modern electrical development could have taken place. This is probably the most important invention that the society ever directly encouraged, for, as stated in the work under review, it is disappointing that the names of Watt, Crompton, Arkwright, and others are missing among those rewarded by the society.

The author says: "The best reason that can be suggested is that all these men were in advance of their time. Like all great inventors, they had to wait for recognition until they had overborne the opposition of ignorance and of rival interests, and it was then too late for prizes or contributions." Further, the society in its early years excluded all patented inventions from those eligible for premiums, continuing this practice up to about 1844, when wiser counsels prevailed and the rule was abandoned.

Another electrical contrivance of value, namely, the Smee galvanic battery, received in 1840 the reward of a gold medal, while in 1841 Robert Murray received a silver medal and 10*l*. for his invention of the now universally used method of obtaining a conducting surface for electro-deposition by means of plumbago. As recorded by Sir Henry Wood, however, perhaps in early days the society effected less by means of its medals and premiums than it did by its success in the starting of new movements. Allusion has already been made to its influence on the great exhibitions, but, as is pointed out by the author, the society also played a great part in regard to reform of the Patents Acts; in connection with artistic copyright; in the starting of mechanics' institutes

throughout the country; in promoting technical education; in reference to national musical training; in regard to postal reforms; in the institution of public examinations for various purposes, and numerous other subjects of public interest.

In later years the "Cantor" and other lectures by eminent scientific men on all manner of subjects have more and more become one of the chief elements of the society's well-known usefulness.

This is made evident by the author, who also gives accounts of other of the society's manifold activities in various directions, which cannot here be mentioned for want of space.

It should be added that Lord Sanderson, G.C.B., chairman of the council of the society for the years 1911–1913, contributes an illuminating preface. A. A. CAMPBELL SWINTON.

HOUSEHOLD SCIENCE.

Physics of the Household. By Prof. C. J. Lynde. Pp. xi+313. (New York. The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 5s. 6d. net.

THE author of this book is professor of physics in the Macdonald College, an affiliated college of the McGill University, Montreal, where a school of household science is one of the branches of the institution, and it is for students of household science that the book is written. It presents the subject of physics in close relation to its domestic applications, and abounds in illustrations and examples of household appliances and processes. It should be of great use to science teachers, especially those who have to teach girls, in reminding them of the range of familiar things and topics of physical interest that lie in the home environment, and that often lie unheeded and unexplained.

The suitability of the book for students themselves is, perhaps, more open to discussion, and it is more than likely that it will come under the censure of teachers who are wedded to the conventional form of text-book. The chief ground of attack would no doubt be that so far as the general principles of physical science are concerned, the elucidation is cramped and obscured by the weight of illustrations of their practical application. To treat the subjects of mechanics, heat, electricity and magnetism, light and sound and their applications in three hundred pages has led to a certain breathlessness of style, and some topics are treated very vaguely.

The gaps in the knowledge of those in control of the household that are the most conspicuous and seem to call most loudly for repair, do not relate so much to the design and principles of construction of appliances, as to the conduct of operations. An increased apprehension of the application of the lever principle or of the construction and *modus operandi* of an electric bell is all to the good, but it is not to be compared with a real live knowledge of the laws of heat and the capability of thinking and acting within them in the great field of household operations to which they apply. It is extraordinary to see the woodenness with which a woman armed with the conventional "heat" of the school or college textbook will face simple problems of heating or cooling as they arise in the household. This defect is not to be repaired merely by a rational account of the principles on which heating appliances are constructed. To instil real activity of mind it is necessary to teach in terms of problems with a wide range of experimental exercises.

For the reasons indicated above, it is fair to say that the value of Prof. Lynde's book to students must depend very largely on the laboratory work that accompanies it, and on the constant raising of questions and corollaries by the teacher. This, however, is true of most textbooks, and it must not lead us to undervalue one that has so large an element of originality and is so likely to be useful. A. S.

HOG-SPEARS AND FISHING-RODS.

(1) *Modern Pig-Sticking.* By Major A. E. Wardrop. Pp. xii+304. (London: Macmillan and Co., Ltd., 1914.) Price 10s. net.

(2) *Fishing and Philandering.* By A. Mainwaring. Pp. 254. (London: Heath, Granton and Ouseley, Ltd., n.d.) Price 6s. net.

(1) WHAT fox-hunting is to England, pig-sticking is to India, with the difference that the latter has that spice of personal danger from attacks on the part of the quarry which, to the regret of many sportsmen, is entirely lacking in the former. Both, too, have nowadays this in common, namely, that in their headquarters they depend to a greater or less degree on protection for their quarry—a fact which may come as a surprise to those unacquainted with India at the present day, and the great diminution in the numbers of its big game which has taken place in many districts. The headquarters of pig-sticking are the "khadirs," or river-valleys, of the Ganges and Jumna in the respective districts of Meerut and Muttra; and to old Anglo-Indians who have ridden or shot in the khadir, Major Wardrop's gossipy book will come as a delightful reminiscence of bygone days. To the newcomer in India it will serve as an incentive to rival the deeds of his predecessors in one of the most noble and exciting of all field-sports.

How well qualified is the author (aided by contributions from other hog-hunters) for his task may be inferred from the statement that he has been present, to the best of his belief, at the death of between seven hundred and eight hundred boars. To stay-at-home people such numbers may savour somewhat of exaggeration, but any such misgivings may be dispelled by reference to the final chapter of the book, where he will learn that the average annual bag of the Muttra tent-club alone is 210 head.

Major Wardrop gives his readers a glimpse of early pig-sticking by recalling the almost forgotten fact that for the first quarter of last century the universal weapon was the long throwing spear, and that the modern short "jobbing" spear did not come into use until 1830. In the penultimate chapter he discusses the paraphernalia and technique of the sport. For the contents of the intermediate chapters the reader must be referred to the book itself, which he will probably not leave until he has read it from cover to cover.

(2) An equally delightful volume is the second on our list, although it has to be confessed that its contents include more "philandering" than "fishing"; but since it teems with anecdotes which can scarcely fail to raise a hearty laugh, its appearance in these troublous times should be very welcome. Like the first, this volume will prove of interest to Anglo-Indians, as it contains a chapter of mahsir-fishing, coupled with the author's experiences among what he is pleased to denominate Indian trout. As regards the remainder of the book, perhaps the most valuable chapter to the practical angler is that dealing with the use of shrimps as a bait, as practised in Ireland, a considerable portion of which originally appeared in the *Field*. Like most anglers who have tried their hands on fish of many kinds, Mr. Mainwaring unhesitatingly awards the palm, from the point of view of sport, to the lordly salmon, although he confesses to be no adherent to the "dry fly" mode of catching his fish. The general scope of the volume is well indicated by its title, and the author does not even touch upon the natural history side of the subject.

R. L.

MATHEMATICAL TEXT-BOOKS.

(1) *Elements of Algebra.* By G. St. L. Carson and Prof. D. E. Smith. Part i., pp. v+346. (London and Boston: Ginn and Co., 1914.) Price 3*s.*

(2) *John Napier and the Invention of Logarithms,* 1614. A lecture by Prof. E. W. Hobson. Pp. 48. (Cambridge University Press, 1914.) Price 1*s.* 6*d.* net.

(3) *An Elementary Treatise on the Calculus for Engineering Students.* With numerous examples and problems worked out. By J. Graham. Fourth Edition. Pp. xi+355. (London: E. and F. N. Spon, Ltd., 1914.) Price 5*s.* net.

(4) *Constructive Text-book of Practical Mathematics.* By H. W. Marsh. Vol. iv.: Technical Trigonometry. Pp. x+232. (New York: J. Wiley and Sons. Inc.; London: Chapman and Hall, Ltd., 1914.) Price 6*s.* 6*d.* net.

(5) *Arithmetische Selbstständigkeit der europäischen Kultur.* Ein Beitrag zur Kulturgeschichte von Prof. N. Bubnow. Aus dem Russischen übersetzt von Prof. J. Lezius. Pp. viii+285. (Berlin: R. Friedländer und Sohn 1914.) Price 10*s.*

(1) THE teaching of algebra is still in the experimental stage, and is likely so to remain for many years to come. There are extremists in each camp. There are those who feel that no real progress can be made until considerable manipulative skill has been acquired, and those who hold that the real educational value consists in the absorption of certain general ideas which are largely independent of algebraic drill. The authors of this volume claim to steer a middle course. How far they have succeeded in solving the puzzling problem with which educationists are faced to-day can only be decided by trial. Certainly there are many good features in their book, which is based on the formula rather than the problem. But until an actual trial is made of their methods, it is impossible to pronounce with any certainty on the merits of their scheme, for the ramifications, affecting as they do the whole scheme of education of the non-specialist, are particularly intricate. We shall look forward with interest to the second volume.

(2) In view of the tercentenary celebration of the publication of John Napier's "Mirifici Logarithmorum Canonis Descriptio," under the auspices of the Royal Society of Edinburgh, the issue of this small volume comes at an opportune moment. Most schoolboys have heard of logarithms and realise their practical utility; but few of them are acquainted with their history, and fewer still with the form in which they originated. Dr. Hobson gives in a simple and very readable manner a comprehensive account of their discovery and evolution; an engraving of Napier and a reproduction in facsimile of a page of the Descriptio add to the attraction of a book that should find its way into every school library.

(3) The opening chapters of this text-book contain in outline such parts of algebra, trigono-

metry, and co-ordinate geometry as are requisite for a study of the calculus. Differentiation and integration are taken separately, on ordinary lines. Applications are then made to Fourier series, moments of inertia, pressure, electricity, etc., and the concluding chapters deal mainly with differential equations and their use in physics. There is not any particular note of originality, but the treatment is good, and should enable engineering students to acquire a satisfactory acquaintance with infinitesimal methods.

(4) The aim of this text-book is to bring the subject of trigonometry into as intimate a relation as possible with those problems of modern life which are most likely to interest the ordinary student. The author believes that too much importance is attached to surveying and ship-problems and too little to technical industries. Consequently many of the questions, and a number of excellent diagrams, deal with different forms of machinery and scientific instruments.

(5) This is a German translation of a Russian treatise. It is intended to form one of a series of investigations into the early development of mathematics in Europe. The present volume deals mainly with the evolution, structure, and use of the abacus. The author has made a careful study of the writings of Gerbert, and has attempted to remove some of the many obscurities they contain. Two other volumes are promised, one dealing with the history and origin of our figures, and the other with the history of Euclidean geometry in Latin civilisation.

BY-WAYS OF MEDICINE.

(1) *The Ileo-Caecal Valve.* By Dr. A. H. Rutherford. Pp. vi+63. (London: H. K. Lewis, 1914.) Price 6*s.* net.

(2) *I.K. Therapy: with Special Reference to* Tuberculosis. By Dr. W. E. M. Armstrong. Pp. x+83. (London: H. K. Lewis, 1914.) Price 5*s.* net.

(3) *Clinical Examination of the Blood and its Technique: a Manual for Students and Practitioners.* By Prof. A. Pappenheim. Translated and adapted from the German by R. Donaldson. Pp. viii+87. (Bristol: J. Wright and Sons, Ltd., 1914.) Price 3*s.* 6*d.* net.

(1) THE contents of this book constituted a thesis for the M.D. degree submitted to the University of Edinburgh. The term ileo-cæcal valve is applied to the orifice between the small and large intestines and the anatomical structures immediately adjacent and intimately concerned with this orifice. The author shows that divergent views have been expressed regarding the form and structure of this valve, divergences due partly to the method of preparation of the specimens and partly to variations in the valve itself. From an examination of a living subject, and from a series of thirty-two specimens removed soon after death and suitably treated, the author believes that he is able to describe the normal appearance of the valve, the function of which is to regulate the flow of semi-fluid bowel contents through the orifice and to prevent regurgitation. The book is illustrated with coloured diagrams and a number of excellent half-tone plates.

(2) "I.K." therapy has been evolved as the result of many years' labour by Carl Spengler, of Davos. It is chiefly directed against tuberculosis, but is being extended to other bacterial infections. The exact details of the preparation of the remedy have not been published, but the principle employed is the immunisation of a rabbit by means of intra-muscular injections of tubercle virus. The animal is then bled and the *whole* blood (not the serum only) is taken, laked, and high dilutions are prepared, it may be up to one hundred million. Spengler maintains that the red-corpuscles are carriers of the immune substances to a degree far exceeding that of the serum. These immune bodies ("Immunkörper," hence the title "I.K.") are the active therapeutic constituents. They possess partly lytic or solvent action on the tubercle bacillus and partly antitoxic or antidotal action against the tuberculous toxins.

The author describes in detail the above considerations and discusses the treatment of tuberculosis with I.K. serum. As regards the results obtained with it, the statistics are few and incomplete, though those who have employed it claim that cure of pulmonary consumption may be anticipated in all but the most advanced cases. Unfortunately, in estimating the gravity of a case of pulmonary consumption, it is impossible to allow for the extraordinary spontaneous improvement and recovery which sometimes occur in these patients, and more or less selection, in some instances unconscious, is practised by the physician, so that we believe that the only true test of *any* form of treatment lies in treating alternate cases only of a long series—a mode of trial which has yet to be applied to tuberculin and all other forms of treatment.

Dr. Armstrong has given a very useful summary for those who may desire to apply I.K. treatment, and has also included details of some beautiful staining methods for the tubercle bacillus and of the precipitin reaction for the diagnosis of tuberculosis which have likewise been devised by Dr. Carl Spengler.

(3) This little book, while forming a useful guide to the clinical examination of the blood, contains little that cannot be found in several well-known manuals on this subject. The only novelty, in fact, which we notice in it is the particular technique employed by Prof. Pappenheim. In some respects, indeed, it is lacking. Thus we find no mention of a common method of enumerating the leucocytes by an examination of microscopic fields in the preparation employed for a red-cell count, and there is no connected account of the blood-picture of pernicious anæmia and of the leukæmias. The nomenclature of the blood-cells and their variations is also unusual and difficult to follow by those accustomed to British nomenclature. In some respects the book is interesting reading, *e.g.* Prof. Pappenheim's views on the derivation of the leucocytic cells. The book contains two beautiful coloured plates of the blood-cells and numerous figures in the text.

R. T. HEWLETT.

OUR BOOKSHELF.

The Annual of the British School at Athens. No. xix. Session 1912–1913. Pp. viii + 314. (London: Macmillan and Co., Ltd., 1914.) Price 25*s*. net.

THE most valuable contribution to this issue of the annual is the report by Messrs. R. M. Dawkins and M. L. W. Laistner on the famous Kamares Cave in Crete. This has been known for more than twenty years as a prehistoric sanctuary, but its complete investigation was carried out only in 1913 under the auspices of the British School at Athens. The early fame of the cave was due to the discovery in the early 'nineties of a number of vases and a few figurines. The work has now been successfully accomplished under considerable difficulties. The general result is that the votive objects which form so striking a feature of other caves and mountain sanctuaries in Crete—the libation tables of Psychro, the shields and bronzes of the Idæan cave, and the figurines of Petsofá—are conspicuously absent. The question then arises whether the Kamares Cave was really a sanctuary or only a shelter. The writers conclude that its position renders its use as a shelter improbable; the finds themselves, if they do not positively suggest a sanctuary, equally negative the idea of a dwelling, because houses of the Bronze Age in Crete invariably yield obsidian, while not a single flake was found in this cave. The pottery, again, does not suggest domestic uses. On the other hand, the restricted range of the pottery shapes suggests a sanctuary in which votive vessels were deposited. The cave, in short, was probably a sanctuary of the tutelary divinity of the mountain.

Another side of the subject is illustrated by a report in the same issue of the Journal by Dr. J. Hazzidakis, of an early Minoan sacred cave at Arkalokhori. Here some interesting vases were unearthed with remarkable bronze swords or daggers. Double axes, undoubtedly symbols of the deity worshipped by the Cretans in the prehistoric period, lead to the conclusion that during the whole of the long period of the Bronze Age, the Minoan periods of Sir A. Evans, the Cretans practised one and the same cult, and this is as much as to say that they were, all through, one and the same people.

The Fauna of British India, including Ceylon and Burma. Edited by Dr. A. E. Shipley, assisted by G. A. K. Marshall. Orthoptera (Acridiidæ). By W. F. Kirby. Pp. ix + 276. (London: Taylor and Francis, 1914.) Price 10*s*.

THE lamented death of Mr. W. F. Kirby left his memoir on the locusts of British India not quite completed. So far as completion was possible it has been effected by the kind offices of Mr. C. O. Waterhouse, who has compiled many of the diagnostic keys. The memoir, which is an admirable piece of systematic work, deals with no fewer than 329 species of Acridiidæ.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Wet Bulb Temperature and Climatology.

IT is rather disappointing to find, according to your report of the proceedings of the Section of Physiology of the British Association, the discussion upon climate had to be abandoned because no one was prepared to follow up Prof. Osborne's contribution to it. For the points raised by Prof. Osborne, according to what we gather from your short report (p. 322), are of great and vital interest. He emphasises the importance of the readings of the wet-bulb thermometer as indications of what one might call the evaporative quality of the atmosphere as it affects the economy of the human body. Unfortunately the wet-bulb thermometer is untrustworthy for several reasons, and it is well known that physicists treat it with scant respect. Its indications depend in an uncertain way on the physical condition of the air surrounding it, and no one has been able to give a satisfactory method of deducing from its readings the value of the vapour pressure of the atmosphere. Recent experiments of ours with the Kata thermometer prove beyond question that the rate of evaporation from the skin depends directly on the defect of the actual vapour pressure in the surrounding air from the vapour pressure in contact with the skin, and the value of the air vapour pressure can be determined very easily by means of a couple of readings of the dry and wet Kata thermometer.

In order to investigate fully the relation between the climatological condition obtaining in different parts of the United Kingdom and the cooling and evaporative power of the air as measured by the Kata thermometer, we would welcome the help of

volunteers in town and country districts, who would take daily readings with the Kata thermometer, according to directions accompanying each instrument, which we would supply. The time for taking an observation need not be more than five or six minutes. Full details of the Kata thermometer, its construction and use appear in Dr. Hill's Report of Ventilation recently published by the Local Government Board. If any of your readers are interested enough in the matter to take these readings we should be glad if they would communicate with us.

Forests and Floods.

IN the issue of July 16 NATURE published a letter on the above subject in which I showed that pulverised soil holds more of the rainfall than the same soil after it is consolidated by time and rainfall, and it was pointed out that trees by the growth of their roots prevented the consolidation of the soil, and so enabled forest lands to retain more of the rainfall than undisturbed ground.

In that letter it was mentioned water passed more quickly through consolidated soil than through the same soil after it is pulverised. I have recently had an opportunity of observing how this peculiarity of dry soil acts in its disposal of the rainfall. In this district we had a very dry autumn; there was only 0·43 of an inch of rainfall in the 37 days extending from September 18 to October 24. The soil in the part of the garden to be referred to is of a light and sandy nature, and became very dry, though the plants seemed to get enough moisture for their requirements. The soil at the surface and to a depth of at least one foot seemed to be very dry. Before the end of the drought there were some cold nights, and the surface began to look more moist; this would probably be caused by the condensation of the rising vapour in the cold surface soil. When the rain began on October 25 the surface was thus in a good condition for absorbing it, and as the rainfall was never at any time heavy, and was well distributed over the eight days, during which 1·5 inches fell, none of it would run off the surface, as even during very rapid rainfalls the water easily enters that light soil. A day or two after the rain had ceased I was putting in some bulbs in the border, and was much surprised to find that below a depth of a little more than 3 inches of damp soil all underneath was as dry as it was before the rain began; while I find from tests made with soil lifted from the border, dried and broken up, that 1·5 inches of water wetted it to a depth of 6 inches. It was shown in the previous letter that pulverised soil holds a good deal more water than thoroughly wetted consolidated soil, so that the border was only moistened by the rainfall to one half the depth it would have been if all the rainfall had been retained by the upper layer of soil. The water evidently had not gone uniformly through the soil, but had made drainage tubes at certain places through which it had passed underground, leaving parts of the soil dry. This we might expect to happen if the soil was not easily wetted, or there were certain parts where the soil was more prepared to take water than at others. Such parts we might suppose to be those up which the water vapour rose most freely, and would therefore be damper, or the water may have escaped down the outsides of the roots of the plants. Now in well stirred soil there are none of these preferential routes for the escape of the water.

In illustration of these preferential routes one might point to the condition of the soil on vertical cuttings which one sometimes sees where roads are cut through banks, or on any deep cutting made in soil. It will be noticed that these cuttings have no vegetation on them, and that the soil gradually weathers away, leaving an overhanging turf. It will be noticed that the soil on the face of the bank under the turf remains dry, all the summer at least, however heavy the rainfall. The water evidently does not percolate straight to the soil underneath, but takes a preferential route, backwards from the turf, and downwards behind the dry soil. The dry soil seems to reject the water, which prefers to pass through the damp soil behind it. It was noticed at the end of November this year that these banks were still dry though 6·4 inches of rain had fallen since October 25.

Some soils seem to have very little affinity for water, and act very much in the same manner as most substances do towards mercury. For instance, when one watches the seashore on a calm sunny day while the tide is rising one often sees all kinds of dry particles which are much heavier than water floating on the surface; these particles may be sand or other earthy matter. Again, when walking over bare sandy soil one sometimes sees a curious illustration of this objection of dry sand to being wetted. If the weather has previously been very drying and there comes a shower of rain, some of the little hollows in the sand will get full of water, and retaining it as well as if they were made of puddle clay. Of course these cups are very shallow, otherwise the hydrostatic pressure would be sufficient to break the water film between the grains of sand.

However, repulsion of the water by ordinary soils does not seem to explain the passage of the rainfall through the soil without wetting it equally. A small clod of soil from the border referred to was dried, after which it was placed in a shallow vessel in which was less than 1 mm. of water. The clod quickly absorbed the water, raising it to its top surface, which was fully 1 cm. above the level of the water.

It is difficult to explain this preference of the water for certain parts of the soil, where the soil wets so easily on contact with it. Is it possible that the water by sinking a little deeper at certain places comes to exert a kind of negative hydrostatic pressure, and so draw the water from the surrounding area? This, if once started, would have a gradually increasing influence owing to the increasing "head."

The border referred to was opened up at a number of places on November 23, after nearly 4 inches of rain had fallen, and even then there were parts of the soil quite dry a few inches below the surface. It is evident that something is still required to explain these preferential routes of the water in dry consolidated soil. There are none of them in pulverised soil, and this points to the probable advantage in "dry farming" of stirring the soil to a sufficient depth to retain the whole of the rainfall, in addition to the usual practice of stirring the surface soil after rainfall to form a mulch to check its loss by evaporation.

JOHN AITKEN.

Ardenlea, Falkirk, December 5.

On an Apparently Distinctive Character of the Genus Bufo.

ON p. 38 of Mr. G. A. Boulenger's valuable work on the "Tailless Batrachia of Europe" it is stated of the vertebral column of the Anura that "In those forms in which the vertebræ are procœlous the eighth

is biconcave; the ninth being invariably biconvex." The same statement appears in the "Amphibia and Reptile" volume of the Cambridge Natural History, published some four years later (1901).

So far as I am aware, exception has never been taken to this statement. When, therefore, last year, I had occasion to examine the vertebral column of an Indian toad, *Bufo melanostictus*, I was surprised to find that the eighth and ninth vertebræ were not as described, but that, on the contrary, both were procœlous, resembling in this the seven preceding vertebræ.

At first I supposed that this was merely an abnormality resembling the condition found by Lloyd Morgan in *Rana temporaria* in 1886, and recorded by him in these columns (vol. xxxv., p. 53). I examined, however, five other specimens of *B. melanostictus* and also two of *B. andersonii*, and discovered that, in every case, all the vertebræ were procœlous, exactly as in my first specimen.

I could only come to the conclusion that, in these two species at least, we had exceptions to the rule laid down in the works quoted. On my return to England, therefore, I took an early opportunity of consulting Mr. Boulenger upon this point, who very kindly permitted me to examine a large collection of skeletons of Bufo.

Including my own specimens, more than fifty vertebral columns were examined, these belonging to some forty different species of Bufo, and it then became apparent that what I had been disposed to regard as an exceptional state of affairs, obtaining in a couple of Indian toads, *was actually an invariable condition, and, moreover, one apparently diagnostic of the genus Bufo*, for not a single specimen showed either an amphicœlous eighth or a biconvex ninth vertebra. In every case the centrum of the ninth vertebra, although hollow in front, has, of course, the usual double convexity behind.

London, W.C.

A Lunar Halo.

A REMARKABLE coloured halo forming a complete circle about the moon was witnessed by me on Wednesday evening, December 2, at 7.15, my position being in North Shields. I am seventy-nine years of age, and never saw anything similar—that is, encircling the moon. It only lasted about seven or eight minutes. I am wondering if anyone else took much notice of it.

An entire ring and colours were distinctly visible. The inner part—that is, to the commencement of the halo or rain-circle—had a remarkably globular appearance, with the moon as an apex, and was the most prominent part of the phenomenon.

The moon at the time was very bright, but shining through light fleecy clouds at a great height; then the yellowy appearance commenced as shown, terminating with a dark orange rim.

The altitude of the moon would be about 60°, direction S.E., wind W.

COLLOIDAL CHEMISTRY IN RELATION TO INDUSTRIES.

I.

WHEN the development of some branch of science reaches the stage at which a separate literature with its own terminology begins to grow up, the question of its practical utility or its value to the arts begins to be asked. Whether research has to justify itself by such directly or indirectly useful results is at least arguable, but it must be admitted that the question is particularly natural when raised in connection with a discipline like colloidal chemistry which is concerned, *inter alia*, with substances such as form the raw materials or the products of important arts, many of which, like ceramics, dyeing, tanning, the making of bread and of fermented liquors, are as old as history.

Where industries have empirically reached a high degree of perfection, the chief function of science is to provide the explanation of processes which are the outcome of experience, generally with the result that improvements become possible which experience alone cannot suggest. In judging a new branch of chemistry it is too often overlooked that even inorganic chemistry has largely played this part and has not yet quite succeeded in it in some respects: thus the theory of a process as important and familiar as the lead chamber process of making sulphuric acid is still highly controversial. On the other hand, organic chemistry provides many instances of the opposite way in which science may assist industry: by producing new bodies the properties of which are anticipated on theoretical grounds.

While, therefore, too much must not be expected of a science as young as colloidal chemistry, there is no doubt that it is destined to be of considerable value to a great number of industries in both the directions indicated above. Probably the most convenient method of showing this will be to state, without undue technicalities, a number of fundamental propositions which have now been firmly established and to illustrate their bearing on industrial processes and problems.

There is an immense amount of material to prove that the physical properties of a body may be varied continuously between wide limits by simply altering the size of its particles present or—as it is technically called, "dispersed"—in another medium, below a certain maximum limit. This is strikingly the case with the most obvious property, colour: thus, colloidal gold can be obtained red, purple, blue, or green in solutions containing the same amount of metal, and silver solutions of the same concentration may range from colourless through yellow, red, and purple to blue. Colourless or slightly coloured substances, *e.g.* sulphur, may form brilliant blue solutions. Solid colloidal solutions are also known to exist, examples of which are ruby glass, coloured by gold or copper, and the blue rock salt occurring at Stassfurt, which is coloured by metallic sodium.

The possibility of obtaining colour by dispersing a colourless substance in a colourless medium has been suggested as an explanation of the striking tint of a very puzzling class of bodies, the artificial ultramarines. Their chemical composition is very uncertain, but none of the compounds of which they are a mixture are at all likely to be

blue. Moreover, the ingredients used can, on one hand, be varied considerably without affecting the colour, and, on the other, batches of exactly the same composition may vary in colour from the desired blue to a greenish-white owing to variations in the process of fusion. The suggestion has been made, and supported by a good deal of evidence, that these variations may be due simply to differences in the "degree of dispersity," *i.e.*, in the size of the particles of one constituent disseminated through another. The same explanation has been tentatively put forward by Wo. Ostwald to account for the peculiarities of a very interesting group of dyes, the sulphide dyes—peculiarities which are not easily accounted for by their constitution alone.

It is, of course, well known that certain inorganic pigments, obtained by precipitation, vary in colour according to the concentrations and temperatures of the reacting solutions: thus, cadmium sulphide may be any shade from salmon pink to golden yellow. The reason is again to be found in the different size of the particles of precipitate which—up to certain limits—tends to increase with decreasing concentrations. There is a possibility of still further reducing this size with resulting changes in tint and incidentally with an increase in covering power, by adding to the solutions extremely small amounts of some organic colloids like glue or casein—a procedure which deserves extensive investigation by those interested.

Among the most important and most exhaustively investigated properties of colloids are their electrical characteristics. To describe these as briefly as possible, we may say that finely divided substances in contact with water and a few other liquids become electrically charged. In the majority of cases the charge is negative, but the oxides and hydroxides of a number of metals and a few dyestuffs are positive. The amount and eventually the sign of these charges can be modified by the addition of acid or alkali: thus, negatively charged particles become more so in alkaline media, while acid in increasing amounts diminishes and finally neutralises negative charges. Both these effects find technical application: thus, very fine precipitates or slimes which obstinately refuse to settle in neutral or alkaline liquids come down rapidly if the latter are made acid. The effect of acidity is to neutralise the negative charges on the particles, and their mutual electric repulsion, which helps largely to keep them in suspension. On the other hand, the addition of alkali to clay slip (the particles of which are also negative) has the opposite effect of suspending or "dispersing" the particles, so that the slip loses its plasticity and can be cast in moulds, a procedure which is employed on a large scale.

Owing to the charge on particles in contact with a liquid—which, as need scarcely be said, assumes the opposite charge—a relative movement of the two phases takes place in an electric field, that is, when electrodes connected to a source of current are immersed in the liquid. If the particles are freely suspended, they move towards the electrode having the opposite sign; if, as is sometimes the case, the solid is aggregated into a porous diaphragm, the liquid flows through the diaphragm towards the other pole. To take a concrete example: particles of carbon are negative and therefore travel towards the positive pole or anode; if they are formed into a fixed diaphragm, for instance, a plate of porous carbon, the water—which is positively charged—flows through this diaphragm to the negative pole or kathode. The movement of particles in the electric field is called cataphoresis; the flow of liquid through a diaphragm electro-osmosis. Both phenomena have been applied industrially by Count Schwerin. Thus, clays can be freed from iron oxide by being suspended in water in an electric field, since clay particles are negative while iron oxide is positive, so that the two substances travel to opposite electrodes. Spongy substances having a cellular structure, like peat, can be freed from water by being placed between a perforated plate acting as kathode while a second plate resting on the peat serves as anode. The solid being negative, the water is positive and flows to the kathode, escaping through the perforations in the latter. Both processes are capable of varied and extensive applications, many of which are being developed.

It is highly probable that electric factors play a considerable, although by no means clear, part in the various processes for separating sulphide ores from gangue with the aid of oil, particularly in the Minerals Separation process, which consists in adding to a slightly acid pulp made from the ore, part of which must be exceedingly fine, a minute quantity of oil and agitating in such a manner that a considerable quantity of air becomes mixed with the liquid. As soon as agitation ceases the air rises in the form of bubbles which carry the sulphide to the top, while the gangue sinks to the bottom. The necessity for acid reaction, in conjunction with known differences in the electrical properties of oil, quartz and air surfaces in contact with acid water, is strong evidence that the electrical properties of suspended particles play an essential part in the process, and its future investigation will have to take them into account to a much greater extent than has been the case up to the present.

Our knowledge of the effects of the two factors discussed so far—size and electric state of particles—has been gained through the study of colloidal solutions, chiefly of metals and sulphides, *i.e.*, of suspensions in which the diameter of the particles lies below the limit of microscopic visibility, roughly speaking, below 200 $\mu\mu$ (1 $\mu\mu$ = one-millionth millimetre). While the preparation of such solutions is of the greatest theoretical interest, and some are used therapeutically, they have found only a few technical applications worth mentioning.

E. HATSCHEK.

"FIELD-WORK" WITH THE BRITISH ASSOCIATION IN AUSTRALIA.

IN connection with the recent visit of the British Association to Australia, in addition to presidential addresses and evening discourses and the more formal sectional proceedings, all of which have now been fully recorded in NATURE, much good scientific work, especially in connection with the natural history sciences, was carried out by means of special meetings, expeditions, and discussions of a more or less informal character, kindly and wisely arranged by the local men of science for particular groups of the over-seas party. Moreover, on the visits paid to university laboratories, museums, and other institutions by many of the party, problems for investigation were pointed out, and plans for future research and co-operation were suggested, of value to hosts and guests alike; and it is not improbable that some of these informal conferences may have as great an effect upon the advancement of science in Australia as any of the more public meetings of the Association.

It is impossible to enumerate all the opportunities for useful work thus given to the visiting men of science, but a few of the leading occasions that were made by the Australian naturalists for bringing biologists and geologists into direct contact with the problems of wild nature may be here briefly indicated. Some of these informal expeditions and discussions, it may be added, led to the appointment of Australian research committees, to which grants were given by the British Association Committee of Recommendations meeting at Sydney on August 25.

The week or more spent by members of the "Advance Party" in Western Australia was almost wholly devoted to work in the field, both on land and water, and Prof. Dakin, one of the local secretaries and leader of the zoological excursions to the Yallingup Caves and Mundaring Weir and a dredging expedition on the Swan River, has already given some account of this field-work in NATURE for September 24. But in addition to these larger parties, groups of zoologists and others were taken on occasions to visit points of interest on the Darling Range and elsewhere, where Peripatus (*Peripatoides gilesii*, Spencer) and other rare and interesting organisms were to be found. Of scarcely less interest to zoologists and anthropologists were the discussions which resulted from visits to the collections at the Perth Museum under the direction of Mr. B. H. Woodward and Mr. Alexander, and to those at the University made by Prof. Dakin on his recent visit to the Abrolhos Archipelago (the subject of a communication to Section D at Sydney). Throughout the visit to Western Australia, although no formal sectional meetings were held, the conferences with local men of science at the University, the Museum, and in the field, dealt largely with questions of local research, and may confidently be expected to result in further investigations.

During the time of the Adelaide meeting a party of geologists and chemists visited the celebrated Broken Hill mines and the smelting works at Port Pirie for the purpose of studying the occurrence of the ores and the methods employed in working and smelting. Another party of geologists, led by Mr. W. Howchin, the discoverer of the local evidences of glaciation, at the same time visited the Sturt River to examine the Cambrian glacial beds, and also explored the Permo-Carboniferous glacial beds and the Archæocyathine lime-stones of Hallett's Cove, and finally the granitic rocks of the southern sea-coast in the neighbourhood of Victor Harbour. Several small bands of zoologists made observing and collecting trips from Adelaide to Lake Alexandrina, Victor Harbour on the coast, the Mount Lofty Range, and elsewhere, at all of which localities objects of interest were seen and material collected which may lead to research in the future.

One of the most interesting excursions from Adelaide was that arranged for the anthropologists, by Prof. Stirling, to Milang, on Lake Alexandrina, for the purpose of inspecting a number of men, women, and children from the Mission Station, including some full-blooded aborigines. These gave displays of dancing, boomerang-throwing, hut-building, and basket-making, and some of the British Association party collected information in regard to cat's-cradle games and native genealogies.

FIG. 1.—Black swan on nest in a river of S. Australia.

Interesting botanical excursions were arranged from Adelaide by Prof. T. G. B. Osborn, one to study the Salicornia scrub and the mangrove swamps of the coastal region, one to various localities on the Mount Lofty Range to see the fern gullies and the scrub of the higher regions, and a third to Mannum, on the Murray River—all of ecological interest.

At Melbourne the time and attention of over-seas members were naturally more fully taken up

with the formal programme of sectional meetings and addresses in the city, but during the week-end various opportunities were made for exploring the natural history of the neighbourhood. The geologists were taken to Macedon to examine the alkaline igneous rocks, and to Bacchus Marsh for the Permo-Carboniferous glacial tills lying upon striated surfaces of still older rocks. Other groups of geologists were taken to Ballarat and to Bendigo. Parties of zoologists and botanists under the guidance of Prof. Ewart and others, were taken through fine scenery to various points of interest, such as Marysville, Emerald, the National Park at Wilson's Promontory, Warburton and Cement Creek, to see the celebrated big-tree country and the tree-fern gullies. But here, again, it must be remarked that a large number of smaller trips were made by experts for special purposes under private guidance, resulting in consultations between the local scientific men and their European guests.

From Sydney there were excursions of very general scientific interest to the Blue Mountains, which afforded the geologists the opportunity of studying the leading features of the geological structure of New South Wales and of the remarkable elevation, which this, in common with many other parts of the continent, experienced in Tertiary or Post-Tertiary times. These excursions were also extended to the Jenolan Caves, which are typical, but very magnificent, examples of stalactitic caves in limestone of Silurian age. Amongst other interesting features were seen the remains of an aboriginal skeleton in one cave and of a wallaby's bones in another embedded in the stalagmitic floor. Other geological excursions to West Maitland and Newcastle gave an opportunity of examining the productive coal measures of the colony. The Blue Mountains and Jenolan expeditions were, however, of interest also to zoologists and botanists, who were enabled to study in their native haunts such rare and interesting forms as Peripatus and land Planarians, and to see many of the characteristic birds and insects of the country. Other excursions from Sydney were naturally rather of a marine biological character. Prof. Haswell and Dr. S. J. Johnston organised a collecting party, which visited various parts of Port Jackson in a steam launch in order to explore the wonderfully rich invertebrate fauna exposed at low tide. Another opportunity was given by Prof. Haswell to a small party of zoologists to collect choice material from one of the islands in the harbour.

In connection with the marine fauna the question of more fully exploring the Australian fisheries was under consideration at several centres, and it seems probable that a more thorough investigation of the coastal waters and their contained plankton by modern oceanographical methods will be undertaken at an early date. Another outcome of informal conversations was the resolution, brought before the Committee of Recommendations for adoption by the Council of the Association, welcoming the project to convert a portion of Kangaroo Island in Southern Australia into a Government reserve for the protection of the fast-disappearing native land fauna.

From Sydney a number of smaller informal excursions were arranged by Prof. Lawson for the purpose of studying the botany of the Port Jackson neighbourhood, including the National Park. Another important botanical excursion, under the guidance of Mr. J. H. Maiden, visited the Bulli Pass and the Burrinjuck Dam, passing through interesting country and a rich fern vegetation.

Queensland, like Western and South Australia, was felt to be a centre for work in the field rather than for sectional meetings and discussions. The expeditions from Brisbane included the gold and copper mines of Mount Morgan and the Gympie gold field, and, also for geologists, those to the Glass-house Mountains, a series of Trachytic volcanic necks rising abruptly from the plain (see Fig. 3), and to Ipswich to examine the Trias-Jura coal measures and associated volcanic rocks. Zoologists, along with botanists, were given interesting opportunities of seeing and collecting the characteristic plants and animals both from cultivated and wild country on the expeditions to Nambour, the Blackall Range and the Maroochy River, Cleveland, Bribie Island in Moreton Bay, and on the expedition to Dr. Jean White's Prickly Pear experimental station at Dulacca. The field-work organised in connection with the section of Agriculture has already been noticed, in NATURE for November 19.

FIG. 2.—British Association party on an expedition in southern Queensland.

A good deal of research, definitely planned in relation to the Australian meeting, and resulting

in some cases in papers or addresses before the sections, was carried on during the voyage out by some members of the "Advance Party." On the blue-funnel liner *Ascanius* Prof. G. W. Duffield made observations on the variation in the force of gravity over the floor of the ocean, and Prof. W. A. Herdman examined and preserved samples of the plankton from the surface waters running continuously through fine nets, day and night, between Liverpool and Fremantle. Both these researches were very materially promoted by the managers of the Blue Funnel Line, who most generously fitted up a special laboratory for each of these purposes, and gave great assistance on board and other facilities for carrying on the scientific work. Some other researches were also carried out on other routes, and on the return voyages. Preliminary accounts of these investigations were given at the Australian meetings, but

FIG. 3.—One of the "Glass-house" mountains of Queensland named by Capt. Cook in 1770, visited by the British Association in 1914.

further results, both from the work on board ship and from some of the field work in Australia, may confidently be expected in the future.

W. A. H.

THE HEALTH OF THE EXPEDITIONARY FORCE.

WE may well be thankful that the news from the Front continues to report favourably of the general health of our men. It need scarcely be said that the labour of housing and treating so many severely wounded is colossal; and we know, all of us, that the proportion of heavily infected wounds is unhappily and inevitably high. Indeed, the wonder is, that every wound is not heavily infected: for we may be sure that no clothes, no hands, no skin, can be clean in action: we must not talk of "clean wounds," where complete cleanliness is impossible: we must only say that some wounds healed well, in spite of the conditions under which they were made.

The urgency and the frequency of the heavily infected wounds have brought all men to recognise the abiding rightness of "Listerism." There was a popular notion that "antiseptics" had been abandoned for "aseptics"; that the surgeons merely sterilised their instruments, dressings, etc., by heat, and no longer needed to use carbolic acid and other antiseptic substances; and, for a great part of the work of surgery, this popular opinion had reason. The set and formal operations, done after due preparation under conditions chosen for the patient's safety and convenience, have come to be more aseptic than antiseptic in their method—so far as it can be excusable to put the two words against each other. But, even over these formal exercises of surgery, there is room for some individualism; and the entire disuse of antiseptic agents is neither possible nor to be desired. Now, across the fine-drawn details of surgical practice in peace, and all the nicely calculated less and more of the antiseptic method and the aseptic method at this or that quiet hospital, comes the overwhelming rush of legions of gunshot wounds, many of them frightfully extensive, many left for days without sufficient treatment, and all of them more or less heavily infected.

The surface of the soil, cultivated and manured to the very utmost of its capacities, is loaded with bacteria of all sorts. Among them, are those of gangrene and of lockjaw. It is a hard fact, that the earth which our men are defending is one of their enemies: dug-up for trenches, ploughed-up by artillery fire, churned-up into mud, it provides "infective material" alike for the just and the unjust. Against these evils, Army surgeons are employing the full strength of "Listerism." Iodine, that excellent antiseptic, used in French surgery long before Lister, is coming into its own again; and the use of carbolic acid and of spirit is general and resolute. Of course, regard must be observed to the time which is lost between the infliction of the wound and the first systematic dressing of the wound; he is fortunate, who receives thorough treatment within 24 hours. Happily, against tetanus, our surgeons have the tetanus-antitoxin: it is a second line of defence, beyond the use of antiseptics. It can scarcely be reckoned on to cure tetanus, once the infection has flared up. But it can be reckoned on, with full confidence, to prevent the flaring up.

On the medical side of news from the Front, a matter of great interest is the occurrence of typhoid in the Belgian army. We may be sure that the fever is not limited to that army; and we may be fairly sure that there will be, before long, many more cases. It is, of course, the mild unsuspected cases, and the carrier cases, which are the danger. Something would be gained, if only the soldier would cover up his excrement, after the rule ordained by Moses; but he will not

always take the trouble, and typhoid thus is conveyed by flies, or by direct fouling of clothes and hands and food and utensils. Enough has been talked about water-borne typhoid and milk-borne typhoid: we want more talk about man-borne typhoid.

The protective treatment against typhoid has, on the whole, met with very little opposition, and none of real authority. Certain statements of disastrous results have been inquired into, and have been found not true. Not that no ill-effects have ever followed; but these are rare. The main fact, that the protective treatment is indeed protective, has been proved past all possibility of the least shade of doubt.

That old scourge of armies and of jails—typhus fever—has long ceased to trouble our country; probably most doctors now in practice have never seen a case of typhus. It may appear, some day, a most unwelcome visitor, in the western theatre of the war. It is conveyed by body-lice. It is said to be endemic in Silesia. It may find its way westward: or a trace of it, amid the desolation and wreckage of Belgian villages, may flare up into widespread trouble. Happily, the vigilance, the incessant zeal, of all branches of the Army Medical Service, and of all the many societies working at the Front for the welfare of the Army, will continue to bring forth good fruit. It is not possible, with such splendid organisation, such generous devotion, that any grave outbreak of infection should pass neglected; and, when the medical and surgical history of the present war comes to be written, it will be a fine record of good work accomplished on a grand scale.

STEPHEN PAGET.

THINKING ANIMALS.[1]

ABOUT ten years ago it became known that "Clever Hans," an Arab stallion owned by a Herr von Osten in Berlin, was able to answer arithmetical and other questions, tapping out the reply with his fore-foot. Notoriety led to heated controversy, and the appointment of committees to investigate. The second of these, under Prof. Stumpf, resulted in Pfungst's book, explaining everything in terms of signals consisting in slight movements made unconsciously by some person present knowing the answer. This seemed to have solved the problem finally until the appearance of Krall's book in 1912. The author, a wealthy jeweller of Elberfeld and friend of von Osten's, had after the latter's death continued to experiment, obtaining results which, he claimed, refuted Pfungst's explanation. This claim found support in a report signed by the zoologists, Kraemer, Sarasin, and Ziegler, asserting that signalling was excluded since correct answers were given even when none of the human participants was visible to the animal. The opinions expressed on Krall's book vary from that of Prof. Dexler—"a shameful blot on German literature," to that of Prof. Ostwald, who foresees that it will "as clearly mark the beginning of a new chapter in the doctrine of man's place in nature as Darwin's chief work did in its day."

As to the problem itself, a definitive solution could result only from a free and impartial testing of the animals; as it is one can only indicate probabilities. Intentional deceit is almost certainly too simplicist an explanation, and is in any case inadequate. On the other hand, the probability of obtaining correct answers by chance has been underestimated in view of the number of unsuccessful attempts and the greater frequency with which certain numbers occur. Very much must be allowed for this and other weaknesses of testimony, the demonstration of which has been one of the successes of applied psychology, but which, as every newspaper now shows, are seldom given weight in practice. They particularly affect some at least of the would-be crucial tests. Nevertheless much remains, of which the following main explanations have been offered.

The answers are evidence of mathematical intelligence. This, although a highly developed "number-sense" has been found in persons of low general ability, and even in the feeble-minded, conflicts with all that we know from other sources about the animal mind. Detailed scrutiny of Krall's account of his teaching shows that the problem often *could* not have been understood from his exposition. Again, the correcting of a single false figure is done quickly and certainly, as might be expected if signals were being given, since these would be facilitated by concentration of the signaller's attention; if the errors are mistakes of calculation it is odd. Finally, the inability of the animals to prove their understanding by action, compared with their eloquence in the language of taps, is extremely suspicious.

The answers are due to memory. The horse's memory is, no doubt, excellent for some things, and the theory has advantages, but also serious difficulties. To associate eight taps with one symbol and nine with another, the horse must be able to distinguish the two series. But it seems probable that animals cannot distinguish numbers beyond four or five. Rothe trained his dog to come only at the fifth whistle—but this only if the whistles were at regular intervals: his horse would take four lumps of sugar in preference to three, but confused four and five. Again, the horse's eye, while very sensitive to movement, is probably unsuited to the clear perception of complex visual forms such as written numbers, and, as a matter of fact, the animals seem to attend to the questioner more than to the blackboard. Finally, the mistakes in cube root, etc., questions strongly suggest the use of tips.

The animals are responding to unconscious signals. Krall claims to have refuted this by "ignorant" experiments, but these are relatively few and seem all to have some weak spot. Thus Mackenzie reports that Rolf, the Mannheim dog, described a picture on a card held so that the holder could not see it; unfortunately, the picture was a red and blue cross, and there is reason to think that dogs are nearly colour-blind. Nevertheless, the fair number of "peep-hole" experiments and the case of the blind horse, Berto, seem to stamp as inadequate Pfungst's theory of *visually* perceived movements. Yet no other one mode of signal seems sufficient for all cases, while Hacker did actually get answers by moving his foot. Again, it is unlikely that the many individuals who have obtained answers should all make precisely the same unconscious movements. These difficulties disappear if we suppose the animals not to be blindly reacting to one specific stimulus, but to be interpreting more or less intelligently a general type of unconscious emotional or ideomotor expression—movement, variation of respiration, etc.—possibly always complex and varying with the individual and occasion. Both horses and dogs are notoriously sensitive to shades of emotional expression, and recent work by the Pawlow school indicates that dogs can hear sounds so faint as the beating of the heart. It is true, any theory of unconscious signalling presents difficulties. Units, tens, etc., are tapped with different feet; the spelling of verbal answers is phonetic, and *spontaneous* utterances are recorded, including a letter dictated by Rolf! Can the subconscious be credited with so much? The solution, if it ever comes, can scarcely fail to illuminate, if not the animal mind, at least that of man.

C. S.

THE REV. SIR JOHN TWISDEN.

AT his great age of nearly ninety, Sir John F. Twisden, whose death was announced last week, had survived most of his time, the generation of William Thomson and Todhunter, who could give a detailed account of his life and work, very valuable in its day.

The *Times* of December 8 describes the curious revival of the dormant baronetage, taken up by Sir John late in life, but his retirement from the Professorship of Mathematics at the Staff College must have taken place much earlier than 1885, as a consequence of the Cardwell scheme, which had decreed that mathematics was no longer of any use to a Staff Officer.

How Napoleon would smile if he could hear it! The sequel has proved that the economy was fatal to efficiency, when we consider the costly blunders of the Staff in South Africa; and here we are engaged in a war the greatest in the history of the world, and it is a Mathematical War.

After one old-fashioned battle in the open, both sides have dug in, and the war has become a vast siege, where all arms, horse, foot, and dragoons, are turned into garrison gunners, as I predicted in these columns nearly thirty years ago. This was the war for which we were not prepared.

Artillery science is our great requirement. Cavalry work is turned over to the motorist, to scour the country and round up the picturesque old-fashioned Uhlan. In South Africa we see how De Wet, the redoubtable cavalry leader, is run down ignominiously by motor-cars. It had not dawned on our military intelligence to compare by a slight mathematical calculation the available energy, in foot-pounds or ton-miles, of a gallon of petroleum against the equivalent weight of oats. But here was a specimen of the sort of education given by Twisden to the Staff College in his excellent "Practical Mechanics," a book too little known, but containing what Maxwell called the gentlemanly knowledge of the subject, which no Staff Officer should be without. The first chapter of it is a liberal education in elementary gumption, cleverly disguised in what appears a very simple question of no apparent difficulty, always, however, strong enough to unhorse the unwary.

This elementary instruction is being acquired by the junior ranks at the front at a vast expense, and the young officer can say, in the words of Hamlet, "I once did hold it, as our seniors do, a baseness to be scientific, and laboured much how to forget all learning; but now it did me yeoman's service."

G. GREENHILL.

NOTES.

THE Hunterian Oration of the Royal College of Surgeons of England will be delivered by the president—Sir Watson Cheyne—on February 15, but the customary dinner in the evening will not be held.

WE regret to see the announcement, in the Proceedings of the Chemical Society, that Dr. C. R. Crymble, of University College, London, who was a fellow of the society, was killed in action on November 20.

WE learn from the *Times* that Prof. A. Van Geuchten, who was professor of systematic anatomy and neuro-pathology at Louvain University, has died suddenly at Cambridge, where he was receiving hospitality as a refugee.

PROF. C. S. SHERRINGTON, Fullerian professor of physiology at the Royal Institution, will deliver a course of six lectures at the institution on muscle in the service of nerve, on Tuesdays in January and February next.

THE President of the Board of Agriculture and Fisheries has appointed Mr. E. J. Cheney, lately one of the assistant secretaries of the department, to the office of chief agricultural adviser to the Board, and Mr. F. L. C. Floud to be an assistant secretary of the department.

PROF. T. A. JAGGAR, director of the Hawaiian Volcano Observatory, and a group of his assistants, had a narrow escape of their lives during a recent ascent of Mauna Loa. The volcano had become active, discharging large quantities of lava. The scientific

party, while making an ascent to study the eruption, was caught in a snowstorm and nearly overwhelmed by snowslides almost in the path of the lava streams.

La Nature has again made its appearance—the first time since the beginning of August, when publication was suspended on account of the war, most of its staff having joined the colours, while its printers, photographers, and engravers had ceased work. The date of No. 2149 of our interesting contemporary and namesake was August 1, and that of the next issue, No. 2150, is December 12. The articles in this issue deal almost entirely with subjects relating to the present war, among them being armoured trains, the spirit of science in the time of war, Cracow, the defence of Belgium by inundations, and dum-dum bullets. We trust that an unbroken and long existence is now in store for this weekly review of science and its applications to art and industry.

The death is announced, at sixty years of age, of Mr. W. W. Rockhill, who did some valuable scientific exploration in China and Tibet under the auspices of the Smithsonian Institution about twenty-four years ago, and was the author of several important works upon this and other Oriental subjects. In 1884, when attached to the U.S. Legation in Peking, Mr. Rockhill began the study of the Tibetan and Chinese languages, with the view of undertaking exploration in Tibet. Four years later he started from Peking, and was across the frontier in March, 1889. Though he had to abandon his intention to visit Lhasa, he carried out successfully a long journey through much unknown country, and the narrative of his expedition is described in his "Land of the Lamas," published in 1891. His second great journey, described in his "Diary of a Journey through Mongolia and Tibet in 1891 and 1892," earned for him the gold medal of the Royal Geographical Society. During the eleven months which this journey lasted, Mr. Rockhill travelled 8000 miles, surveyed 3400 miles, and crossed 69 passes, all more than 14,500 ft. above sea-level. The volume in which he describes this journey takes a notable place among serious works on Central Asia. Mr. Rockhill was the leading American authority on Chinese matters, and he was on his way to Peking, where he was going to take a new appointment as adviser to President Yuan-Shi-kai, when he was taken ill. On December 4 he was removed from the steamer on which he was a passenger to the hospital at Honolulu, where he died from heart disease.

The issue of the *British Medical Journal* for December 5 contains a statement of the schemes for research drawn up by the Medical Research Committee for the National Health Insurance Joint Committee, and since approved by the responsible Minister. The grants in aid of medical research arise from the annual revenue accruing from the penny in respect of each insured person (payable out of moneys provided by Parliament) to be applied for the purposes of research. The total amount available for 1914 is 56,000*l.*, of which 12,065*l.* has been spent on the purchase of Mount Vernon Hospital, and 7533*l.* on repairs, equipment, and salary. Administration is estimated to cost nearly 3000*l.*, and the research scheme, including a provision for additional grants for laboratory expenditure, more than 24,000*l.* This leaves an estimated balance of nearly 10,000*l.*, which, it is expected, will be reduced by the demands for special work needed in connection with the war. This special work is the extension of existing facilities for bacteriological investigation of infected wounds at the general military hospitals, including Territorial general hospitals, and the organisation for the adequate compilation of the medical and surgical statistics of the war. Among other subjects of medical research for which provision has been made are such matters as tuberculosis, rickets, and rheumatic infections. The research committee proposes, in order that researches carried out at different centres may be co-ordinated, to establish "special investigation committees" composed of one or more of the scientific members of the research committee, of members of the staff of the Central Institute, and of directors or workers in other research centres. The committee contemplates the publication of reports of work done upon special subjects with assistance from the research fund.

Twenty-five years have passed since the death of that eminent Russian traveller, N. M. Miklukho-Maklay. An account of his researches in geography and anthropology by Mr. N. A. Yanchuk has been translated in the December issue of *Man* by M. A. Czaplicka. He was a member of various scientific expeditions to the Canary and Madeira Islands, Morocco, New Guinea, Java, Malacca, and Australia. On his return to Russia in 1887 he commenced the preparation of a complete account of his travels, of which only one volume was completed before his death in the following year. Since then his papers have remained untouched. It may be hoped that on the conclusion of the war arrangements may be made for the publication of this valuable material. Meanwhile the bibliography of numerous papers contributed to scientific societies, which is appended to this article, will illustrate his marvellous activity and the wide range of his investigatons in geography and anthropology.

An account of the trout or charrs of New England is given by Mr. W. C. Kendall, of the United States Bureau of Fisheries, in vol. viii., No. 1, of the Memoirs of the Boston Society of Natural History, and is rendered especially valuable by a series of seven very fine coloured plates illustrating the different species. Referring in his preface to these plates, which have been reproduced by Werner and Winter, of Frankfurt, the author says, "the paintings were made by the painstaking artist, Walter H. Rich, of Portland, Maine, of whose work the only possible criticism is it is too conscientiously true to life." The author has done his work with great thoroughness, both as regards the detailed scientific descriptions of the different species and varieties, and as regards the account of their habits and the conditions under which they are caught. The report should be equally useful to the naturalist and to the fisherman.

The fishes obtained by the *Terra Nova* on Captain Scott's Antarctic Expedition are described by Mr. C.

Tate Regan in vol. i., No. 1, "Zoology," published by the British Museum (Natural History). Twelve of the species are regarded as new to science, four of them being new generic types. All but three of the twenty-five species collected by the expedition belong to the group Nototheniiformes, and the author gives a table (p. 26) showing in detail the distribution of this typical Antarctic group. Following the detailed descriptions of the fishes are two sections of a more general character, the first dealing with the distribution of Antarctic and Subantarctic fishes, and the second with the Antarctic continent during the Tertiary period. The author's conclusion is that neither the fresh-water fishes nor the marine fishes, whether Antarctic or South Temperate, support the theory that Antarctica has connected Australia with South America in Tertiary times, nor does he consider that the distribution of other groups of animals confirms such a view.

THE first part of a series of publications under the general title, "Beiträge zur Kenntnis der Land- und Süsswasser-fauna Deutsch-Südwestafrikas," which was published in the spring of the present year, contains some results of a scientific expedition to German South-West Africa, conducted by Dr. W. Michaelsen, of Hamburg, in 1911. At the same time Dr. Michaelsen publishes the first part of a series dealing with the marine fauna not only of the German colony but also of the whole West African coast, under the title, "Beiträge zur Kenntnis der Meeresfauna West-afrikas." A general account of Dr. Michaelsen's expedition, written by himself, is given in the former of the two works, which also contains reports on the Bryozoa by Kraeplin, the Copepoda by van Douwe, the Oligochæta by Michaelsen, the Isoptera by Sjöstedt, and the Skorpiones and Solifugæ by Kraepelin. In the volume on marine fauna the Hydrozoa and Pennatulacea are described by Broch and the Gephyrea by W. Fischer. Both publications are well illustrated with text figures and plates, and will add to the reputation as a scientific traveller which Dr. Michaelsen has already established by his reports of his earlier journeys to the Straits of Magellan and to Australia.

THE second part of vol. i. of the Journal of the Natural History Society of Siam contains a series of excellent papers and notes on the fauna of the country, and is well illustrated. It opens with the description of three new snakes, by Dr. G. A. Boulenger, and also contains the second part of a paper on the snakes of Bangkok, by Mr. Malcolm Smith, who, in a separate note, records for the first time the occurrence in Siam of that venomous species, the Indian crait (*Bungarus candidus*). The list of papers is completed by one on the birds of Bangkok, by Mr. W. J. F. Williamson, and a second, on those of the Raheng district, by Mr. C. S. Barton. In a note on the occurrence of an oily secretion in a wild ox during the "must" season, Mr. K. G. Gairdner, if we may judge from the figure he gives of its skull, appears to have mistaken a tsaine, or bautin (*Bos sondaicus porteri*), for a gaur (*B. gaurus*).

THE probable effects of the war on horse- and cattle-breeding in this country, and the measures that will have to be taken at its close to replenish our stock of horses, and at the same time to meet the great foreign demand for pedigree-cattle of all kinds which is likely to arise, loom large in the "Live Stock Journal Almanac" for 1915. Among others who write on this subject, Col. G. C. Ricardo is of opinion that in the future Government ought to buy remounts as two-year-olds, in order to help breeders. In another article Messrs. Stratton and Thomas discuss the future of cattle after the war, and point out the heavy drain that will almost certainly take place in our pedigree-stock when peace is proclaimed. Mr. Frank Webb writes to much the same effect, and suggests that in the not very distant future Russia will become a large buyer. The general opinion seems, indeed, to be that British and other pure bred stock will eventually oust the mongrel breeds from the civilised world; and, in consequence, that the prospect for breeders will ere long be of the brightest. In the matter of illustrations and in general get-uo the present issue fully maintains the high reputation of this excellent almanac, which is certainly a wonderful shilling's-worth.

THE *Bulletin Trimestriel*, 1913, continues the summary of the plankton observations carried out by the International Council for the Exploration of the Sea during the years 1902–08. In this third part of the plankton *Résumé* ten groups are dealt with, the more lengthy articles concerning the Diatoms, the Radiolaria, and the second part of the Peridinidæ. In the 105 plates, most of which concern the Diatoms and Peridinidæ, the observed distribution of many important species is charted for the four quarterly cruises, distinctive symbols marking the different years of observation. In the text, so far as possible, a uniform method is preserved, the species of the several groups being discussed in relation to the seasonal horizontal and vertical range of occurrence in the different areas, the hydrographic relationships, and other points contributing to a fuller knowledge of the species and its part in the marine bionomics of North European waters. Much previous work has been incorporated, and when the magnitude of these international investigations is remembered, involving as they do the careful study of many thousands of hauls, made at some hundreds of stations more or less regularly visited during these years, and extending from the Barents Sea to the Bay of Biscay, the importance of this valuable work to marine science may be justly estimated.

THE annual report of the Royal Agricultural Society just issued is a record of a busy and successful year. The 1914 show at Shrewsbury was especially notable for the excellence of the exhibits, while the live-stock entries were, with one exception, the largest on record. Attention is directed to the cutting off of the supplies of kainit and other potash salts owing to the war. As no regular supply is to be obtained outside Germany, the farmer and the manufacturer of artificial manures are adversely affected. It is suggested that the practice of kelp burning may be revived, while Peruvian and other guanos may be used to supply the necessary potash to a limited extent. The Woburn

Experimental Station, besides carrying out the usual field trials on crops of various kinds, has tested the influence of magnesia in place of lime on a wheat crop. The value of crushed oats with separated milk as a food for young calves, both spring- and autumn-born, is proved by the calf-rearing experiments begun in 1912 and still proceeding. In addition to much advisory work on the extermination of insect pests and animal parasites, the Zoological Department is conducting a research into the relation of pheasants to agriculture. The society's programme for 1915 is a full one, only a few features being omitted owing to the abnormal conditions now prevailing.

THE use of fish as cattle food has a novel sound, but it appears to be a common practice in various parts of the world. In Shetland and Iceland dry salt fish is fed to cattle, sheep, and even to horses. So long ago as 1853 Sir John Lawes carried out experiments at Rothamsted on the feeding of pigs with dried Newfoundland codfish. He found that the fish-fed pigs were fat and well ripened, and there was a very good proportion of increase to food consumed. Some recent experiments at the Agricultural College, Coimbatore, made at the instance of Sir F. Nicholson, director of the Madras Fisheries Bureau, have brought to light some further interesting facts. Mr. R. Cecil Wood, in describing the experiments, mentions that certain special cattle kept for display of strength at village festivals in Nandyal are fed with mutton, while it seems a fairly common practice to make use of bandicoots when killed by pounding them in a mortar and feeding them to cattle. In Mr. Wood's experiment two lots of heifers were fed on a dried fish diet and normal diet respectively. The animals took some little time to get used to the fish, but then ate it readily enough. At the end of six months the fish-fed heifers showed an average increase of weight of 54 lb. per head, as against 70 lb. for the normally fed animals. Although fish does not compare favourably with ground-nut so far as fattening value is concerned, it is suggested that on the coast a considerable saving might be effected by its use.

THE cultivation of rice in Spain affords an excellent example of the success attending a highly perfected system of agriculture. Most of the rice land is situated in the province of Valencia, where the cultivation was introduced at the time of the Moorish conquest. It is interesting to learn from Mr. E. J. Butler, in the *Agricultural Journal of India* for October, that many of the Oriental practices followed, and especially that of transplantation unknown elsewhere in Europe, are similar to those employed in India, and may probably be traced to the prolonged occupation of this district by an Eastern people. Although the total production of rice in Spain is the lowest of the six rice-growing countries, the yield per acre is double that obtained in Italy and Egypt, and more than six times the official figures for India. This result is due to the thorough cultivation of the fields with specially designed implements, to the system of transplantation, and the use of large quantities of suitable nitrogenous and phosphatic manures. The fear of encouraging malaria has hitherto acted as a deterrent to the extension of the area under rice in Europe, but at the recent International Rice Congress at Valencia the view was put forward that this prejudice is unfounded, provided that certain precautions are observed. If this view gains credence it can scarcely be doubted that there will be a material increase in the European production of this cereal.

THE relations between the two mineral representatives of iron disulphide, pyrite and marcasite, are further explored by E. T. Allen, J. L. Crenshaw, and H. C. Merwin in a paper in the *American Journal of Science* for November (p. 393). The formation of marcasite from acid and of pyrite from alkaline solutions is shown by experiment and also by natural occurrences. Wurtzite and zinc-blende are proved to have similar relations, the former being, moreover, the unstable form.

IN view of the rarity of fossil remains of apes and monkeys much interest attaches to the description by Dr. A. Smith Woodward, in vol. lxx (pp. 316–20, plate xliv.) of the Quart. Journ. Geol. Soc., of an form of the jaw at and near the point of insertion *fontani*, from the Upper Miocene of Seo de Urgel, Lérida, Spain. In several respects, notably in the form of the jaw and near the point of insertion of the digastric muscle and in the small size of the first molar, Dryopithecus approximates to the contemporary macaque-like genus Mesopithecus, and is therefore a primitive type.

PROF. A. C. LAWSON, at the invitation of the Geological Survey of Canada, has revisited the pre-Cambrian area of Rainy Lake, where he first demonstrated in 1885 and 1887 the intrusive nature of much of the "Laurentian" gneiss. His results are now issued as Memoir 40 of the Canadian Survey, dated 1913. The names Coutchiching and Keewatin are retained for the two series penetrated by the Laurentian gneiss, the former being free from volcanic matter, and the latter, overlying it, being largely volcanic. The second intrusive gneiss, which is later than the Seine (Huronian) sedimentary series, is now styled Algoman by the author. The influence of Prof. Lawson's original papers has been far-reaching. As recent evidence, we may mention Mr. A. L. Hall's address on the Bushveld Complex (Proc. Geol. Soc. South Africa, 1914. p. xxii.), and Mr. P. A. Wagner's account of the gneisses of Southern Rhodesia (Trans., *ibid.*, vol. xvii., p. 39).

IN the September issue of the Proceedings of the Philadelphia Academy, Mr. D. M. Barringer adduces further evidence in favour of the theory that the so-called meteor crater of Arizona, in place of being due to volcanic action, is really the result of the impact of a vast fall of meteorites. Of the occurrence at a remote epoch of such a fall there is ample evidence. One of the points on which the author lays special stress is the occurrence in the crater of large quantities of a quartz-glass, which was undoubtedly formed by the fusion of part of a bed of white sandstone occurring at a depth of about 350 ft. below the level of the plain, and not outcropping for a distance of seventy miles. This quartz-glass is stained with nickeliferous iron, which could only be of meteoric origin, and this

fact, coupled with the lack of any evidence that crystalline quartz can be fused by the heat engendered during volcanic action, is regarded as conclusive testimony in favour of the impact theory. Corroborative evidence is afforded by the fact that intense heat is produced by the impact of big shells fired against armour-plating. The mass to which the origin of the crater is attributed was probably a dense cluster of iron-meteorites, which may possibly have formed the head of a small comet.

THE publications of the Norwegian Meteorological Institute for the year 1913 (Rainfall Observations and Year-book, both containing actual readings and mean values) are prepared in the usual careful way, and scarcely call for special remarks beyond those referred to in our previous issues. The year-book contains hourly and other observations at Green Harbour, Spitsbergen; the summary for 1912 shows that the yearly temperature was $-10.4°$ C.; January, $-24.4°$ (February $-26.3°$), July, 4·2; maximum, 9·9° on July 22; minimum $-44.3°$ on March 31. The yearly rainfall (or melted snow) was 305 mm., on 124 days. The annual report shows that the success of ordinary weather forecasts, and notices for herring fisheries, was very satisfactory; storm warning telegrams are issued from Bergen. We note that Mr. A. S. Steen, formerly assistant-director, has succeeded Prof. H. Mohn in the directorship of the Meteorological Service, which position the latter held with much distinction from the establishment of the service in the year 1866.

SOME time before the loss of the *Titanic* Prof. Barnes, of Montreal, carried out a series of measurements of the temperature of the sea in the neighbourhood of icebergs, and came to the conclusion that the presence of an iceberg could be detected by a slight rise of temperature it produces in the sea-water around it In the summer of 1912 a party from the Bureau of Standards took automatic records of the temperature of the water during the patrol of the U.S.S. *Chester* and *Birmingham* in the North Atlantic, and their results are published in vol. x. of the Bulletin of the bureau. They show that the changes of temperature which occur in the sea far removed from icebergs are at least as great and sudden as those found in the vicinity of bergs, and that no positive conclusions as to the presence of bergs can be drawn from such changes. They find also that in the neighbourhood of a berg the temperature of the water is reduced more often than raised. These conclusions are almost identical with those arrived at during the cruise of the *Scotia*, sent out to the Newfoundland bank by the Board of Trade in the summer of 1913, except that on the *Scotia* small rises of temperature in the neighbourhood of bergs were more often recorded.

THE Bureau of Standards at Washington has issued a circular (No. 47) in which the tables of equivalents of United States customary and metric weights and measures are revised and brought up to date. It contains a useful series of conversion tables giving the equivalents of the metric and customary weights and measures from 1 to 999 units. From the introduction and definitions which precede the tables it would appear that for all practical and most scientific purposes the United States yard and pound are the same as those in the United Kingdom. The United States gallon (which is used for the measurement of liquid commodities only) is, however, only five-sixths of the imperial gallon, while the United States bushel (used only in the measurement of dry goods) is approximately thirty-two thirty-thirds of the imperial bushel. The bushel and gallon of the United States are not connected by the relation 8 to 1 as are those used in this country. The troy pound and the apothecaries pound are apparently still recognised in the United States as customary weights, although they have long died out in Great Britain. It may be of interest to note that the fundamental standard metre established in the United States by Act of Congress and by order of the Treasury is the international prototype metre, whereas the primary standard metre in the United Kingdom is the national prototype No. 16, which is shorter than the international metre by six-tenths of a micron.

AN important paper on the resins present in hops (*Humulus lupulus*, L.) has been published by Ö. Winge and J. P. H. Jensen in the *Comptes rendus* of the Carlsberg Laboratory (vol. ii., part 2, p. 116). It is shown that in the past a mistake has been made in considering one of the resins of hops, namely, the so-called γ-resin, as valueless; on the contrary, during the brewing process it both gives taste to the wort and helps in the precipitation of proteins. The total quantity of resins extracted from the hops by cold ether and determined by titration is an approximately accurate expression of the bitterness value of hops. Other data recorded show that the analytical methods hitherto used, which are based on the separation of the so-called soft resins from the hard resins, rest upon an insecure basis and give misleading results.

No. 4 of the Proceedings of the Institute of Chemistry contains an account of the steps taken by the institute in conjunction with the Board of Trade, the Society of Chemical Industry, and other bodies, to consider the needs of this country as regards chemicals, dyestuffs, glass, and porcelain vessels, which have hitherto been manufactured in enemy countries. A committee, which was appointed on September 22, after taking evidence, has reported that there is every prospect of the chemical glass industry being taken up and worked satisfactorily in this country provided that the manufacturers can be afforded some guarantee of permanency for their enterprise, and that they may have some reasonable assurance that at the conclusion of the war the newly developed industry will not suffer from foreign competition, hitherto made possible by economic conditions which do not prevail in this country. Several firms have stated their intention to undertake the manufacture of chemical glass ware, whilst others are already experimenting with a view of supplying porcelain, crucibles, basins, and funnels. Later, at a meeting of the council of the institute, held on October 30, it was resolved to appoint an advisory committee to conduct research on glass, to be carried out in the laboratories of the institute with a view to arrive at

suitable formulæ to be freely available to manufacturers. Another committee has been formed to consider the needs of this country as regards laboratory reagents and the standards of purity necessary for such substances.

PROBABLY the most interesting structural steel work on the new Lötschberg-Simplon Railway is the steel arch bridge over the Bietsch Valley, of which an illustrated description appears in the *Engineer* for December 11. This bridge is remarkable for the fact that it is built on a short-radius curve of only 300 metres, and also on a gradient of 22·2 per 1000. The situation is over a craggy ravine, between two tunnels piercing the spur on either bank. The arch has a span of 95 metres between the centres of the hinges and a rise from this chord of 23·79 metres. Supported partly upon this arch and partly by the masonry approach arches are two trussed girder spans. These girder spans are attached to the back of the central arch by means of pivoted expansion brackets, and this part of the design is of peculiar interest in view of the complexity of the movements arising from change of temperature and vertical and lateral loading. The three structural elements in the bridge are all rectilinear, while the bridge floor and its bracing alone are curved and continuous between the pier abutments.

THE thirty-first annual issue of the "Year-Book of the Scientific and Learned Societies of Great Britain and Ireland" has now been published by Messrs. Charles Griffin and Co., Ltd. This useful reference volume is a record of the work done in science, literature, and art during the session 1913–1914 by numerous societies and Government institutions, and has been compiled from official sources. On the whole it provides a comprehensive survey of the activities of associations with which it is concerned, but we have failed to find any reference to the Wireless Society of London, the Illuminating Engineering Society, and the Historical Association. It is a pity, too, that in a volume published at the end of 1914 the extended reference to the British Association should deal almost wholly with the 1913 meeting at Birmingham. The volume, the price of which is 7*s*. 6*d*. net, deserves a place in every reference library.

MESSRS. J. WHELDON AND CO., 38 Great Queen Street, W.C., have just issued a classified list of books and other works on mineralogy, metallurgy and mining, geology and palæontology, and related subjects. The catalogue includes recent purchases and selections from several libraries, and it should be seen by geological bibliophiles and librarians of scientific societies

MESSRS. G. P. PUTNAMS SONS ask us to say that the price of "The Essence of Astronomy," by Mr. E. W. Price, reviewed in NATURE of November 12 (p. 280), is not 10*s*. 6*d*. net as there stated, but 3*s*. 6*d*. net.

OUR ASTRONOMICAL COLUMN.

COMET 1913*f* (DELAVAN).—The following ephemeris is taken from the Ephemeris-Circular of the *Astronomische Nachrichten* (No. 469, 1914), being communicated by J. Fischer-Petersen and Vinter Hansen of the Copenhagen Observatory :—

12h. M.T. Berlin.

Two photographs of this comet are reproduced in the current number of the Monthly Notices of the R.A.S. (vol. lxxv., November, 1914). They were taken on September 20 and 26 with the 3¼-in. portrait lens and 30-in. reflector of the Royal Observatory, Greenwich.

THE SPANISH SOLAR ECLIPSE EXPEDITION.—The Madrid Observatory dispatched an expedition to Theodosia, in the Crimea, to observe the total eclipse of the sun on August 21. The party included MM. Ascarza, Carrasco, and Tinoco, with one or two voluntary helpers. The weather seems to have been favourable at their station, and the results obtained were satisfactory, and are briefly described in the *Comptes rendus* for November 30 (vol. clix., No. 22, p. 738). The corona is described as of a form analogous to that of minimum sunspots with polar rays a little more pronounced. Photographs of the spectra of the corona and chromosphere were successfully secured, and, in M. Carrasco's case, with special attention to the red, yellow, and green regions. While details regarding the wave-lengths will be published later, M. Carrasco directs attention to a red coronal radiation, the wave-length of which he gives as λ 6373·87 Å U. He describes the green coronal radiation as being very feeble or absent.

THE RECENT TRANSIT OF MERCURY.—Accounts of the observations of the transit of Mercury in November last are published by numerous observers in several journals. In the Monthly Notices of the Royal Astronomical Society (vol. lxxv., No. 1, November) papers are communicated by the Royal Astronomers of Greenwich and Edinburgh, Mr. R. Jonckheere, Prof. Fowler, and Dr. J. L. E. Dreyer. The different phases seemed to have been well observed at Greenwich, and the Astronomer Royal states that "none of the observers saw the 'black drop,' a halo round Mercury or a bright spot on the planet. The phenomenon appeared just as might have been expected from geometrical considerations." This communication is accompanied by a plate illustrating seven positions of the planet, taken with the photoheliograph just about the times near the beginning of the transit. M. Jonckheere discusses the 368 measures of the diameter of the planet as made at the Royal Observatory, Greenwich, by several observers during the transit. At the Royal Observatory, Edinburgh, no distinctive marking on the planet's disc could be detected nor any halo, and the second internal contact was noted as "quite clean," no ligament of any kind being visible.

Prof. Fowler's observations corroborate the above. An additional observation by him to determine by spectroscopic means whether there was any strengthening of the telluric lines near the limb of the planet led him to conclude that no effect of the kind was seen. Dr. Dreyer's observations at the Armagh Observatory show that while he observed no halo round the planet, he noted the black drop at egress and a bright point or dot on Mercury's disc. In the *Comptes rendus* for November 23 (vol. clix., No. 21) MM. Gonnessiat and Chrétien present two notes on the transit.

ATMOSPHERIC POLLUTION.

AT the International Conference on Smoke Abatement held in London in March, 1912, a committee representative of the Smoke Abatement Societies and of the more progressive municipalities of the United Kingdom was appointed, to promote the systematic and scientific study of atmospheric pollution, in the urban and industrial districts of this country. Dr. W. N. Shaw, director of the Meteorological Office, was elected chairman of this committee. Numerous meetings were held in London during 1912 and 1913, in order to select a standard method and type of apparatus for collecting the impurities, and also to make preliminary arrangements with the various local authorities who had consented to take part in the investigation. The actual observations were commenced in twenty-two different cities and towns in March of the present year, using the method and standard form of soot- and dust-gauge recommended by the committee.

The principle of the method used is that of collecting the soot and other impurities that fall by their own weight, or are carried down by the rainfall in

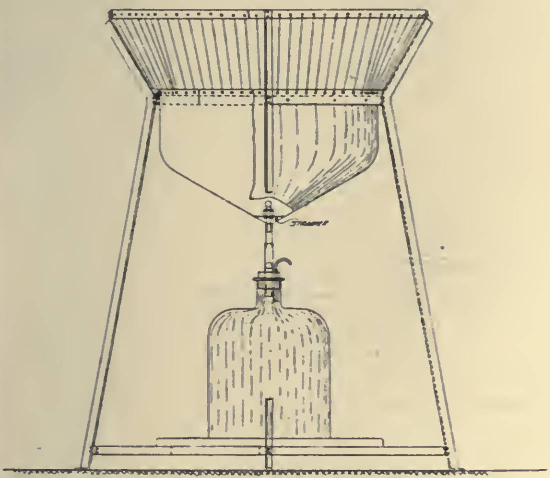

FIG. 1.—Soot Gauge. Standard form.

one month, in a large funnel of enamelled iron, with a catchment area of four square feet. These soot and dust gauges are placed in some central position of the town or district on the ground-level, in open spaces free from wind eddies and from abnormal soot and dust. The collected water and deposit are removed once a month, for measurement and examination by the official city chemist, and the following constituents of the rainfall and solid deposit are recorded :—Volume of water collected, total solids, total soluble matter, total insoluble matter, tarry matters, non-tarry carbonaceous matter, sulphates, chlorides, ammonia and lime. The relationship between the amount of tarry matter and the total carbonaceous matter enables one to judge how far the domestic chimney is responsible for the soot-fall in each locality. Factory furnaces and factory chimneys produce under normal conditions little tarry vapour, for the temperature of the furnaces is sufficiently high to ignite and burn these vapours before they escape into the atmosphere. The greater portion of the tar in town and city smoke comes, therefore, from the coal used for domestic heating and cooking purposes.

The standard gauge is shown in Figs. 1 and 2. It consists of a circular open-topped vessel of enamelled iron, supported in a heavy galvanised iron frame, and is provided, as shown, with bottles for holding the month's fall of soot- and dust-laden rain-water. On the first or last day of each month the soot and other solid matter deposited on the interior of the vessel is rinsed down with some of the collected water, and a new set of bottles are placed in position to receive the new month's rainfall.

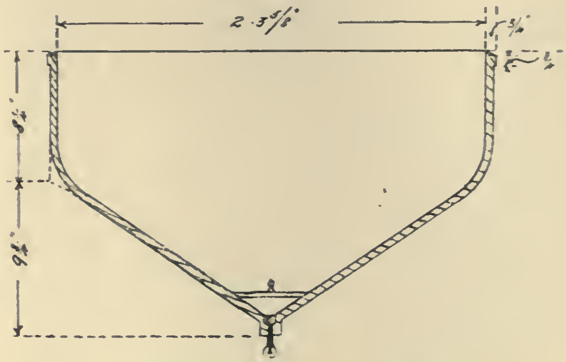

FIG. 2.—Section of Standard Soot Gauge.

The health authorities of the following towns and cities are joining in the observations :—Aberdeen, Ayr, Birmingham, Coatbridge, Exeter, Glasgow, Greenock, Hull, Liverpool, Leith, London (County Council), London (City Corporation), London (Meteorological Office), Malvern, Manchester, Newcastle-on-Tyne, Oldham, Paisley, Plymouth, Sheffield, Stirling, Wishaw, and York. In many cases two or three gauges will be installed at different centres, but at present London is the only city from which returns

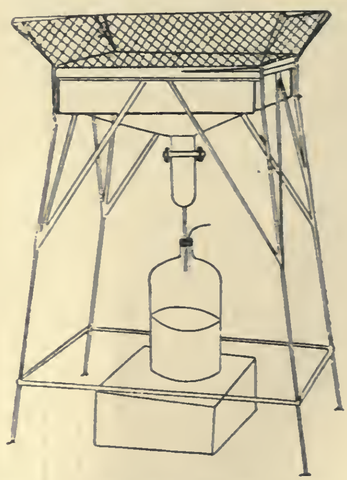

FIG. 3.—Soot Gauge used for *Lancet* observations.

have been published where more than one gauge is in use.

The committee, which is now receiving and co-ordinating the results, has just published the figures obtained in thirteen of the above observation centres in April and May of this year. Although these are incomplete, owing to the absence of results from Manchester, Glasgow, Sheffield, Leeds, Newcastle, and other important manufacturing towns, the figures

are sufficiently interesting and important to be reproduced here.

TABLE I.—*Summary of Reports per Month ending April* 30, 1914.

Place	Rainfall in millimetres	Metric tons of deposit per sq. kilometre in month of April					
		Insoluble matter			Soluble matter		
		Tar	Carbonaceous other than tar	Ash	Loss on ignition	Ash	Total solids
England—							
Exeter	32·30	0·04	2·05	4·71	0·97	1·61	9·38

York	33·73	0·02	0·85	3·15	1·08	1·35	6·45
Scotland—							
Greenock	52·30	0·04	1·93	4·51	1·39	2·25	10·12
Leith	46·10	0·49	0·79	2·92	1·19	1·19	6·58
Paisley	49·68	0·15	4·53	6·66	1·20	1·99	14·53

Adding together the results recorded in Tables I. and II., and arranging the towns in order of the magnitude of their fall of soot and dust in the two months, we obtain the figures given in Table III.

TABLE III.—*The Soot and Dust Fall of various English and Scotch Towns in April and May.*

Name of town or city	Metric tons per sq. km. in two months			
	Total solids		Tar, soot, and grit	
Liverpool	36·51		23·78	
Paisley	30·42		22·05	
Newcastle	29·64		23·63	
Kingston-on-Hull...	25·41		16·08	
London (Central)...	33·5	Average 24·8	26·26	Average 17·3
,, (East) ...	21·6		12·85	
,, (West) ...	19·2		12·69	
Greenock	19·76		10·96	
Exeter	18·12		12·78	
York	14·64		9·56	
Leith	12 23		8·56	
Malvern	4·45		1·05	
Birmingham (one month only)	29·86		20·89	

The difference between the figures in the second and third columns of this table gives the soluble solid matter brought down by the rain.

It is surprising to find that the atmosphere of Birmingham and of many northern towns is considerably dirtier than that of London, which in this respect has a reputation it does not deserve. Malvern is seen to be far the cleanest town in the list, since the total soot and dust-fall in April and May, 1914, only amounted to 4·45 tons per sq. km., or to about one-fifth that of London, and one-eighth that of Liverpool during the same two months.

Figs. 1 and 2 are sectional elevations of the standard gauge, while Fig. 3 shows the gauge used for the observations of London's soot-fall, carried out in 1910–11 by the *Lancet* and the Coal Smoke Abatement Society.

THE NATURAL HISTORY OF AN AMERICAN DESERT BASIN.[1]

THE staff of the Botanical Research Department of the Carnegie Institution of Washington has made many valuable contributions to natural science, particularly in the study of desert vegetation, at the Desert Laboratory, Tucson, Arizona. The recently issued monograph on the Salton Sea is in many respects unique, for it deals with a remarkable series of phenomena, opportunities for the study of which are but rarely presented. That the Desert Laboratory workers have taken full advantage of this opportunity is evident from the perusal of this volume, interesting to the geologist, the geographer, and, above all, to students of plant ecology. The chief interest of this fine piece of co-operative research centres, as the editor and chief contributor point out, around the fate of organisms overwhelmed by floods, in the physical changes which follow emersion, and in the biological mechanism of reoccupation of sterilised areas as they emerge from the water—episodes which must have been repeated many times in the history of the earth's surface. The report gives the results obtained by the investigation from various points of view of the phenomena presented by a desert basin

[1] "The Salton Sea: a Study of the Geography, the Geology, the Floristics, and the Ecology of a Desert Basin." By D. T. MacDougal and Collaborators. Pp. x+182+32 plates. Publication No. 193. (Washington: Carnegie Institution, 1914.)

which has been the scene of alternate submergence and desiccation.

The Cahuilla basin, lying to the west of the lower (southern) portion of the main delta of the Colorado River, was in Tertiary times cut off from the sea and so became a brackish inland lake (Lake Cahuilla). The lake bed, now called the Salton Sink, has its upper margin about 20 ft. above mean tide-level, while its lowest point, now beneath the water of the present lake (Salton Sea), is 280 ft. below this level. On either hand of the Sink, which is oblong in outline (about eighty miles long and thirty miles in greatest width), there rise arid and sun-scorched low mountains, chiefly of granite, the slopes and waterless cañons of which bear a scanty vegetation. The Sink is practically a level plain, with no irregularities of surface to vary the effects of sun and wind, with a uniform temperature and uniform deficiency of atmospheric humidity and precipitation, the latter being on the average 2·7 in. a year. The ancient lake which originally filled the Sink had almost or entirely disappeared by evaporation, leaving a series of beach-lines, but during 1905 and 1906 the cutting of canals and the resulting escape from control of the Colorado River water resulted in a partial re-flooding of the basin and the formation of the Salton Sea, threatening the restoration of the former lake conditions and necessitating the removal of the Southern Pacific Railway track for sixty-seven miles to a higher bed. In 1907, however, the railway engineers stopped the deluge by re-diverting the Colorado water to the Gulf of California, and the gradual disappearance by evaporation of the Sea then began and is still in progress. Since 1907 the average annual rate of lowering of level by evaporation has been about 5 ft., while the concentration of the water has risen until the proportion of total solids is now more than 1 per cent. Succeeding the chapters on the geology, geography, climate, and water analyses, the remainder of the report (pp. 48–182) is devoted to the biological results obtained. Prof. G. J. Peirce gives an interesting account of the behaviour of the micro-organisms found in the Salton Sea, and in the strong brines from which salt is crystallising out naturally or in the artificial salt-pans on the shores of the lake. It has long been known that various organisms live under what are commonly regarded as fatal conditions—*e.g.* the mould-fungi which thrive on solutions of strychnine, formalin, carbolic acid, etc., the insects in oil-wells and asphaltum, those in hot springs and in snow, and so on—but in these cases the conditions are fairly stable, and it is harder to understand how organisms like the brine-shrimps (Artemia) and various protozoa, flagellates, and algæ found in the Salton Sea and other strong brines can exist under conditions ranging from rain-diluted sea-water to concentrated brine from which common salt crystallises. The lower organisms upon which the brine-shrimps and protozoa feed are mainly Pyramimonas, Dunaliella, Carteria, and various bacteria. The latter are entirely different from the bacteria which cause putrefaction in waters of the usual concentrations, and which are killed by the Salton brine—a concentrated solution of sodium chloride and of magnesium salts. The most conspicuous are a chromogenic form which gives a red colour to the salt in the salt-pans and to fish pickled in the salt, and a cellulose-destroying form which attacks stems and other plant-remains submerged in the lake.

A rocky island in the Salton Sea, Southern California, formerly submerged but now exposed by the recession of the lake owing to continued evaporation. The rock shows colonisation by a desert shrub, *Pluchea sericea* (Compositæ).

The present flora of the Salton Sink includes 179 species of seed-plants, the great majority being salt-plants (halophytes) and plants adapted for life under dry conditions (xerophytes); the former are mainly members of the Chenopodiaceæ. Apart from the salt-mud plants, the vegetation of the Sink is a part of the general flora of the Colorado desert, differentiated mainly by the great preponderance of species of the orache genus (Atriplex) in its composition, and it is of a remarkably uniform character. Three main communities or associations can be distinguished, according to the nature of the soils—coarse-grained, detrital slopes, clays, and mound-forming drifted materials.

The longest report (pp. 115–72) is that by Dr. MacDougal, dealing with the movements of vegetation in the area. The phenomena observed on the emersed

lands of the Sink are widely different from those hitherto investigated in the case of Krakatau, the cooling lavas of the Hawaian Islands, newly-made land about the mouths of rivers, etc. The chief features in the re-vegetation of the beaches successively exposed each year by the recession of the water are described in detail, but the following were the chief points to be taken into account in noting the progress of re-vegetation. As the salt content of the water increased by about 18 per cent. in each succeeding year, each emersed strand would be saturated with a soil solution of the concentration and composition prevalent in the period preceding emergence, and the desiccation of the emersed strands would proceed at a rate determined by the character of the soil (*e.g.* its capillary raising power), and by the composition of the infiltrated lake water. The re-vegetation of the strand bared in 1907 was chiefly due to the rising water picking up seeds lying on the surface and leaving them on the wet flats, but since that year the plants invading the new strands were carried there as seeds by the wind, by flotation, or by birds, only those plants surviving as could withstand the rapid warming of the shallow water on the mud flats, which increased its toxicity for seeds and seedlings, and the rapid desiccation of the surface soil, which increased the difficulties of the rooting and establishment of the plants.

The report is illustrated by thirty-two beautiful collotype plates, and interesting as are the results already obtained, the continued investigation of the phenomena presented by the re-vegetation of this sterilised desert basin area under difficulties which will become increasingly great as evaporation proceeds will doubtless yield even more valuable results in the future.

F. C.

FINISHING TEMPERATURES OF RAIL STEEL.

REPRINT No. 38 of the Technologic Papers of the Bureau of Standards, by Messrs. Burgess, Crowe, Rawdon, and Waltenberg, deals with observations on the finishing temperatures and properties of steel rails. The principal objects of the research were to "determine from measurements taken in representative rail mills, the present American practice regarding the temperatures at which rails are rolled, to demonstrate the ease and accuracy with which such temperatures may be measured, and to find out what the 'shrinkage clause' in rail specifications really means."

The authors have found that ingots for rails are rolled at temperatures ranging from 1075° to 1150° C., and that the variation from one ingot to another in a series of 20 to 40 is only 10° to 20° C. The rails are finished at temperatures which may vary between 880° and 1050° C., but which usually come within 50° C. of 935° C. With uniform mill practice the rails of 100-lb. section will be finished at some 10° to 20° C. hotter than 90-lb. rails, and about 50° C. hotter than 75-lb. rails. The melting or freezing range of such steels extends from about 1470° to 1530° C., *i.e.* to nearly the melting point of iron. The critical Ac 1 point was found to occur within 7° C. of 732° C. for the ten samples of Bessemer and open-hearth steels examined. On cooling the corresponding Ar 1 point occurs between 680° and 650° C.

In all cases, therefore, the temperature at which the rolling of the rails ceases was at least 200° C. above the critical point, and there is no doubt that the rolling temperatures could with advantage have been carried much lower than they actually were. A rail of 100-lb. section, cooling freely in the air from 1070° C., reaches the recalescence point (Ar 1) in about 8½ minutes; and the maximum difference in temperature between the centre and the outside of the head is about 85° C. at 1000° C., becoming 0° at the recalescence point. A comparison of the "shrinkage clause" specification with the expansion of rail steel shows that this clause permits the finishing of rails at 1120° C., which is 450° C. above the critical range of such steel and is *above* the temperature at which many rail ingots are rolled in practice. In its present form, therefore, the clause has absolutely no significance.

FOREST ENTOMOLOGY.

A VALUABLE Bulletin (Entom., No. 7) of the Canadian Department of Agriculture on forest insect conditions in British Columbia, has been lately issued by Mr. J. M. Swaine. The author deals mostly with the Scolytidæ injurious to the more important species of pine, spruce, and fir; he gives interesting summaries of the life-histories, illustrated by excellent figures of the beetles, their larvæ, and their characteristic brood-galleries in the bark of the trees.

The "large larch sawfly" (*Nematus erichsonii*)—notorious for its ravages in the Cumbrian Lake district—continues to occupy the attention of zoologists in the University of Manchester. Mr. R. A. Wardle contributes to the last number of the *Journal of Economic Biology* (vol. ix., No. 3) some notes on the life-histories of two of its parasites hitherto unrecorded; these are *Zenillia pexops*, a Tachinid dipteron, and *Hypamblys albopictus*, an Ichneumon-fly. The first-stage larva of the latter, with its relatively big head, elongate tail-process—variously interpreted as a blood-gill or a pro-leg—and paired, limb-like outgrowths on the body-segments, is remarkable. Several of these young grubs may occur in one sawfly caterpillar, but apparently only one of them is able to pass through the subsequent larval stages and become in due course a pupa. There appears to be rather severe competition among the various parasites of the Nematus, so that there may be danger of their weakening one another in the process of reducing the numbers of their host.

The pine weevil (*Hylobius abietis*) is one of the most abundant of our native woodland insects. Mr. J. W. Munro has lately published (Proc. R. Phys. Soc. Edinb., vol. xix., No. 6) the fullest account yet available of the reproductive organs in both sexes.

AUSTRALIAN HANDBOOKS FOR THE BRITISH ASSOCIATION.[1]

IN connection with the recent meeting of the British Association in Australia, official handbooks were issued for the Commonwealth and for all the States—Western Australia, South Australia, Victoria, New South Wales, Queensland, and Tasmania. Copies of all were distributed among the visiting party, in most

[1] The Commonwealth of Australia. Federal Handbook prepared in connection with the 84th meeting of the British Association for the Advancement of Science, held in Australia, August, 1914. Edited by G. H. Knibbs. Pp. xvi+598. (Melbourne: Mullett.)

Handbook and Guide to Western Australia. Prepared for the Members of the Advance Party of the British Association for the Advancement of Science. Pp. vi+118. (Perth: F. W. Simpson, 1914.)

Handbook of South Australia. British Association for the Advancement of Science. Australian Meeting, 1914. Adelaide. Joint Editors: D. J. Gordon and V. H. Ryan. Pp. 328. (Adelaide: R. E. E. Rogers, 1914.)

British Association for the Advancement of Science. Australian Meeting, 1914. Handbook to Victoria. Prepared under the direction of the Victorian Executive Committee, by A. M. Laughton and Dr. T. S. Hall. Pp. xvi+382. (Melbourne: A. J. Mullett, 1914.)

British Association for the Advancement of Science, 1914. Handbook for New South Wales. Pp. xiv+621. (Sydney: E. Lee and Co.)

Our First Half-Century. A Review of Queensland Progress. By Authority of the Government of Queensland. Pp. xxviii+258. (Brisbane: A. J. Cumming, 1909.)

British Association for the Advancement of Science. Tasmanian Handbook. Pp. iv+348. (Hobart: J. Vail, 1914.)

instances before the travellers had left home, so that it was competent for the recipients to inform themselves thoroughly on Australian topics before reaching the country. Members joining locally in Australia received the Commonwealth volume and that relating to their own State. The volumes are not uniform in style, though they were all prepared on an approximately uniform plan, specially for the occasion, with the exception of the Queensland volume, which was that originally issued in 1909, by authority of the Government, under the title of "Our First Half-Century," in commemoration of the jubilee of the State.

The volumes form a fine monument to the scientific achievements of Australian workers, for they contain chapters by acknowledged experts in every department of science—natural, economic, social, and political. Thus the Commonwealth volume, edited by Mr. G. H. Knibbs, the Commonwealth statistician, and published at the charge of the Federal Government, contains chapters on the history of Australia, by Prof. Ernest Scott, of Melbourne; the aborigines, by Prof. Baldwin Spencer; physical and general geography, by Mr. Griffith Taylor; climate, by Mr. H. A. Hunt; vegetation, by Mr. J. H. Maiden; animal life, by Prof. W. A. Haswell; geology, by Prof. Edgeworth David, Prof. E. W. Skeats, and Messrs. T. S. Hall, W. S. Dun, and F. Chapman; astronomy and geodesy, by Mr. P. Baracchi; pastoral and agricultural development, by Mr. G. A. Sinclair; mining fields, by Mr. E. F. Pittman; manufactures, etc., by Mr. Gerald Lightfoot; education, by Prof. F. Anderson; political systems, by Prof. Harrison Moore; and miscellaneous notes, by the editor. This is in itself a very notable list, and while some of the names in it reappear among those of the contributors to the States volumes, we find also in these the names of other well-known workers in special fields, too many to detail here.

It is the purpose of the Commonwealth volume to provide a general scientific survey of Australia, while the States volumes give details each for each. While absolutely perfect co-ordination between the various volumes was scarcely to be expected, the many writers have clearly received and acted upon very precise editorial instructions as to their different fields, and duplication has been avoided as far as possible. Thus, even if the visit of the association had effected no other good, it has brought into existence a remarkable compendium of present knowledge of the continent of Australia and its resources, and a record of progress in human endeavour to make use of those resources, such as exists probably for no other country which is at a similar stage of development. These volumes, therefore, apart from their intrinsic interest and value at the moment, will become a valuable historical record. Frequently throughout them all writers are found to look forward to fields of future work, whether in the direction of pure scientific research or of economic development in which science will play a leading part.

In most of the volumes there are many excellent photographic reproductions, though the New South Wales book is less satisfactory than the rest in this respect. Particular mention may be made of a coloured plate in the Western Australia volume representing some of the wild flowers for which the State is famous. When photographic illustration is so successfully carried out, it is the more notable that the draughtsmanship and reproduction of maps is generally not so, and the valuable material which is available in the departments of geology, meteorology, and others suffers to some extent, though not always, in its representation by this means.

These handbooks were supplemented by booklets dealing with many of the excursions undertaken by members from different centres, so that the scientific interests of the visitors were provided for at almost every step, even if the guidance and verbal demonstrations given by their leaders on the spot had been less efficient than it was. The subject-matter of each State handbook is arranged under headings broadly similar to those of the Commonwealth book detailed above, with the exception of the Queensland volume, which, having been prepared, as has been seen, for a different purpose originally, deals more exclusively with historical, economic, and social topics than the others. From the point of view of the natural sciences this is unfortunate, but with such a book already in existence it was perhaps not to be expected that another should have been compiled.

It may be well to make clear that the British Association is not concerned in the issue of these books, which were compiled and issued by the Australian authorities; it is not stated whether they will be made accessible to the public.

CHEMISTRY AT THE BRITISH ASSOCIATION.

MEETINGS of the Chemistry Section were held only in Melbourne and Sydney, but in each of these cities they extended over three days. There were two joint discussions with other sections, and a number of locally contributed papers showed that in both Victoria and New South Wales a considerable amount of chemical research is being carried out, some happily on lines of special interest and value to Australia. It is to be regretted that such local features as the natural products of the characteristic Australian indigenous flora and the important problems connected with soil should not earlier have attracted local chemists, but as two sectional committees of the association are now engaged in examining the natural plant products we may hope that much will be recorded before the ever-increasing destruction of native trees and plants precludes any attempts at completeness.

MELBOURNE.

After the president's address Prof. Masson described an ingenious rearrangement of Mendeléeff's periodic table, by means of which many of the existing difficulties are removed. Instead of writing the elements in their eight groups in a two-dimensional figure throughout, Prof. Masson uses a mixture of two and three dimensions. Suppose the elements (rare earths excepted) be written in the order of their atomic weights on the inside of the covers of a book in horizontal lines, and the rare elements in their appropriate place along an uncut leaf, a fair picture of the arrangement is given. The rare earths follow each other along a horizontal series with little difference between any two members, but the end members of the series approximate to the ordinary elements found on the extreme right-hand side of the left-hand cover and the left side of the right-hand cover in the same horizontal line as the rare earths. Prof. Masson places hydrogen with the halogens, a position that is at least disputable, though by doing so the inactive gases at once form a complete series. Several properties of hydrogen and the hydrides are held to justify this position and the atomic weight of fluorine is almost the mean between those of hydrogen and chlorine.

Mr. F. H. Campbell described a method for the determination of vapour pressures the principle of which is that a liquid saturated with a suitable gas

(usually hydrogen) is allowed to evaporate into an enclosed space filled with the same gas at the same temperature and pressure. After the volume has been restored to its original value the increase in pressure is recorded on an open manometer.

A new method for determining the specific heat of liquids was described by Mr. E. G. Hartung. It consists in measuring the lowering of temperature of a known amount of the particular liquid on the introduction of a definite weight of dry ice contained in a thin glass bulb, and the method claims attention on account of its simplicity, rapidity, and accuracy, except in the case of viscous liquids like glycerine. The formation of nitric and nitrous acids in the rainfall near Melbourne has been correlated with the weather conditions by Mr. G. V. Anderson, and reveals the fact that the nitrous acid attains a maximum in winter, and a minimum in summer. It further varies with the type of weather, the total oxidised nitrogen attaining a maximum with monsoonal and a minimum with Antarctic conditions.

A joint discussion with the Physics Section on the structure of atoms and molecules has been referred to elsewhere in NATURE. It will suffice here to say that there appears to be a gulf between the views of the physicist and chemist, and little attempt made to bridge it. The former concentrates attention on the internal atomic structure, at present of only secondary importance to the chemist, while on the chemically all-important matter why atoms combine in definite ways to form molecules he has little or nothing to say.

The Melbourne programme was completed with papers by Prof. G. T. Morgan on residual affinity and co-ordination, and by Dr. A. Holt on a comparison of the phenomenon of the occlusion of hydrogen by charcoal and by palladium.

SYDNEY.

A joint discussion with the Agricultural Section on metabolism occupied one day, and was a most successful feature of the sectional programme. It was opened by Prof. H. E. Armstrong, and among the various speakers may be mentioned Mr. A. D. Hall, Mr. Darnell-Smith, Profs. B. Moore, Waller, and J. B. Wood. The discussion covered a considerable field, and for convenience may be divided into three parts. The earlier part was devoted to what may be called the formaldehyde problem and enzyme action. It cannot be said that any very definite conclusion was reached, but many interesting views were put forward, so that though the photo-synthetic processes associated with assimilation may still be said to demand further attention, great advances have been made along this line of research. Enzyme action is a fruitful field for speculation. It may be true, as suggested in the discussion, that for the metabolic synthesis of protein and fat from carbohydrates a linkage and co-ordination of an endothermic with an exothermic reaction is necessary, and that for such synthesis a colloidal regulating mechanism must be furnished by an adsorption of enzymes into the cell protoplasm, but enormous difficulties are presented to the experimental proof of such views, and when we are told that an enzyme being a colloid has its action determined by its previous history, and hence that two portions of the colloid may act differently, confusion and difficulty of proof becomes greater. This part of the discussion was full of interest, for it showed the keen attention that is being paid to those all-important subjects.

Production of fat and skin temperatures was next considered, and the conclusion was reached that though many factors come into play, fat production is associated with low skin temperatures. As the air temperature rises the skin temperature may be higher than that of the internal organs, and hence skin temperatures must not be carelessly employed as an indication that an animal is a good or bad doer, for fat production and internal temperature must also be related.

The discussion was concluded by papers dealing with cyanogenetic plants and distribution of nitrogen in seeds by Dr. J. M. Petrie. It appears that in New South Wales more than a thousand species of plants have been examined for hydrocyanic acids and cyanogenetic glucosides, sixty of them giving positive results, and of these forty-four were native to the State, and represented seventeen natural orders. Some plants which are cyanophoric in Europe do not appear to be so in Australia, whilst in others, the Australian grown plant retains its glucoside to maturity instead of losing it when half-grown. A series of specialised papers, six of which were contributed locally, were read on another day, but it is only possible here to enumerate their authors and titles. Prof. G. T. Morgan, "Non-aromatic Diazonium Salts"; Prof. Robinson, "Researches on the Synthesis of *iso*Quinoline Alkaloids"; Mrs. G. M. Robinson, "Condensation of Cotarnine and Hydrastinine with Aromatic Aldehydes"; Dr. H. McCombie, "Influence of Substituents on the Velocity of Saponification of Phenyl Benzoate"; Dr. A. Holt, "The Colouring Matters of Certain Marine Organisms"; Prof. Fawsitt, "The Corrosion of Iron and Steel by Artesian Waters in New South Wales"; Dr. G. Harker, "The Use of Waste Gases of Combustion for Fire Extinction and Fumigating Purposes"; Mr. S. Radcliff, "The Extraction of Radium from Australian Ores"; Mr. G. J. Burrows, "The Inversion of Cane Sugar by Acids in Water-Alcohol Mixtures."

An experimental lecture by Prof. H. B. Dixon on gaseous explosions and a beautiful demonstration of optical properties of crystals and liquid crystals by Prof. Pope completed the programme. Both were attended by large and appreciative audiences. In conclusion it may be said that the work of the section was in every way successful, and was almost double in amount that at an ordinary meeting in Great Britain. The audiences, too, were good, and though the Australians are so distant from their brother chemists in Europe they exhibit an interest and enthusiasm not always seen in meetings of the section at home.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GLASGOW.—The University Court has framed an Ordinance establishing the degree of B.Sc. in applied chemistry. The curriculum extends over four years, and includes nine full courses of study, of which five at least must be taken in the University or in the Royal Technical College affiliated thereto. After the usual preliminary examination, courses in mathematics, natural philosophy, and chemistry are prescribed, followed by a first science examination. Thereafter the student may pursue courses of study in advanced chemistry, inorganic, physical, and organic; technical chemistry and chemical engineering; engineering drawing; practical physics; and one of certain special branches, such as fuels, dyeing, oils, sugar, biochemistry, and technicological mycology (fermentation). Or, on the metallurgical side, he may take courses in advanced chemistry (inorganic), geology, and mineralogy; engineering and drawing; metallurgy, including fuels; electrical engineering; and one of certain special branches, such as precious metals,

non-ferrous metals, iron and steel, and alloys, and their treatment for engineering purposes. These courses are followed by a final science examination in which special distinction may be obtained in particular subjects. The degree is to be of an honours standard, and will qualify for subsequent admission to the doctorate, on the production of original work of distinction. The Ordinance will be duly submitted for the approval of his Majesty in Council. The joint resources of the chemical departments of the University and the Technical College will make it possible to provide for a complete scheme of instruction and training in preparation for the degree, which will be a valuable qualification for the chemical industries. The step taken by the University is particularly opportune in present circumstances.

DR. T. H. HAVELOCK, F.R.S., has been appointed to the recently created chair of applied mathematics and mathematical physics in Armstrong College, Newcastle-on-Tyne, in the University of Durham.

SIR ROBERT G. C. MOWBRAY, BART., Prime Warden of the Worshipful Company of Goldsmiths, will distribute the prizes at the Sir John Cass Technical Institute on the evening of Wednesday, January 13, 1915, and on the same occasion will open the new metallurgy laboratory for the mechanical testing of metals and alloys, presented to the institute by the Goldsmiths' Company.

THE annual meeting of the Mathematical Association will be held on January 9, 1915, at 2.30 p.m., at the London Day Training College, Southampton Row, London, W.C. The president, Sir George Greenhill, will give an address on mathematics in artillery science, and Dr. W. P. Milne will speak on the teaching of modern analysis, Mr. A. Lodge on circles of curvature, and Mr. R. C. Fawdry on practical work in connection with mathematics.

THE Cambridge University Calendar for the year 1914-15 has now been published. The last issue of the "Calendar" had reached unwieldy dimensions; it contained 1547 pages. The size of the present issue is 1064 pages, and this reduction has been effected in two ways, namely, by transferring some Tripos Lists to "The Historical Register," and retaining only the lists for the preceding ten years, and by treating "The Student's Handbook" as a companion volume and omitting from the calendar the information about examinations which the former book already contains.

THE annual meeting of the Geographical Association is to be held on January 7, 1915, in the Jehangier Hall, University of London, South Kensington. At the morning session, which will begin at 10.30, a lecture will be delivered by Mr. P. M. Roxby on some aspects of the geography of China, and a discussion on the value of surveying in teaching geography will be opened by Messrs. Ernest Young and J. A. White. In the afternoon at 2.30 Mr. Hilaire Belloc will give the presidential address, and afterwards a discussion on the place of map tests in examinations will be opened by Dr. J. F. Unstead and the Rev. W. J. Barton.

IN the recently published report of the United States Bureau of Education for the year ending June 30, 1913, some interesting statistics are provided relating to the 596 American institutions of higher education from which the bureau receives reports. The total sum received in gifts and bequests, excluding grants by the United States, different States, and municipalities, reported for the year was 4,930,392*l.*, showing a decrease of 26,226*l.* Of this amount 895,316*l.* was for increase of plant, 825,980*l.* for current expenses, and 3,209,096*l.* for endowment. Forty-five institutions reported gifts above 20,000*l.* Among the institutions most generously treated, the following may be mentioned: Harvard University, 419,090*l.*; Columbia University 284,361*l.*; Yale University, 283,787*l.*; University of Chicago, 261,586*l.*; University of California, 249,192*l.*; Trinity College, N.C., 240,639*l.*; and Massachusetts Institute of Technology, 214,322*l.* The income of the 596 institutions was during the year from State and municipal grants, 3,809,965*l.*; from invested funds, 3,313,962*l.*; and from fees for tuition and other educational services, 4,183,835*l.*

THE council of the London (Royal Free Hospital) School of Medicine for Women has made a public appeal for the sum of 25,000*l.* to pay for additional buildings urgently needed, and their equipment. The school was the first women's medical school in the kingdom, and since it was opened in 1874 it has been continuously successful. Of the thousand or so women now on the medical register more than six hundred are former students of the school. For its work in the past and to secure provision of sufficient numbers of medical women in the future, more lecture-rooms are essential, as well as additional laboratory accommodation and new research rooms. A site has been secured and plans have been prepared and approved, but funds are needed to pay for the buildings shortly to be commenced. It is hoped that in spite of the many demands made upon national generosity at the present time, there are yet sufficient people interested in the work and medical education of women to provide the 25,000*l.* required. Donations or promises should be sent to the London (Royal Free Hospital) School of Medicine for Women, 8 Hunter Street, W.C., addressed to the hon. treasurer, Mr. M. J. Henderson.

ALDERMAN SIR JAMES HENDERSON, of Belfast, occupied the position of chairman of the Library and Technical Instruction Committee, Belfast, from the inception of the committee until the date of his death in May of the present year, and to his memory a portrait in oils was unveiled in the Municipal Technical Institute, Belfast, on Wednesday, December 9. Sir James Henderson was identified in a very intimate manner with the remarkable progress which technical instruction has made in the city of Belfast, and the development of the corporation education scheme owed much to his unceasing efforts. The portrait was presented by the principal, staff, and students of the institute. It is to be hung in the library of the institute, where—as was said by the principal of the institute in his explanatory remarks at the ceremony—it will be a reminder not only to the present generation, but also to future generations, of teachers and students of the magnificent work that was done by the first chairman of the Technical Instruction Committee and of the splendid contribution Sir James had made to the great cause of technical instruction in Ireland. The Lord Mayor of Belfast (Councillor Crawford McCullagh), who unveiled the portrait, made reference to the many civic activities of the late chairman of the Technical Instruction Committee, adding that the Municipal Technical Institute would in itself be a lasting monument to the fine public spirit and enthusiasm of him who was depicted in the portrait. At the conclusion of the proceedings a booklet, containing a reproduction of the portrait, and also an address given by the principal at the meeting of the staff and students at which the memorial was decided upon, was distributed to the members of the audience. The portrait, which is an admirable likeness, was painted by Mr. W. G. Mackenzie.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, November 27.—Dr. A. Russell, vice-president, in the chair.—A. F. **Hallimond**: Note on the conduction of electricity at point contacts. The "characteristic" or volt-ampere curves given by various "point" contacts when the voltage is slowly varied are dealt with. The curves were plotted by means of a form of rocking mirror galvanometer, which projected the characteristic as the path of a spot of light on the screen, the co-ordinates being respectively proportional to the current and voltage. The first part describes the behaviour of a typical contact, zincite-tellurium. The second part describes the results obtained on examining the characteristics for the forty-five contacts possible between ten chosen substances. The results in all cases are similar to those given by zincite-tellurium. No line could be drawn separating "metallic" contacts from those in which one or both conductors were "crystals." In the third part the conclusion is drawn that in a contact yielding the unilateral (high resistance) curve, the resistance lies within the surface of the member standing higher in the series.—T. **Barratt**: Thermal conductivity of badly conducting solids. The thermal conductivities of typical solids of low thermal conductivity have been determined by the method employed by the author for pure metals and alloys. The substances tested include electrical insulators, such as glass, fused silica, and ebonite, various kinds of wood, and some partial conductors of electricity—viz., carbon and graphite. It has been shown that the thermal conductivity k is given by

$$k=\frac{H^2 \coth^2 al}{pqhV^2},$$

or, where "l" is sufficiently great,

$$k=\frac{H^2}{pqhV^2},$$

Where H is the heat given to one end of the specimen, of length l, perimeter p, and cross-sectional area q; V is the difference of temperature of the "hot" end of the specimen and the enclosure; h is the heat lost from 1 sq. cm. of the surface per second when its temperature is 1° C. above that of the enclosure; and

$$a=\sqrt{\frac{hp}{qk}}.$$

In nearly every case the simpler form of the equation could be used. For the first time in the measurement of thermal conductivity a direct comparison of this quantity in the case of a non-metal has been made with that of a metal—viz., bismuth—the conductivity of which is of the same order of magnitude as those of some of the non-metals. The results agree well with those obtained by Prof. Lees's "disc" method in cases where direct comparison is available.

Geological Society, December 2.—Dr. A. Smith Woodward, president, in the chair.—Prof. T. McKenny **Hughes**: The age and character of the Shippea Hill man. A description of the skeleton, and of the circumstances in which it was found, is given. The mode of formation of the deposit in which the remains occurred is discussed. The Pleistocene deposits of the Fenland were, it is considered, laid down in a depressed river-basin behind a breached seaward barrier. Gravels of the age of *Elephas antiquus* and *Rhinoceras merckii*, as well as gravels of the age of *E. primigenius* and *R. tichorhinus*, occur within the Fenland; but they are distinguishable from the gravels which are sometimes associated with the peat and clay, and pass under them. The fauna also of the peat- and clay-deposits is quite different. In an embayed part of the Fen, close behind the island known as Shippea Hill, the skeleton was found in the peat, a few inches above the clay which is considered to be the equivalent of this Littleport Cockle Bed. When first dug out the skull was in fragments, and the calotte, with its prominent brow-ridges, suggested to many a greater affinity to the Neanderthal type, and a greater antiquity than appeared probable when the rest of the cranium was added to it.—C. **Dawson** and Dr. A. Smith **Woodward**: A bone implement from Piltdown (Sussex). Excavations have been continued in the Piltdown gravel round the edge of the area previously explored. Rolled fragments of highly mineralised teeth of Rhinoceros and Mastodon were again found, but no human remains were met with. The most important discovery was a large bone implement now described. This specimen was found in dark vegetable soil beneath the hedge which bounds the gravel-pit, not far from the spoil-heap whence the right parietal bone of the Piltdown skull was obtained two years ago. On being washed away the soil left no stain on the bone, which was covered with firmly adherent yellow clay, closely similar to that of the flint-bearing layer at the bottom of the gravel. The bone itself is highly mineralised, and agrees exactly in appearance with some small fragments of bone discovered actually in place in the clay just mentioned. There can be no doubt that the implement was found by workmen digging gravel from the adjacent hole, and thrown away with other useless débris. It is a stout and nearly straight narrow flake of bone, 41 cm. long, and varying from 9 to 10 cm. in width, with the thicker end artificially pointed, the thinner end artificially rounded. It appears to be a longitudinal strip flaked from a limb-bone by a blow at the thicker end, in the same way as flint implements were flaked from their original cores. Direct comparison suggests that it was taken from a Proboscidean femur as large as that of *Elephas meridionalis*. In microscopic structure it agrees with Proboscidean bone. The ends of the implement are shaped by cutting, and bear no marks of grinding or rubbing. Most of the cut facettes are small, and many suggest that they were made by a primitive tool, presumably a flint. The rounded end seems to have been trimmed for comfortable handling. The thick pointed (or, rather, keeled) end shows signs of battering or scratching by use. Just above the pointed end one lateral edge of the bone is marked by a large smooth groove running across from the inner to the outer face of the bone. It seems to have been originally a perforation from which the outer wall has been accidentally broken away. Within it on the inner face is the beginning of a second similar perforation, as if an attempt had been made to repair the damage. The conclusion is that the implement is unique, and no explanation of its specific use is given.

Linnean Society, December 3.—Prof. E. B. Poulton, president, in the chair.—R. C. **McLean**: An ecological journey in South America.—C. **West** and Hisayoshi **Takeda**: *Isoëtes japonica*, A. Br. *I. japonica*, A. Br., which has a fairly wide distribution in Japan, is the largest known species of this genus; according to Makino, a diameter of 8 cm. is attained by the caudex of very large specimens. The tri-lobed caudex consists of two distinct structures, viz., *stem* and *rhizophore*, to which the leaves and roots are respectively attached. But owing to the stunted growth of the plant, all external morphological differentiation between the two organs has been completely lost.

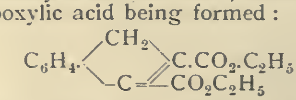
Mathematical Society, December 10.—Sir Joseph Larmor, president, in the chair.—E. H. **Neville**: Simultaneous equations, linear or functional.—Prof. W. **Burnside**: Cyclotomic quinquisection.—Prof. D. **Buchanan**: Oscillations near the isosceles triangle—solution of the three-body problem.—Prof. E. T. **Whittaker**: Larne's differential equation and ellipsoidal harmonics.

CAMBRIDGE.

Philosophical Society, November 23.—Prof. Newall, president, in the chair.—F. A. **Potts**: The colour variations of the fauna associated with crinoids. The commensals of the crinoid *Comanthus annulatum*, which is found in vast numbers on the reefs of Torres Straits, include amongst the Crustacea two species of Alpheids, three Galatheids, a Periclimenes, an Isopod, and an Amphipod. There are also brittle-stars, a polychæt, and many Myzostomids. In most cases the commensals match the host in colour and arrangement of the markings. As the crinoid varies from very light- to dark-coloured types there is also a great variability in the commensals. In the Crustacea there is an alternation of darkly pigmented stripes with non-pigmented areas, and the relative proportions of these vary with the coloration of the host. The phenomenon is best studied in the two species of Synalpheus.—Dr. H. B. **Fantham** and Dr. Annie **Porter**: Some insect flagellates introduced into vertebrates. Insect flagellates, *e.g. Herpetomonas jaculum*, Léger, from *Nepa cinerea*, and *H. ctenocephali*, Fantham, parasitic in the dog-flea, *Ctenocephalus canis*, can live inside certain vertebrates (*e.g.* mouse and dog respectively), and can multiply therein. This the authors have shown experimentally. If such flagellates be inoculated intraperitoneally or are fed by the mouth in food, the flagellates can find their way into the blood-stream and internal organs (*e.g.* liver, spleen, bone-marrow) of the vertebrate host. The insect flagellates are pathogenic to the vertebrates experimented upon, producing symptoms like those of leishmaniasis (kala-azar). The oval, post-flagellate forms appear to be more capable of developing in vertebrate hosts than are other stages of the herpetomonad parasite of the insect. It may be expected that the various leishmaniases, occurring in different parts of the world, will prove to be insect-borne herpetomoniases.—W. R. **Thompson**: Some notes on insect parasites. These notes deal with the question of the cuticula of the Arthropods as a means of defence against parasites. An attempt was made to show that by its thickness and resistance, by the cuticular appendages such as spines and hairs, and by the process of the moult which is in strict correlation with the development of the cuticula, a very considerable part of the parasitic invasion is arrested. The heavy parasitism to which the Arthropoda are often subject was held to be due in part to the fact that many of the parasites are also Arthropods inhabiting the same environment as their hosts, in part to the structure and physiology of the Arthropods themselves, which offer as hosts an environment especially favourable to the development of parasitic organisms.—G. L. **Purser**: Preliminary notes on some problems connected with respiration in insects generally and in aquatic forms in particular. Aquatic insects were separated into two groups, true and false, according as they made use of the oxygen in the pond-water or not. Among the true group were mentioned Sialis, Gyrinus, and the Trichoptera, which have the simplest type of tracheal gill. The Ephemeridæ and Odonata were shown to have lamellate gills in which a pigment, which has been named Spadicin, is present. No explanation of its function has stood the test of facts except a respiratory one, but evidence for this is indirect only. The blood-gills of Chironomus were mentioned, and the question of the origin of a treacheal system and the problem of ecdysis of the tracheal system in true aquatic forms were discussed.—N. **Wiener**: The shortest line dividing an area in a given ratio.

PARIS.

Academy of Sciences, November 30.—M. P. Appell in the chair.—Gaston **Darboux**: The integration of a partial differential equation of the second order with two independent variables.—André **Blondel**: The calculation of the potential energy of a bobbin through which a current is flowing in the case of winding in place. A bobbin is placed in a magnetic field and a wire, carrying an electric current, is wound on this. No induced E.M.F. is produced, and several theoretical deductions based on this fact are given.—E. **Colardeau**: Method for the exact localisation of projectiles in wounded persons by the radiographic method. The method detailed permits the exact localisation of the projectile within five minutes of the measurement of the photographic plates.—Victoriano F. **Ascarza**: The total eclipse of the sun of August 21, 1914, observed by the Spanish expedition at Theodosia (Crimea). Observations were possible of the second and third contacts and the total phase, but clouds somewhat interfered with the work. Photographs were taken with two spectrographs, one fitted with a Rowland grating, the other with a prism, special attention being given to the infra-red region (see p. 432).—P. **Carrasco**: Physical observations made at Theodosia during the total eclipse of the sun of August 21, 1914.—M. **Fournier**: General conditions of aptitude at high velocities of a hull in navigation.—J. **Bougault**: Indene-dicarboxylic and hydrindenedicarboxylic acids. A study of the condensation of benzyloxalacetic ester with sulphuric acid. The reaction is not analogous with the condensation of the lower homologue, phenyloxalacetic ester; the ester of a new indene-dicarboxylic acid being formed:



Proofs of this constitution are given.—René **Régamey**: Cancer in plants. Proofs are given of the existence in plants of a cancerous disease differing from Smith's crown gall, spontaneous in the oak, and inoculable into other plants. It is produced by a bacterium capable of isolation and cultivation in artificial culture media. The parasite is intracellular in the tumours.—P. **Carnot** and B. **Weill-Hallé**: Biliculture in typhoid fever. Two alternative methods of obtaining bile from the patient are described. The cultivation of the typhoid bacilli present in the bile is easy, pure cultures being readily obtainable. The course of the disease can be followed, and the method is especially valuable in tracing the persistence of infection in convalescents and typhoid carriers.—Paul **Godin**: a premonitory sign of pulmonary tuberculosis.—F. **Bordas** and M. **Brocq**: Water supply to armies in the field. It is accepted as fundamental that all water drunk should be previously boiled, and the most practical way of ensuring this is to insist that weak tea should be the ordinary drink. For an army of 1,000,000 men, drinking one litre every twenty-four hours, this implies a daily consumption of 15,000 kilograms of tea. The problems of making and distributing the tea at the front are discussed. The same boilers can supply not only water for drinking but warm and sterilised water for the treatment of the wounded.—L. G. **Seurat**: Precocious copulation in Oxyuris.—A. **Sartory** and Ph. **Lasseur**: Contribution to the study of a new pathogenic Oospora (*Oospora bronchialis*). This new organism was isolated from a case in which the most prominent

symptom was foul-smelling breath and putrid expectoration. The fungus was shown to be pathogenic to the guinea-pig and rabbit, producing bilateral purulent pleurisy. Treatment with potassium iodide caused marked improvement.—F. **Kerforne**: The systematic position of the deposits of iron ore in the lower Ordovician in the region of Châteaubriant.

ROGER BACON AND GALILEO.

(1) *The Life and Work of Roger Bacon.* An Introduction to the Opus Majus. By J. H. Bridges. Pp. 173. (London: Williams and Norgate, 1914.) Price 3*s.* net.

(2) *Roger Bacon.* Essays contributed by Various Writers on the Occasion of the Commemoration of the Seventh Centenary of his Birth. Collected and edited by A. G. Little. Pp. viii + 426. (Oxford: Clarendon Press, 1914.) Price 16*s.* net.

(3) *Dialogues Concerning Two New Sciences.* By Galileo Galilei. Translated from the Italian and Latin into English by Henry Crew and Alfonso De Salvio. Pp. xxi + 300. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 8*s.* 6*d.* net.

THE seventh centenary of Roger Bacon's birth has been happily signalised by the republication in a separate handy volume (1) of the admirable "Life and Work" which the late Dr. Bridges prefixed to his edition of the "Opus Majus"; and by the issue from the Clarendon Press of a collection of essays (2) by eminent specialists, British and foreign, dealing with the different aspects of Bacon's work. To this volume the editor, Mr. A. G. Little, contributes an introductory life, valuable both for its own sake and because the author quotes at length a lucid and judicial estimate of Bacon from a lecture by the late Prof. Adamson.

Dr. Bridges's volume is, perhaps, the best estimate in short compass of Bacon's work and significance. The Oxford essayists follow practically the same order of topics, but treat them in greater detail;—Bacon's indebtedness to Robert Grosseteste (Dr. Baur), his relation to thirteenth century philosophy (M. Picavet), to philology (Dr. Hirsch), the Latin Vulgate (Cardinal Gasquet), mathematics (Prof. Eugene Smith), optics (Prof. E. Wiedemann), alchemy (Mr. Pattison Muir), medicine (E. Withington). Dr. Vogl discusses Bacon's curious theory of the transmission of force in the "De Multiplicatione Specierum"; Prof. Duhem shows wit as well as learning in his amusing history of the principle that nature abhors a vacuum; and Colonel Hime deduces from the ninth, tenth, and eleventh chapters of the "Epistola de Secretis Operibus," unintelligible as they stand, the complete Waltham Abbey formulæ for the refinement of saltpetre and manufacture of gunpowder, by methods which must delight the Shakespeare-Baconians or the admirers of Poe's "Gold Bug."

It is easy to exaggerate Bacon's actual achievements. These masterly essays leave the impression that he made few, if any, positive additions to science. "He gives no evidence of his own proficiency in calculation, nor does he show any conception of the nature of algebra." In geometry "he distinguishes between axioms, postulates, and definitions . . . but he makes no attempt to advance the science or to prove a single theorem." One-fifth of the "Opus Majus" is devoted to optics, but apparently he did little more than reproduce the Arabian tradition through Alhazen, with references to the Greek school of Euclid and Ptolemy. Though he quotes from Philo of Byzantium and Hero of Alexandria the classical experiments of the "chantepleure" and the adhesion discs, he argues the question of the vacuum as a pure Aristotelian and accepts without trial the supposed experimental fact that no power on earth would suffice to lift an inverted glass out of a bucket of water without first tilting the edge to admit air. "On aime à faire de Roger Bacon un adepte précoce de la méthode expérimentale; des pages comme celles-ci nous montrent assez qu'il expérimentait seulement en imagination." It does not do to read into his doctrine of the "Multiplication of Species" a forecast of the wave-propagation of light through the æther; or into the famous passage where he seems to anticipate the steam engine, the aeroplane, and the submarine more than a conviction, quite remarkable for his day, that the proper study of nature would work miracles in the service of man.

Bacon's greatness rests on other grounds. A good Catholic, he was yet of the pestilent class of innovators. He attacked authority. His strong character and original mind set about shaking itself free from the "horse-load" of verbal controversies that filled the schools of his day. He was no mathematician and not much of an experimenter; but it is his immortal glory that he was the first to state explicitly the true method of science, the union on equal terms of mathematics and experiment, with deeper insight than his great namesake who, three hundred years later, thought only of experiment and classification, ignoring the use of deduction. He urged the study of languages and philology in order to provide accurate texts of the Bible and Aristotle, denouncing in unmeasured terms the vices and luxury of the clergy, the stupidity of the philosophers content with their barren summaries and versions by those who knew neither the language of their authors nor the subjects they wrote about. He even dared to find many of the Christian virtues among the wise men of Arabia and the East, and valuable stores of knowledge unknown

to Aristotle. It was the aim of his life to sweep all this intellectual treasure house into the service of the church.

"He was aiming at an enlarged and renovated Catholicism," says Dr. Bridges, "which should bind together and incorporate all that was best and noblest in Hebrew, Greek, and Arabic tradition in the fabric of the Christian Church, for the spiritual government of the world. The keystone of the fabric was supplied by the mistress-science, theology, resting on Mosaic and Christian revelation, consolidated by Aristotelian philosophy, and penetrated by the vital and progressive spirit of natural science."

Profs. Crew and de Salvio have done a great service in their admirable translation (3) of Galileo's less-known dialogues, "Concerning Two New Sciences," *i.e.* strength of materials and dynamics. For though it is Galileo's astronomical work, with its dramatic consequences to himself, which sticks in the popular imagination, he stands among the greatest of the pioneers rather by reason of his advances in mechanics. He was the founder of modern physics, the first to put in practice the method urged by Roger Bacon, where mathematics and experiment go hand in hand.

This book should be in the hands of all teachers and, better still, of all students of mechanics. In the cut and dried text-book, the science leaps to birth full-armed in its panoply of dry propositions; but here we see it emerging step by step at the touch of genius from the very problems of practical life from which it took its rise, and the gain in reality is beyond belief. These are real dialogues, between Salviati, who represents Galileo's views, Sagredo, a wit and scholar, and Simplicio, an Aristotelian philosopher. The conversations are natural, discursive, yet closely reasoned. The Aristotelians are given more than fair play, for Galileo puts into Simplicio's mouth better arguments than they had advanced themselves. The inimitable style, with its lucid simplicity, its flashes of humour and sarcasm, gives the same instant impression of modernity that one gets on dipping after a long interval into one of Plato's dialogues. It loses nothing in the translation, where occasional racy Americanisms—"on time," "cuts no figure," "cut loose from"—seem quite in place.

The lapse of three hundred years is vividly realised in passing from Roger Bacon's scholastic Latin to these conversations that might have appeared in a modern review; from the dim, though explicit, formulation of the true method to its full and easy employment. Here is complete mathematical equipment (of the time) and every deductive conclusion is instantly put to the test of experiment. And surely the experiments are among the simplest and most truly elegant of all time. The guess that the speed acquired by bodies falling down inclined planes between two fixed horizontal levels is the same for all slopes and just sufficient to carry them to the original level *up any slope* (for otherwise a body might be made to lift itself unaided above its level) is tested by the most beautiful experiment of all—where the pendulum is set swinging and when the string is intercepted by a nail fixed at any height, the bob is found always to rise to the same level whatever circle it is compelled to pursue. Here, too, is the immediate inference of the First Law of Motion. For if the slope up which the body travels towards its original level is gradually reduced to the horizontal, *it will never get there*, and will therefore go on for ever, being now under the action of no forces!

There follows the famous discussion of falling bodies. The change of the point of view is at once apparent when the fruitless question *why* they fall is set aside until it is found *how* they fall. Simplicio suggests the natural view that the speed acquired is proportional to the distance fallen. But this is shown to be an impossible form of motion, since it implies that it takes as long to fall an inch as a mile. Is it then proportional to the time? In that case it is shown that the distance is proportional to the square of the time; and this is verified by the experiment of the inclined plane and water-clock. One wonders whether most to admire the theoretical insight or the experimental skill. Gravity, therefore, adds equal speeds in every second, however fast the body is moving. This is at once extended to the case of a body projected *across* gravity, horizontally, and the whole theory of the parabolic path of a projectile is deduced. The dialogues are full of interesting digressions, *e.g.* on various orders of infinity (worthy of modern transcendentalists), terminal velocities, brachistochrones, vibrations of stretched strings, the theory of harmony and discord. What a genius!

There are parallels as well as contrasts between these two great men. Both were so convinced of the value of experience that they sought to learn from common people. Thus Bacon, speaking of Peter of Maricourt:—

"One man I know, and one only, who can be praised for his achievements in this science. . . . He is ashamed that any things should be known to laymen, old women, soldiers, ploughmen, of which he is ignorant. Therefore he has looked closely into the doings of those who work in metals and minerals of all kinds." And again, "They are willing to lower themselves to the level

of husbandmen, of poor women, of children. Many things are known to the simple and unlearned which escape the notice of the wise."

In this spirit Galileo opens his dialogues:—

"The constant activity which you Venetians display in your famous arsenal suggests to the studious mind a large field for investigation, especially that part of the work which involves mechanics; for in this department all types of instruments and machines are constantly being constructed by many artisans, among whom there must be some who, partly by inherited experience and partly by their own observations, have become highly expert and clever in explanation."

Three hundred years again, and Faraday, perhaps Galileo's only superior as an experimenter, writes down:—

"Whilst passing through manufactories . . . we are constantly hearing observations by those who find employment in those places, and are accustomed to a minute observation of what passes before them, which are new or frequently discordant with received opinions. These are generally the result of facts, and though some are founded in error, some on prejudice, yet many are true and of high importance to the practical man. Such as come in my way I shall set down here, without waiting for the principle on which they depend."

This is indeed the scientific spirit, a long, long way from the schoolmen!

Both Bacon and Galileo were good Catholics, and both had sympathisers among the magnates of the Church, including the Popes. Yet both were imprisoned and had their teaching condemned, and both may be said to have forced their own imprisonment. Relying on their protectors in high places they attacked the orthodox teaching of their times, and with characteristic weapons, Bacon with the bludgeon of savage invective, Galileo with the rapier of irony and sarcasm. Yet though suppressed for the moment, their work was not in vain. It was a passage from the "Opus Majus," quoted verbally in Pierre d'Ailly's "Imago Mundi," which Columbus cited as one of his inspirations to the discovery of the New World, and his proposals for the reform of the Calendar bore fruit in the sixteenth century. So, too, when Milton found Galileo practically a prisoner at Arcetri, old, bereaved, grievously ill and blind, it might have seemed that the powers of obscurantism had prevailed. But the very year when he lay broken and dying there was born in Lincolnshire a child, Isaac Newton, who was destined to bring his work to a triumphant conclusion and place him on a pinnacle of glory. You cannot crush the human spirit. In these days we may take courage from these two great men, for even though freedom should be trodden under the iron heel of military despotism, which God forfend, it will revive again, and this time it will not wait three hundred years for its resurrection.

TOOTH OF MAN AND BEAST.

A Manual of Dental Anatomy, Human and Comparative. By Dr. C. S. Tomes. Seventh Edition. Edited by Dr. H. W. Marett Tims and Prof. A. Hopewell-Smith. Pp. vi+616. (London: J. and A. Churchill. 1914.) Price 15s. net.

IF one imagines, for tableau representation, a quickening of the action in the slow-moving epic of organic evolution, a forward position of immense significance was surely in sight when the scaly armour of certain fishes became so elaborated that they went forth muffled in spines to the very lips. And the defence and protection was completed—and something more than these was initiated—when the dermal spines were drawn over the lips and carried into the mouth itself, there to form the beginnings of those wonderfully diversified structures which are known as teeth. Many eminent workers have, along various byways of inquiry, been attracted to, and held by, the study of odontology, and have helped to build up a most noticeable body of scientific knowledge. Tomes's "Dental Anatomy" still holds the field as, perhaps, the most successful effort to gather and arrange the facts, and present them in a "manual" suitable for students and beginners. The author and his editors are to be congratulated upon the production of the seventh edition, in which the make-up is improved by a larger page and type, and by bringing the matter descriptive of illustrations directly under each figure, instead of at the foot of the page.

The desire of the editors "to incorporate in the volume the results of recent research" has not brought about the addition of much new matter. But the ordinary student is not likely to be found grumbling before such a well-spread table; the number of published "note-books" and compilations of the "cram" order that have sprung from the parent work of Tomes shows that he suffers gladly any reduction of bulky fare. The acute controversies that turn upon such problems as enamel formation, dentine innervation, and the homologies of teeth, remain apparently unsettled, and in regard to these and many other disputed points there may be some disappointment that, after the lapse of a decade, the very wide catholicity of Mr. Tomes's interesting discussions

has not now been amended in the direction of more definite leading and instruction. Now and then the accepted facts are so entangled in lengthy argument—of historical interest merely—that the student must have difficulty in picking them out.

The chapter on the development of the jaws is brought up to date by the inclusion of a section prepared by Prof. Fawcett, giving the results of his own recent investigations. The editors may not yet have noticed that the end of this excellent *résumé* is wrongly indicated by misplaced quotation marks. In another part of the same chapter, on p. 237, the omission of "so that" from the beginning of the sixteenth line is probably unintentional. The statement that the first permanent molar of man makes its appearance "about the eleventh year" is an example of the undetected clerical slip that occasionally bears a charmed life through successive editions.

In regard to the difficulty of deciding what teeth may be missing in dentitions that are reduced in number from the so-called "typical" mammalian formula, Dr. Marett Tims has added a useful reminder: "It is doubtful whether the homologies of the teeth, when one or more of the series is absent, can be correctly interpreted from an examination of the skulls of adult animals, whether recent or fossil." In order to determine the position of any tooth vestiges present, a microscopical investigation of the developing tooth should (he says) be made whenever possible. The same writer contributes a series of diagrams which indicate clearly the number of dentitions represented in the various groups of the mammalia.

Mr. Tomes's criticism of the well-known Cope-Osborn theory of the evolution of mammalian teeth has, in the present edition, been qualified by one or two editorial notes presaging a more diminishing belief in the doctrine of trituberculism. Cope's *kinetogenesis* idea of the evolution of tooth forms, either by a sort of plastic yielding, or a stimulus to the formation of new cusps at the points of the greatest wear, can scarcely be thought to have survived the disintegrating objections clearly and restrainedly put forward by Tomes. In the second part of this edition, the arrangement of the orders has been altered and brought somewhat nearer to a logical sequence. The teeth of primates are dealt with in the last chapter, and here are placed tentatively—yet with a painstaking attention to the honourable rights of precedency—the five or so known types (including the recently-discovered *Eoanthropus dawsoni*) that lie upon or near to the line of descent of later man. Adjudgment of the conflicting claims of these "poor relations" to be the direct ancestors of modern man is a most difficult matter. The subject is naturally a widely attractive one, so that when discussions of it are forward even those not ordinarily concerned with dental science will prick an ear and often draw near to take a hand. But when, as often happens, the clues to the interpretation of fragmentary remains of man or animal have to be sought mainly in the imperishable teeth, the very fullest available knowledge of all the tooth tissues must be applied to the problem.

In the sifting and evaluation of evidence, many of Tomes's discussions are models of scientific criticism. His handling of debatable subjects is marked also by a literary style of charm and flexibility, in which he moves smoothly and easily forward towards a concentration on the essential or significant points. It can safely be said that responsibility for the editorship of this new edition has fallen into competent hands. While that is so, many will hope that Mr. Tomes may continue to hold at least a watching brief for odontology.

ECONOMIC ENTOMOLOGY FROM WEST AND EAST.

(1) *Manual of Fruit Insects.* By the late M. V. Slingerland and C. R. Crosby. Pp. xvi+503. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 8s. 6d. net.

(2) *Indian Forest Insects of Economic Importance: Coleoptera.* By E. P. Stebbing. Pp. xvi+648+lxii plates. (London: Printed by Eyre and Spottiswoode, Ltd.; sold by Constable and Co., Ltd., and others, 1914.) Price 15s.

(3) *Crop Pest Handbook for Behar and Orissa (including also Western Bengal).* Department of Agriculture, Behar and Orissa. Pp. xxiii+Leaflets 84+Appendices 21+plates liv. (Calcutta: Thacker, Spink and Co., 1913.) Price 4 rupees.

(1) STUDENTS of applied entomology all the world over remember gratefully the late Prof. M. V. Slingerland, whose writings in the Bulletins of the Cornell University of Ithaca and elsewhere, form a storehouse of information on insect life-histories and on practical means for destroying pests. And now Mr. C. R. Crosby has completed the pious task of editing a quantity of manuscript left unfinished by Slingerland when, five years ago, he was taken from us. The result of this collaboration is a handy volume in which two hundred species of orchard insects common in the United States are described and figured. In the space allotted the descriptions are

necessarily brief, but many facts are conveyed in short paragraphs—thanks to a plain and effective style—while references are given to special memoirs. As might have been expected, the literature quoted is entirely American, though not a few of the insects described are common European pests on which some useful observations have been made on this side of the Atlantic. European workers, however, will be glad to have the American experience with regard to these species, and to others which are near allies of common "old-world" kinds. The few pages of "general considerations" on the structure of insects are the weak part of the book; it is disappointing to see the cuticle called a "shell" on p. 2 and a "skin" on p. 5. The concluding chapter deals with the practical use of insecticides. Illustrations comprise nearly four hundred figures, some of which are reproductions of excellent drawings, while the rest are photographs of somewhat unequal value. Indeed, examples of extremes of merit and demerit in natural history photography might be drawn from this volume.

(2) Mr. E. P. Stebbing, who not long ago left the Indian Forest Service to become head of the Forestry Department of Edinburgh University, has provided in this handsome volume a worthy monument of his work in the East. His "Manual of Elementary Forest Zoology for India," published in 1908, was noteworthy for many original observations on the life-history of Indian forest beetles. The present work—a large royal octavo of more than 600 pages, with 63 plates and 400 text-figures—is entirely devoted to those Coleoptera which are known to be of economic importance in Indian forests. The arrangement is systematic, the large series of beetles described being set forth by their families; it is to be regretted that the grouping of the families is that given by Dr. D. Sharp in the "Cambridge Natural History," a grouping the convenience of which does not atone for its artificiality. In the details of his systematic work Mr. Stebbing has wisely sought help from a number of specialists, for no one man can nowadays deal effectively with all the members of a great insect order from an extensive tropical region. Messrs. C. J. Gahan and G. Arrow of the British Museum, Mr. G. Lewis, Col. F. W. Sampson, Mr. G. A. K. Marshall of our Imperial Bureau, M. P. Lesne of the Paris Museum, and M. G. Severin of the Brussels Museum are among those who have identified, and where necessary described, specimens of their favourite families. The classificatory work may therefore be relied on, and with Mr. Stebbing's accounts of life-histories, habits, effects of the insects on trees, and relation of the insect fauna to the forests in a wide sense, a mass of valuable information is here gathered for the Indian student of the present and the future. As to the illustrations, most of the photographic reproductions are beautiful, and, with the exception of a few rough sketches, the drawings may be highly praised.

(3) A volume consisting of a number of leaflets, briefly describing common crop pests of Behar, Orissa, and Western Bengal is introduced by a preface by Mr. E. J. Woodhouse; he tells us that the work has been compiled by Mr. S. K. Busu, who is responsible for the few fungi that are included, and Mr. H. L. Dutt, who deals with the insects. Among the latter the presence of *Pieris brassicae*, *Aphis brassicae*, and other well-known British crop-pests is interesting. The leaflets are of quarto size, each being illustrated by an admirably printed coloured plate. These plates, which, we are told, "have not been previously published, but are intended for use in memoirs in course of preparation by the Imperial Entomologist," will doubtless make it easy for the Indian farmer to identify his insect enemies. They will also prove of no little service to the working entomologist.

G. H. C.

TEXT-BOOKS OF CHEMISTRY.

(1) *Chimie Physique Elementaire*. By E. Aries. Tome Premier. Les Principes Generaux de la Statique Chimique. Pp. xxx+212. (Paris: A. Hermann et Fils, 1914.) Price 4 francs.

(2) *A Manual of Practical Physical Chemistry*. By Dr. F. W. Gray. Pp. xvi+211. (London: Macmillan and Co., Ltd., 1914.) Price 4s. 6d.

(3) *Notes on Elementary Inorganic Chemistry*. By F. H. Jeffery. Pp. iv+55. (Cambridge University Press.) Price 2s. 6d. net.

(4) *The Elements of Chemistry*. By H. L. Bassett, with an introduction by Prof. W. J. Pope. Pp. xii+368. (London: Crosby Lockwood and Son.) Price 4s. 6d.

(5) *Chemical Calculations*. Pp. vi+136. *Chemical Calculations (Advanced Course)*. Pp. vi+48. By H. W. Bausor. (London: University Tutorial Press, Ltd., 1914.) Price 2s. and 1s. respectively.

(6) *The Fixation of Atmospheric Nitrogen*. By Dr. J. Knox. Pp. vii+112. (London: Gurney and Jackson, 1914.) Price 2s. net.

(1) THE French text-book of physical chemistry would scarcely be regarded in this country as justifying the author's description of it as "elementary." It is essentially an exposition of the work of Willard

Gibbs, with additional theorems and applications developed by the author. Although the book deals with such familiar subjects as chemical equilibrium, the laws of mass action, the phase rule, and osmosis, it does not descend to the discussion of experimental facts, and contains no illustrations of apparatus, no tables of data, and none of the usual graphical representations of equilibria. On the other hand, the mathematical treatment of the problems is very thorough and exact. The book will not be likely to attract the average chemist, who prefers to make use of theories only when they can be kept closely in touch with experiment; but a student who had taken an "honours" degree in mathematics would probably enjoy a course of chemistry in which theory reigns supreme and the limitations of experiment are thrust into the background, or perhaps postponed to a later volume of the series.

(2) Dr. Gray's "Practical Physical Chemistry" contains a series of thirty-nine exercises, which may be carried out by individual students in periods of two to three hours. It is undoubtedly one of the best books of the kind that has yet been published. The exercises deal with real problems and with real apparatus, in a way that should bring the student into touch with modern methods of exact measurement, and make it easy for him to proceed to original work in physical chemistry if the opportunity should arise. The preliminary discussion on "Accuracy" is particularly welcome, and should provide a useful check on the slovenly and inexact measurements which are the chief menace to the success of a course of experimental work in physical chemistry.

(3) Mr. Jeffery's "Notes" are a series of summaries of the data that are necessary for answering ten of the questions that are most commonly set in examinations on chemistry, *e.g.* on acids, salts and bases, oxides, oxidation and reduction, electrolysis, etc. To the student preparing for examinations the advantage of having these data in a compact form will be obvious, though he might well expect to find most of the information in a general text-book. The compilation has been done carefully, and criticism may be confined to points of detail. Thus, it is curious to find no reference at all to the sour taste by which acids first acquired their reputation, although their action on litmus and their electrolytic properties are described; the reader is also not told whether the solubility of metallic hydroxides in caustic alkalies brings them within the category of acids or not. It is, however, satisfactory to find that the author has realised the difficulty of *defining* acids, salts, and bases, and is for the most part content with *describing* their characteristic properties; such a description might well be made into a historical statement showing the gradual development of the idea of an "acid" in the hands of Lavoisier, Berthollet, Gay Lussac, and Laurent, and of a "salt" in the hands of Boyle, Lavoisier, Berzelius, Laurent, and others. In dealing with students, it is a pity to allow them to "obtain" common salt by mixing caustic soda and hydrochloric acid, and to regard this as a "preparation" of the salt; an exercise on the recrystallisation of rock salt or the extraction of common salt (and Epsom salts) from sea-water would be of greater value, and much more in touch with reality.

(4) Mr. Bassett's book is intended for medical and dental students who require to obtain within the course of a single year some knowledge both of inorganic and of organic chemistry. The requirements of such a syllabus are in no way incompatible with a sound scheme of instruction; the study of alcohol, for example, affords excellent material for explaining methods of purification, tests of purity, and the fundamental principles of analysis in a course of general chemistry. Roscoe's "Lessons" may be quoted as a very successful example of a combined course of inorganic and organic chemistry; but the medical student of the present day has been somewhat badly served in the matter of text-books, and Mr. Bassett's book is an attempt to fill a gap that is recognised clearly by those who are responsible for the teaching of medical and dental students.

In spite of certain merits that the book possesses, it is doubtful whether it will secure any extensive foothold in the medical schools. Actual experience shows that it is a mistake to discuss the periodic classification of the elements before any of them have been studied in detail. Moreover, this classification is not a suitable basis for an introductory study of the elements. The author has boldly adopted it, and described the elements in the order in which they occur in Mendeléeff's table. He therefore postpones the consideration of oxygen and chlorine until all the metals, except those of the iron-group, have been described. Here again, as experience shows, he has made a fatal mistake, and not one student in a hundred is likely to benefit by using the scheme which the author has adopted.

Whilst most of his statements are accurate, the author has admitted several errors, from which the student might reasonably expect to be protected. He would be unwise, for example, to assert with the author that barium monoxide is prepared by heating the carbonate, or that in a combustion oxygen is *drawn* through the ap-

paratus. The definitions of acids, bases, and salts are novel, but altogether bad. If they could be taken literally, they would include amongst the bases such diverse substances as oxygen, phosphorus, potassium permanganate, sugar, alcohol, camphor, benzene, toluene, formic acid, oxalic acid, since all these substances can "react with an acid, giving water as one of the products." Amongst the "salts" one would find chlorine, phosphoric acid, oxalic acid, ethyl acetate, ethylene, ether, camphoric acid, nitrobenzene, benzoic acid, carbon monoxide, and carbon dioxide, since each of these may appear in the guise of "substance, other than water, produced by the reaction of an acid and a base," as defined in the opening sentences of the chapter.

(5) Mr. Bausor's two books on chemical calculations may be commended on the ground that the problems bear a very close resemblance to those that would be met with in the actual experience of a chemical worker. No further commendation is needed except to say that the range of subjects and the working out of typical problems are alike satisfactory. The only improvement that may be suggested is to the effect that greater interest would be aroused and more useful information imparted incidentally if the author had drawn more freely on numerical data taken from classical experiments, such as those of Berzelius and of Stas, together with more modern experiments by Morley, Richards, Morse, Guye, and others.

(6) Dr. Knox's monograph on the fixation of nitrogen includes a great deal that has become very familiar in recent years, but the subject has been treated in a very satisfactory way. In addition to the well-known details of the Birkeland-Eyde process, ample space is devoted to the theory of the operations and to the many scientific experiments that have been made to elucidate them. The section on the ammonia equilibrium is particularly welcome, in view of the fact that this method of fixing nitrogen has been exploited in the technical Press to a much smaller extent than the processes described in the other two sections of the book. It is not usual to permit any detailed study of technical processes in an elementary course of chemistry, yet nothing but good would result if this little monograph were added to the curriculum of such a course; the problems with which it deals are so important and the underlying theories are so illuminating that they might well be used to add an element of romance and a new interest to the oft-told story of elementary inorganic chemistry.

T. M. L.

OUR BOOKSHELF.

Pattern-making. By F. W. Turner and D. G. Town. Pp. v+114. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 4*s.* 6*d.* net.

This little book is intended for young pattern-makers, and presents a general survey of the most suitable materials, the special tools, and the fundamental processes of the trade, together with the relations of the pattern-shop with the allied departments, viz., the drawing office, the foundry, and the machine shop. The pattern-maker is principally concerned with the foundry, and throughout the book we find clear and concise descriptions of moulding processes, well-illustrated, together with discussions of the sometimes conflicting requirements of the moulder and pattern-maker, and explanations of the compromises which have to be adopted. In recent years the development of machine tools, both in the foundry and in the pattern-shop, has altered considerably the art of pattern-making and also the stock of hand-tools composing the private equipment of the artisan.

The book contains many interesting devices which have been developed by American workmen for special purposes, and in this respect will be found to be of considerable interest even to older pattern-makers in this country. A special word may be said regarding the illustrations in the book; these are excellent, both as regards the selection of typical examples and also clearness of drawing and reproduction.

We can confidently recommend the book to young pattern-makers and others connected with engineering, not that it will make them good pattern-makers—experience alone will produce this result—but on account of the broadening of views which is sure to be acquired during the perusal of its pages.

Foundations: a Short Text-book on Ordinary Foundations, including a brief description of the methods used for Difficult Foundations. By Prof. M. A. Howe. Pp. vii+110. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 5*s.* 6*d.* net.

In this book the author has treated in an elementary manner both the fundamental principles involved in the design of foundations and also standard methods of carrying out the actual work. Special treatment is given of the footing courses of structures, these being considered apart from the foundation proper. The Rankine theory is adopted for the permissible bearing pressure on soils, and a modified form of Rankine's formula is given; there is a brief discussion of the precautions which must be considered in dealing with various descriptions of soil. Several different methods of construction in the footing courses are given, such as concrete, brick, reinforced concrete, grillage, I beams, and cantilevers; these are clearly described, and the student will have no difficulty in following the methods of calculation. A feature of the book consists in worked-out examples of each case; these will be found to be of

great service to the reader. The treatment of the design and driving of piles is good and up-to-date, as is also that of bridge piers and abutments.

The book possesses the merit of presenting a fairly complete exposition of a rather difficult subject without unnecessary profusion of detail, and will be welcomed by many students who desire more information regarding foundations than is to be found in the text-books dealing with the theory and design of structures generally.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

The Camera in Australia.

Now that most members of the overseas party of the British Association have, happily, returned safely from the meeting in Australia, it seems opportune to remind members of the scheme for the exchange of photographic prints announced in the *Journal* (issued in Melbourne on August 12, 1914, p. 2), for which Dr. A. Holt and myself became responsible. The aim of the scheme was to economise our stock of plates and to prevent unnecessary duplicating of prints. Thus in the advance party in West Australia one member took a photograph of one striking object, a second member of another, on the understanding that all members of the party would be able to obtain, at their own expense, copies of the prints of the photographs, either by an exchange of photographic prints taken by themselves or by payment of the cost of the print supplied. It was an essential feature of the scheme that the photographers themselves should not suffer financial loss in meeting the requests of members for prints.

The scheme is sufficiently comprehensive to include not only illustrations of plants, animals, and scenery, but also of any features appealing to members specially interested in any one of the many Sections of the Association's activities. Thus timber felling, aboriginal camps and their life, manufacturing processes, as well as the lighter side of our visit, such as life on board ship and garden-parties, come within the scheme of exchange. In fact, if any member has photographs of interest taken either in Australia or on one of the many routes members followed to and from Australia it is hoped he will be willing to offer prints of the same to others. Though the scheme was intended in the first instance to apply to members of the overseas party and to local members of the Australian meeting, there is nothing to prevent it from developing so that members of the Association who were unable to attend the meeting may have the opportunity of obtaining a set of the photographic prints offered for exchange.

Will members willing to participate communicate with me as soon as possible? In each case a list of the prints available, together with the address of the supplier and the cost of the prints, should be given. It would be helpful if a set of the prints could also be sent for inspection and subsequent return.

From these lists a general list will be prepared and sent to each participator in the scheme. It will probably be an advantage to all concerned if the exchange is worked from one centre. This we shall be willing to undertake in the hope that all will co-operate by promptness of reply in making the task as light as possible.

It is hoped that the series of prints will serve not only as a permanent record of our unique and delightful experience, but also as illustrative material for teaching, lecture, and museum purposes. Thus members could at this moment help many deserving charities by giving lectures on Australia with these prints for illustration. T. Johnson.

Royal College of Science, Dublin.

Magnetic Disturbances, 1913.

Dr. W. N. Shaw has asked me to send you an account of an examination, undertaken by his instructions, of the Eskdalemuir magnetograms for 1913. The examination indicates that the disturbances from the level of the quiet day inequality fall into two distinct classes A and B.

A.—The disturbance was due to a magnetic force which remained in a more or less fixed direction while changing sign in an oscillatory manner. Throughout the year the direction of this force had an azimuth lying within a range of about 60° on either side of the magnetic meridian and an inclination to the horizontal lying within the narrow limits 0° and 6°. The slope was upwards towards the more northerly end. An especially clear example occurred on March 23d., 14h. to 18h.

Pulsations of periods 2 to 15 minutes fall into this class. A search also brought to light longer periods of 19, 23, and 26 to 30 minutes. Beyond this there are measured periods of 180, 155, 148, 109, 100, 95, 85, 80, 80, 78, 74, 66, 60, 38 minutes, but the measurements have been uncertain to, say 15 per cent., and should perhaps be taken only to indicate the existence of actual periods near 79 minutes and between 150 and 180 minutes. The crowding together of the shorter periods of 2 to 15 minutes is suggestive of a harmonic series. The longest periods noted were recorded on the afternoons or evenings of June 17d., 21d., 23d., July 9d., 10d., 12d., 15d., 18d., 25d., August 7d., 9d., 11d., 28d. Class A appears to resemble the type of disturbance that Birkeland has attributed to a ring-shaped electric current encircling the earth at a great height above the ground in the plane of the magnetic equator. The periods noted above are enormously greater than the time (0·13 second) taken by an electromagnetic wave to travel round the earth. Similarly the wave-length of sodium light is enormously greater than the circumference of the sodium atom. Can there be a similarity of explanation in the two cases?

B.—The direction of the disturbing magnetic force was not fixed as in class A, but wandered about, usually remaining within 60° of a plane normal to the undisturbed force. The large, slow "bays" near midnight usually fell into this class. For example, the bays on October 7d., 0h. to 4h. Sometimes the disturbing force rotated as if it were rigidly attached to an axis nearly coinciding with the direction of the undisturbed force; the rotation was clockwise to an observer looking north and down. Class B appears to resemble the types of disturbance which Birkeland has called "polar" and "cyclo-median."

Class A disturbances sometimes occurred without class B, but class B seldom occurred without A.

Disturbances of the A class were identified by viewing the traces of the components laid over one another and pressed against a window-pane. The correspondence of the oscillations in the three components determined the matter.

Further particulars will be published in the British Meteorological and Magnetic Year Book, part iv. 2, 1913.

It will be interesting to know whether other observers have found corresponding phenomena in working up records for 1913. L. F. Richardson.

The Observatory, Eskdalemuir, Langholm, Dumfries-shire, December 11.

THE QUATERNARY ICE AGE.[1]

THIS handsome volume is a notable contribution to the voluminous literature relating to glacial geology. Its scope is comprehensive, for it describes in a crisp and lucid form the succession of Glacial and post-Glacial deposits in Europe and North America, the living and extinct Quaternary mammals, the successive stages of culture of Palæolithic and Neolithic man, the various theories of the cause of the Ice age, and the isostatic theory of the Quaternary oscillations of sea-level. Much controversial ground is traversed in this wide field. Throughout the volume the author maintains a critical attitude and expresses his opinions freely. His chief aim has been to set forth what he regards as the solid basis of fact which throws light on the history of this fascinating epoch. Hence he discards classifications which, in his opinion, are not supported by conclusive evidence.

At the outset the potency of glacial action in modifying the surface features of a country is recognised. In proof of this contention reference is made to the over-deepening of valleys, the formation of mountain corries, the recession of corrie cliffs by sapping, and the excavation of rock basins due to differential erosion in harder and softer rocks. In the preliminary account of the Glacial drifts the opinion is expressed that many erroneous conclusions regarding the retreat and re-advance of the ice and the occurrence of inter-Glacial periods have been based on intercalations of sand, gravel, and clay between sheets of Boulder Clay. The so-called "Upper Boulder Clay," in many instances, may be merely englacial moraine, which settled down on sub-glacially-formed sediments on the disappearance of the ice. On the other hand, it is admitted that, where these intercalated deposits preserve their horizontality over wide areas, they probably point to retreat and re-advance of the ice. Their inter-Glacial value must be determined by local circumstances.

The author's attitude towards the inter-Glacial question is clearly defined. He is of opinion that the elaborate systems of the older inter-Glacialists may all be set aside as unproved, and that we ought to accept the mono-Glacial hypothesis until we can prove one inter-Glacial period. Nevertheless instances are adduced which prove oscillations of climate of more or less magnitude. The recent researches of Victor Madsen, Nordmann, and Harz on the Cyprina Clays of Denmark, North Germany, and Holland, furnish satisfactory evidence. These fossiliferous deposits occur as transported masses in the Boulder Clay in the east of Denmark and north of Germany, while to the west and south of these areas they are to be found in their original position, resting on Boulder Clay and fluvio-Glacial gravels. Therefore they cannot be pre-Glacial. They must have been laid down during a period of recession of the ice. In view of the width of the belt containing transported masses of these Eemian deposits in the Boulder Clay of the Baltic ice sheet, the extent of the recession cannot be less than fifty miles. But the presence of well-marked southern species in the marine fauna may indicate a greater recession, and probably the complete disappearance of the ice. These investigations confirm the opinion of Prof. James Geikie and others who assigned these deposits to an inter-Glacial period.

The series of Glacial and inter-Glacial periods worked out by Penck and Brückner in the Alps is adopted. Special allusion is made to certain inter-Glacial deposits proving oscillations of climate, such as the "Höttinger Breccia," the "Schieferkohlen" of Dürnten, the plant-bearing beds of Re and Pianico, all of which are doubtfully referred to the Riss-Würm inter-Glacial period. It is further shown how the evidence from plant remains is confirmed by the Quaternary fauna occurring in Alpine lands; the twofold repetition of the arctic fauna comprising the mammoth, woolly rhinoceros, and reindeer, being separated by the inter-Glacial fauna with *Elephas antiquus*, Merck's rhinoceros, and the red deer.

FIG. 1.—The Arctic Fox (*Vulpes lagopus*) in winter coat. From a specimen in the British Museum. From "The Quaternary Ice Age."

In the description of the American drifts the classification presented is not so comprehensive as that of Prof. Chamberlin. It begins with the Kansan Till sheet and ends with the later Wisconsin Boulder Clay. The cautious attitude of the author in dealing with the classic Don valley

[1] "The Quaternary Ice Age." By W. B. Wright. Pp. xxiv+464. (London: Macmillan and Co., Ltd., 1914.) Price 17s. net.

section near Toronto scarcely does justice to the evidence indicating great climatic changes so well described by Prof. Coleman.

In England, only one out of many so-called inter-Glacial deposits is considered to have stood the test of critical examination, viz., the shell-bearing clay of Kirmington, which is overlain and underlain by Boulder Clay. It indicates a recession of the ice-margin between the periods of deposition of the purple and Hessle Clays, when the sea stood at a higher level in the estuary of the Humber than it does at present. The sequence of the drifts, the oscillations of the ice, the westward shifting of the centres of glaciation, and the theory was first advanced by Dr. Jamieson to account for marine sediments of late Glacial age in Scotland. He believed that the earth's crust sank under the weight of ice and rose again when the ice disappeared. The author argues with much ingenuity that the late-Glacial and post-Glacial changes of level in Scandinavia may be accounted for by isostatic recovery from the effects of ice-load combined with a single oscillation of the sea-level.

This volume will be useful to students as a synopsis from a particular viewpoint of modern research in Quaternary geology. The illustrations deserve special mention. In selection and

Photo.] [*R. Lunn.*
FIG. 2.—Section of glacial sand and gravel resting on Boulder Clay on the river Spey, opposite Rothes, Banffshire, Scotland. From "The Quaternary Ice Age."

Glacial drainage as worked out by Mr. Lamplugh, Prof. Kendall and others is clearly set forth.

The classification of the culture stages of Palæolithic man is based on that of G. de Mortillet, and of Neolithic man on that of Montelius. Special emphasis is laid on the great break between the Palæolithic and Neolithic industries of Europe. The transition phases (Campignien, Tardenoisien, and Asylien), which are supposed by archæologists to bridge this gap, fail to demonstrate a passage between the two.

One of the most interesting chapters in the volume is that dealing with the isostatic theory of the Quaternary oscillations of sea-level. This execution they are excellent. Two of them (Figs. 1 and 2) are here reproduced. JOHN HORNE.

WIRELESS TELEPHONY.

THE system of wireless telephony upon which Capt. Colin and Lieut. Jeance, of the French Navy, have been at work for some years has recently been considerably improved, and some very successful experiments were carried out last June, when, during some tests in which long-distance communication was established in France by means of an aerial only 164 ft. high, speech was incidentally overheard on a small amateur installation in Lincolnshire. The continuous

waves used for transmission are produced by three arcs connected in series. Each has a negative electrode or carbon only 1·5 mm. diameter, and a copper disc negative electrode above it, which forms part of the bottom of a cylindrical tank filled with paraffin and cooled by water circulation. The carbon electrodes are beneath this disc, and their height is regulated by means of a crank outside the arc chamber. The arcs, which are very short, burn in an atmosphere produced by mixing acetylene and hydrogen generated from calcium

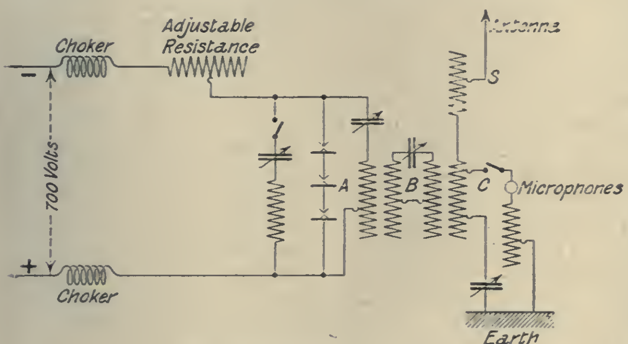

FIG. 1.—Diagram of connections.

carbide and calcium hydride respectively, and this not only prevents the burning away of the carbons, but actually increases their length slightly during operation.

A 750-volt dynamo supplies the three arcs in series, and there is means to regulate its pressure between 500 and 750 volts. Two choking coils (to prevent high-frequency currents from flowing back to the dynamo) and an adjustable resistance reduce the voltage at the terminals of the three arcs to between 250 and 350 volts. A current of from $3\frac{1}{2}$ to $4\frac{1}{2}$ amperes is employed.

FIG. 2.—The microphone and megaphone.

The diagram (Fig. 1) shows the connections of the microphone and the oscillatory circuit. The principal oscillatory circuit consists of an inductance and variable condenser, connected in parallel with the arcs A. An intermediate oscillatory circuit B, consisting of an inductance and variable condenser, is utilised to couple the principal circuit with the aerial, and ensures that multiple waves generated in the main circuit are not transmitted to the aerial, the result being that only a single wave is emitted. The aerial circuit consists of an inductance coupled with the circuit B and a variable condenser. A variable self-induction is also used in the aerial.

In the microphone circuit are nineteen carbon microphones connected in series, and so arranged that they are all acted upon by the voice simultaneously by means of a megaphone. The microphone and megaphone (drawn to different scales) are seen in Fig. 2; the large end of the megaphone covers the microphone. The microphone cells are connected between the variable inductance of the oscillation transformer and earth, as shown at C. This has the double advantage of avoiding sparking, such as always occurs in the microphones when they are placed directly in the aerial circuit, and does not limit the energy which can be taken by them. The station has two complete microphone equipments, with a change-over switch, so that each can be used for a short time and the other microphone allowed to cool, as naturally very large currents are employed.

The transmitting coils consist of flat spirals of copper strip, and the condensers are of the glass-plate type. Arrangements are provided for very exact tuning by means of variable air condensers. The wave-length of transmission can be varied between wide limits; in the official tests a wave-length of 985 metres was used.

HIGH EXPLOSIVES IN WARFARE.

AT the present time explosives are playing such a prominent part in the war that the interest and attention of the most peace-loving citizen are necessarily aroused by the terrible results undoubtedly produced, or are more morbidly affected by the tales of the alleged marvellous effects which are yet to be experienced. A few notes on the most important explosives being used in war may therefore be of special interest just now.

The explosives which can be advantageously employed in warfare are by no means the most powerful which the chemist can produce, or which may even be used in civil engineering or mining operations. The military high explosive must be sufficiently insensitive to shock to prevent its being exploded when struck by projectiles, or when submitted to the shock of being fired from a gun as the charge of shell, else it might prove as dangerous to the user as to the enemy. Thus the nitroglycerine class and many other explosives are excluded.

For many years gun-cotton, containing a considerable amount of moisture, was largely used for naval and military purposes. In the moist state it is extremely safe, but can be easily detonated when a small primer of dry gun-cotton is fired in contact with it. The explosive effect is great, and it provided an excellent and safe explosive for military mines and purposes of destruction, and as a charge for torpedoes. It was not, however, suited for use in shells.

The high explosives chiefly being used in the present war for shell-filling are picric acid, trinitro-

toluol, and ammonal. Picric acid, with or without the admixture of various ingredients, has been in use at one time or another in most countries under the names of melinite, lyddite, shimose powder, etc. Until picric acid came into use, black gunpowder formed practically the only explosive used as a bursting charge for shells, and the use of picric acid was a great advance from the destructive point of view, as its explosive power was very much greater. Picric acid, although sufficiently insensitive to shock, has the property of readily attacking metals and forming picrates, which are much more sensitive and liable to explosion. This involves special precautions in dealing with it, and is an undoubted disadvantage.

Ammonal is a mixture consisting of ammonium nitrate, trinitrotoluol, charcoal, and aluminium in fine powder. It is very safe, and is more powerful than picric acid, but owing to the hygroscopic character of ammonium nitrate, its chief constituent, it has specially to be protected from moisture, which reduces and, if in sufficient quantity, destroys its power of explosion. It is largely used by the Austrians.

Trinitrotoluol is undoubtedly now the most widely used high explosive for military purposes under the names of "Trotyl," "Tritolo," "Tolite," "Tritol," "Trilite," and "T.N.T.," according to the nation using it.

"T.N.T.," as it is called in the British Service, has attained its position by virture of its merits. It is used in a state of great purity; it is chemically stable and without action on metals. It is unaffected by water, and can be fused and run into shells in the molten state. It is less sensitive to shock than picric acid. Hard blocks of suitable size and shape are covered by electro-plating them with a coating of copper, which prevents the blocks from being broken and having their edges chipped. In this form "T.N.T." is used for demolishing bridges, etc. Although not quite so powerful as picric acid, its other advantages make it at present perhaps the best available explosive for military use.

The destructive effect of an explosion is caused by the almost instantaneous conversion of the solid explosive into gases, at a very high temperature, with consequent sudden exertion of an enormous pressure. From the purely disruptive point of view, the composition of the gas produced is not necessarily of importance, the determining factors being the volume of gas, the heat produced, and the velocity of detonation. When however an explosion takes place in a confined space, then in addition to the disruptive or shattering damage, the components of the gas produced may have an injurious effect on anyone having to breathe it.

In the case of explosives for use in civil life, as in mining work, care is taken by adjusting the composition of the explosive that the gases produced shall not have a deleterious effect on the miner. In military operations this consideration does not arise; indeed, it may be maintained the more deadly the effect of the fumes the better.

Picric acid and "T.N.T." are definite chemical bodies, but owing to insufficiency of oxygen are not completely converted into gas on explosion, a considerable amount of carbon being set free. This accounts for the black smoke which is seen when these bodies are exploded.

In the earlier determinations, when explosives which contained insufficient oxygen for complete oxidation of the carbon and hydrogen were fired in a closed bomb, and the resulting gas analysed, it was found that its composition was affected by the density of loading. The higher the density of loading the higher the pressure, accompanied by increase of carbonic acid and decrease of carbonic oxide. Methane, which was absent or only in very small quantities at low densities of loading, increased steadily as the pressure increased. It was, however, recognised that the composition of the gas so found did not necessarily represent the composition at the moment of explosion, for the analysis was made some time after and when the gas had cooled. Consequently reactions had probably been taking place during the process of cooling. Finally, it was thought that the formation of methane was not a real result of explosion, but was due to secondary reactions during the cooling stage. The experimental difficulties of catching and fixing the gases at the moment of explosion were overcome by detonating the explosive in its own volume in a lead or porcelain bomb placed inside a larger evacuated steel bomb. The explosive had in this way to do work in bursting the smaller bomb, and the rapidity of cooling of the gas was thus so greatly increased that secondary reactions practically did not take place. When fired under these conditions, which correspond closely to those which exist when a shell explodes, the gases from ammonal, picric acid, and "T.N.T." were found to contain only small quantities of methane. In addition to carbonic acid, nitrogen, and hydrogen, ammonal contained about 24 per cent. and picric acid and "T.N.T." nearly 50 per cent. of the poisonous carbonic oxide. It is thus evident that where shells burst in confined spaces, in addition to the damage caused mechanically, those persons breathing the fumes may be fatally poisoned or seriously affected physiologically.

It has been suggested that the ingredients of shell charges may contain deadly poisons, but it seems improbable that any poison intentionally added to the contents of a shell would retain its toxic properties after the shock and heat of explosion. As seen above, the gases from the explosives now in use may be sufficiently poisonous under certain conditions.

The subject of explosives seems often to create a state of credulity, and to generate extravagance of statement on the part of the non-expert writer rarely effected by other matters. The unknown sometimes becomes truly appalling under his imaginative pen. Even inventors have been known to make wild statements in regard to their explosives! One should only accept with very many grains of salt the sensational statements which have appeared in some quarters as to the weird and deadly effects of recently-invented ex-

plosives. It is well, therefore, not to have exaggerated ideas of the power of explosives or to be unduly scared by the threat of explosives dropped from Zeppelins. The destructive effect of the large charges which can be fired from the huge howitzers used in the present war is terrible, but explosives have their limits.

While without doubt the damage done locally from the explosion of a large quantity of any explosive which might be dropped by a Zeppelin would be appalling enough, yet, judging from the effects of the accidental explosion of a couple of tons of nitroglycerine during manufacture, its area would be comparatively restricted, and the horrifying suggestions mooted of the coming total destruction of cities by explosives dropped from the sky may be ascribed to the imagination of the over-credulous. W. Macnab.

PROF. INGRAM BYWATER.

On December 18 there died in his house in Onslow Square the greatest Greek scholar of our time. Ingram Bywater was remarkable for the fact that he was imbued with the scientific spirit, and pursued the investigation of Greek thought—what may be called "the Greek thing"—in the true scientific method. He was in close sympathy with scientific men engaged in other branches of investigation, of the methods and results of which he had a remarkable understanding and appreciation.

Bywater was born in 1840, and after early days spent at University and King's College Schools, became a scholar of Queen's College, Oxford; then, in 1863, fellow and tutor of Exeter College. On the death of Jowett in 1893 he was appointed by Mr. Gladstone Regius Professor of Greek. It was chiefly through Bywater's influence that Exeter College was led to offer in 1872 a fellowship in the competition for which biology was to be the chief subject. Huxley and Rolleston acted as examiners on behalf of the College, and I had the good fortune to be the successful candidate. My college rooms were adjacent to Bywater's, and we became constant companions and friends. We often discussed—when the college slumbered—the life and learning of the world and our own special studies in a tobacco-parliament of two during the small hours of the night. I learnt more from him than I can say, and not only enjoyed his wise and humorous discourse and his freedom from pedantry, but formed a warm regard for his fine spirit, his wide learning, and his intellectual veracity. When my fellow-student Moseley—who had not competed for the Exeter fellowship owing to his appointment as naturalist on the *Challenger* expedition—returned from his travels, Bywater proposed that the college should elect him also to a fellowship, which was done.

In 1885 Bywater married the second daughter of Mr. C. J. Cornish, of Salcombe Regis, widow of Mr. Hans Sotheby, a former fellow of Exeter College. The work of her nephews, Charles and Vaughan Cornish, is well known to scientific naturalists. Bywater was singularly happy in his marriage, and after the death of his wife in 1908 never recovered his strength and vivacity. He resigned his professorship, but still gave his services to the University in connection with the Bodleian and the Press. He lived among his books in his London house, where after my own departure from Oxford in 1898 I was his neighbour and constantly with him as in the old days at Exeter College.

He had a most unfavourable opinion of the study of Greek as conducted under the examination and scholarship system at Oxford. "It is not Greek which they study," he said, "but an arbitrary and unreal creation of the examination system and the traditions of college tutors." He complained that when he was professor even those more serious students among the undergraduates who might have profited by his teaching were by college directors of study kept away from his class-room, as they were in earlier days held back from the lectures of Max Müller. Bywater published in 1880 a remarkable piece of research and discovery relating to the fragments of the Greek philosopher Heracleitus, which led to his election as corresponding member of the Royal Academy of Sciences of Berlin. He devoted many years to the criticism of the text of the "Ethics" and the "Poetics" of Aristotle, and in 1899 the Clarendon Press published his *magnum opus*, containing his recension of the text of the "Poetics" with an introduction, translation, and commentary. But the young college tutors had the power of directing their pupils "not to waste their time" with listening to this great and original investigator, and, instead, to work up their Greek in the examination classes of the colleges; and they exercised it! Such is the mischievous result of the English university dry-rot—the examination system.

Only a month ago when my friend had temporarily rallied from the illness which has now ended fatally, he discoursed to me in his characteristically cautious yet vigorous style of German (more especially Prussian) arrogance and intrigue and the boasted "Kultur" of the Germans. He said that the quality of their abundant work, never very high, had deteriorated since 1870, and contrasted their grasping and pretentious attitude at the International Conference of Academies in Vienna, where he represented the British Academy, with the charm and refinement of the leading Austrian delegate, Prof. Suess, the geologist, now also gone from us, who, he declared, justified his name by the sweetness of both his nature and his behaviour. E. Ray Lankester.

SCIENCE IN WARFARE.

We reprint from the *Daily Mail* of December 18 a communication to that journal from a Belgian man of science showing how the Germans are utilising science for their operations in the newly conquered region in Belgium.

Here is a great lesson for us, for our Government cares too little for the nation's need for

science, which is as important for peace as for war purposes.

Meteorology and the Scarborough Raid.

It is by no means surprising that for their raid on the three British coast towns the Germans should have profited so accurately by climatic conditions. When they first entered Belgium their army corps were immediately followed by the full staff of their observatories. On August 16 the astronomers and meteorologists attached to the Aix-la-Chapelle army corps took up their quarters at Liège, and on August 25 they were all at the Brussels Observatory at Uccle, where, on September 1, they were replaced by astronomers and meteorologists from Berlin.

Immediately on arriving at the Brussels Observatory the Germans turned out the Belgian staff. They made use of the Belgian instruments but supplemented them by the very up-to-date instruments they had brought from Berlin. On September 3 they began hunting for a Belgian hydrogen factory where they could obtain hydrogen for filling their testing balloons, by means of which they make their observations for predicting fogs. They used these balloons for forecasting the weather, particularly for the great German attack on Antwerp.

There is abundant evidence that the German men of science followed the same course with regard to the German raid on Scarborough, Hartlepool, and Whitby. They are admirably equipped for forecasting fog forty-eight hours ahead wherever they are. The German Army meteorological stations have certainly been transferred to Ostend and Zeebrugge. They may not be as important as submarines, but these observation stations can render almost as effective aid in Germany's work of destruction as these engines.

NOTES.

M. C. E. Guillaume, the director of the Bureau des Poids et Mesures at the Pavillon de Breteuil, Sèvres, has made it known that the Institute of France has started a hospital, using for the purpose the funds at its disposal, and the voluntary contributions of its members. In Great Britain there are about thirty Associés Etrangers and correspondants of the institute, who have been notified of the action of the institute, and they have responded generously to the appeal of their French colleagues.

We learn from *Science* of the death at sixty-four years of age of Dr. D. E. Salmon, chief of the U.S. Bureau of Animal Industry from 1884 to 1906.

We regret to announce the death, at seventy-one years of age, of Mr. A. R. Hunt, of Torquay, fellow of the Geological and Linnean Societies.

We regret to see the announcement of the death on November 10, at seventy-five years of age, of Prof. N. C. Dunér, secretary of the Swedish Royal Society of Science, Upsala, associate of the Royal Astronomical Society, and author of astronomical works of prime importance.

It is announced that, owing to continued ill-health, Dr. E. F. Bashford has resigned the post of general superintendent of the Imperial Cancer Research Fund, which he has held for the past eight years, and that his resignation has been accepted by the executive committee.

The Royal Geographical Society has arranged two lectures to young people for the new year. On January 4, Mr. C. Carus-Wilson will lecture on the earth's unstable crust; and on January 8 the Rev. T. T. Norgate will take as his subject the theatres of war, illustrated. The meetings will be held in the Kensington Town Hall, High Street, Kensington, at 3.30 p.m. Application for tickets should be made to the chief clerk, Royal Geographical Society, Kensington Gore, S.W.

At the fifth annual general meeting of the Society of Engineers (Incorporated), held on Monday, December 14, the awards of premiums made in respect of papers published in the journal of the society during 1914 were announced as follows:—The president's gold medal to Mr. A. S. E. Ackermann for his paper on the utilisation of solar energy; the Bessemer premium, value 5*l.* 5*s.*, to Mr. A. S. Buckle for his paper on cylinder bridge foundations in the East; the Clarke premium, value 5*l.* 5*s.*, to Mr. S. M. Dodington for his paper on mechanical appliances for the painless killing of animals; the premium, value 3*l.* 3*s.*, for members of affiliated societies, to Mr. R. H. Cunningham (Crystal Palace Engineering School) for his paper on irrigation in India; a society's premium, value 2*l.* 2*s.*, *to* Mr. James Tonge for his paper on uses of the hydraulic mining cartridge. Mr. Norman Scorgie was elected president of the society for 1915.

The Royal Institution has circulated an illustrated brochure which explains for popular purposes the nature and objects of the institution. The institution was established under a charter of George III. in 1800, and enlarged and confirmed by an Act of Parliament in 1810. The objects of the foundation are "to prosecute scientific and literary research; to illustrate and diffuse the principles of inductive and experimental science; to promote social intercourse among lovers of science, men and women; and to afford them opportunities for collective and individual study." It is not necessary to insist upon the value to the world of the scientific work accomplished in the laboratories of the Royal Institution, when the names of a few of the great men who have worked there are recalled: Davy, Faraday, Tyndall, to say nothing of living men of science. The hope may be expressed that there will be no diminution of the usefulness and popularity of the institution in view of the war, but that its influence may become increasingly powerful as the years pass.

A distinguished traveller and servant of the Empire has passed away in Archibald Ross Colquhoun, who died on December 18. He was born in 1848, and his earliest civil service was in the Indian police. From this he passed to the public works department, and then became secretary to a Government mission to Siam, and the Siamese Shan States. Later he was Deputy Commissioner of Upper Burma, but before this, in 1881–82, he made an important journey from Canton to Bhamo, investigating the possibilities for a Burma-Chinese railway route, and also acted as a special correspondent in the French war in Tongking (1883–84). Afterwards, having left Government ser-

vice in the East, he came into contact with Cecil Rhodes, served with the South African pioneer force, and became administrator of Mashonaland in 1890. In later years he travelled extensively and wrote much on South Africa, on the Far East, on the Pacific and the Panama Canal schemes, and on other topics. Some of his books are important contributions to the study of great political questions, such as "The Key of the Pacific" (on the Panama Canal routes), "China in Transformation," "The Mastery of the Pacific," and "The Afrikander Land." He was closely associated with the work of the Royal Colonial Institute, and was editor of its journal, and among various honours he received the gold medal of the Royal Geographical Society.

THE organised methods employed by Germany in commerce, and the means necessary to meet them successfully, were referred to by Sir William Ramsay in an article contributed by him to NATURE of November 12 (p. 275). Sir William deals with the same subject in further detail in a paper just issued by the Institute of Industry and Commerce (Aldwych Site, Strand, W.C.) The German military organisation has its counterpart in their commercial organisation; there exists an Imperial Council the proceedings of which are kept quiet, but which takes into consideration all obtainable statistics, and so far as possible legislates, or endeavours to legislate, on the basis of these statistics. Where fiscal duties are found to be required, such a council puts them on; where there is an advantage in taking them off, they are removed. Where cheap transit is possible they give it; for the railways are the property of the State. In referring to these matters at the annual meeting of the Society of Chemical Industry in 1903, Sir William Ramsay said:—"Is it to be expected that any country can fight such a combination as that without adopting, at all events, something of their methods, or without studying their methods, and without combining together, if not to imitate them, at least to thwart them? There is a military campaign against us, and we must defend ourselves." Sir William points out that it will be necessary, if the future German State is allowed to retain the power of waging an industrial war, to combat it by the action of the organised British nation, that is, by the State. Once that conquest is achieved, we should do well to remember that commerce should be co-operative and not competitive; that it is to our interest not only that we ourselves should prosper, but that others should also prosper; that, indeed, our own prosperity is bound up in the prosperity of our fellow-creatures.

THE Philadelphia meeting of the American Association for the Advancement of Science will open on Monday, December 28, when the retiring president, Prof. E. B. Wilson, of Columbia University, will introduce the president of the meeting, Dr. C. W. Eliot, of Harvard. Addresses of welcome by the provost and the governor-elect will be replied to by President Eliot, after which retiring President Wilson will deliver his address on "Some Aspects of Progress in Modern Zoology." There will be two public lectures, complimentary to the citizens of Philadelphia and vicinity, one on Tuesday night, at 8 o'clock, being by Dr. D. C. Miller, "The Science of Musical Sounds." On Wednesday night, at 8 o'clock, Dr. W. H. Nichols will lecture on "The War and the Chemical Industry." The titles of the addresses by the retiring presidents of the sections are as follows:—*Physics*: Recent evidence for the existence of the nucleus atom, A. D. Cole; *Botany*: The economic trend of botany, H. C. Cowles; *Anthropology and Psychology*: The function and test of definition and method in psychology, W. B. Pillsbury; *Mathematics and Astronomy*: The object of astronomical and mathematical research, F. Schlesinger; *Agriculture*: The place of research and of publicity in the forthcoming country life development, L. H. Bailey; *Education*: The American rural school, P. P. Claxton; *Engineering*: Safety Engineering, O. P. Hood; *Geology and Geography*: The relief of our Pacific coast, J. S. Diller; *Physiology and Experimental Medicine*: The classification of nervous reactions, T. Hough; *Social and Economic Science*: Social and economic value of industrial museums, J. G. Wall; *Zoology*: The research work of the Tortugas Laboratory of the Carnegie Institution of Washington, A. G. Mayer; *Chemistry*: Fermentation, C. S. Alsberg.

AT a good old age—eighty-six—the famous Swiss guide, Melchior Anderegg, has passed to his rest. Born near Meiringen, at which place he died, he was bred and lived, except when undertaking some longer excursion, in the Oberland. He was introduced, if we remember rightly, to the Alpine fraternity by the late T. W. Hinchliff, who described, in his delightful "Summer Months among the Alps," excursions with him across the Strahlegg Pass in 1855 and up the Altels in the following year. Melchior's "great ascents" were rather more than twenty, for his employers, among whom we may number the Walkers, father, son, and daughter, A. W. Moore, H. B. George, F. Morshead, C. E. Mathews, and Leslie Stephen, belonged to the old guard of Alpine climbers and did not consider the charms of an expedition enhanced by needless perils. The more notable of those ascents were Mont Blanc by the Aiguille and Dôme du Goûter, and by the more difficult route from the Brenva glacier; the Col de la Tour Noire, a most laborious pass, near the Aiguille d'Argentière, and the Roththal Sattel, one yet more dangerous, under the Jungfrau; the highest peak of the Grandes Jorasses, the Dent d'Hérens, the Parrot-Spitze of Monte Rosa and its culminating peak by a new route up the Grenz glacier, but probably there were very few of the more noted peaks and passes of the Alps with which Melchior was not acquainted. Besides this, he was an expert wood-carver, and small statues of friends from his chisel have more than once been exhibited in England. Melchior deservedly won the affection of all who had travelled in his company. He was one of nature's gentlemen, and the late C. E. Mathews, whose companion he had been for thirty-four years, truly says in his "Annals of Mont Blanc" that he was "perhaps the greatest all-round guide whom the love of mountaineering has ever produced. . . . It is with a peculiar pleasure and

pride that I record that I never heard him utter a word to which the gentlest woman could object, and that I have never found him unequal to any kind of emergency."

IN the *American Museum Journal* for October-November Mr. G. G. MacCurdy, under the title of "Palæolithic Art as Represented in the Collections of the American Museum of Natural History," describes a number of objects acquired in France in 1912 by Prof. H. F. Osborn and the author. Among the most interesting specimens are a series of the tallies, or *marques de chasses,* which have been interpreted as records of their "kills" by the Aurignacian hunters; a set of perforated teeth, and shells of the Middle Aurignacian period from the Abri Blanchard, Dordogne; a holed limestone fragment, of which the utility is uncertain, it may have been used as a weight; figures of a horse engraved on stone of the Upper Aurignacian period from Roches-de-Sergeac, Dordogne, and of a reindeer on bone from Limeuil.

THE custom of cross-cousin marriage in South India, recently discussed by Dr. W. H. R. Rivers, is further considered by Mr. F. J. Richards in the December issue of *Man.* He arrives at the conclusion that it is based on economic considerations, and, in particular, on the mode of transmission of family property. The Dravidian people follow the rule of matrilinear succession. They subsequently came under the influence of the intrusive Brahmanical culture, in which the rule of patrilinear succession is followed. The effect of this clash of rival cultures was the desire of the matrilinear community to secure the advantages of patrilinear transmission of the estate; that is to say, the natural desire of the father to provide for his offspring might be secured by insisting that a man should marry the daughter of his maternal uncle, of his paternal aunt, or of his sister. This arrangement would enable a matrilinear community to conform to the patrilinear system of inheritance without fear of dissipating the family property, which is dependent on inheritance on matrilinear lines. The present practice of cross-cousin marriage is thus a compromise between the Dravidian rule of succession through the mother and the Brahmanical rule of succession through the father.

NEARLY the whole of part 6 of the tenth volume of Records of the Indian Museum is devoted to an account of fresh-water and terrestrial oligochætous worms, mainly collected in northern India, with descriptions of a number of new species. The author, Dr. J. Stephenson, of the Lahore College, remarks that the most noteworthy item is the occurrence of *Microscolex phosphoreus* (a widely spread species, the original home of which was probably in temperate South America), near Peshawar, at a distance of 700 miles from the sea. Although the dispersal from its original home across the Atlantic and Indian Oceans was doubtless due to the prevalent westerly winds, transport by human agency seems the only explanation of its isolated occurrence in the heart of northern India.

THE *Aarsberetning* of the Bergen Museum for 1913 and the first half of 1914 records steady progress in all departments during the period under review, a satisfactory incident being the bequest of 7000 kr. for general purposes. Numerous additions to the exhibited series of mammals and birds were made, but, judging from some of the figures in the text, there appears room for much improvement in the method of taxidermy. Ocean-surveying and the work of biological stations were carried on with great energy, reports from no fewer than forty-three stations being quoted. The contour of the channels of many of the Norwegian fjords is illustrated by a transverse section of the Sognefjord, in which the sudden descent of the sides and the great depth of the middle are well shown.

DR. W. SØRENSEN has published in French an important paper (*Kgl. Danske Videnskab. Selskabs Forhandlinger,* 1914, No. 3), on the anatomy of the Solifugida, that remarkable order of Arachnida which has attracted many zoologists to its study and which formed the subject of a lengthy memoir by the late H. M. Bernard (Trans. Linn. Soc. Zool., 2 ser., vol. vi.). The author criticises Bernard's work with some severity, pointing out that the latter's belief in the poisonous nature of the Solifugida is unsupported by facts, and that the structures designated by him as "coxal glands" have no openings on the haunches of the foremost legs, but terminate on short processes situated on the dorsal aspect of the appendages of the second pair. These appendages are termed "mandibules" by Sørensen. Considering the anterior position of the excretory organs under discussion, Sørensen's comparison of them with the Malpighian tubes of insects, which are outgrowths of the hind-gut, must remain open to question.

IN a recent issue of the Bulletin of the Imperial Botanic Garden of Petrograd (vol. xiii., No. 4), G. A. Nadson describes a number of interesting sulphur bacteria from brackish water in the Gulf of Finland. Two of the forms described are peculiar from the fact that the cells contain in addition to stored sulphur a substance which readily decomposes into oxalic acid; these bacteria live in badly aerated mud, and by increasing the oxygen supply the oxalite-like substance was found to increase, and the accumulation of sulphur to diminish, and *vice versa.* A remarkable new genus of sulphur bacteria, called Thiosphærella, was discovered, which contained in its cells large quantities of a starch-like substance; the other forms described are new species of the genera Achromatium and Thiophysa.

IN a paper which appeared in the *Annals of Botany* (vol. xxviii., No. cxii.) and of which we have received a reprint, Mr. S. R. Price describes some results obtained in the study of plant cells by the method of dark-ground illumination, a method hitherto but little used in botanical work. The method often reveals new structural features and is useful in establishing the presence of particles which are difficult to see or which are unresolved in direct illumination, but is very restricted in application on account of the difficulty of selecting suitable material for examination. Some of the author's observations indicate possible lines of work rather than completed

results. For instance, it is generally recognised that protoplasm is a colloidal complex, apparently existing both in the hydrosol and hydrogel state, the two states being spontaneously reversible; the process of germination of fungus spores, followed by the dark-ground method, showed the gradual conversion of the gel contents of the spore into a hydrosol on absorption of water, and later a formation of a gel might occur again. The nucleus and chloroplasts are probably specialised parts of the plasma with a hydrogel structure, but only in favourable cases could the nucleus be studied. Particles and vesicular bodies (which the author terms "sap particles") were usually found in the cell-sap and showed a continuous Brownian movement; they usually increased in number with decreasing vitality of the cell.

The problem of the dolomitisation of limestone has received an interesting contribution from Prof. R. C. Wallace, of the University of Manitoba (*Compte-rendu* of the twelfth International Geological Congress, 1914, p. 875). He regards the concentration of magnesium ions in the solution from which dolomite is precipitated as in many cases the determining factor. This concentration at moderate depths of sea-water may determine whether calcite or dolomite is stable; at a certain concentration of magnesium, calcite goes into solution and dolomite is deposited. In a solution in which calcite is stable, magnesium carbonate may be unstable, and may go into solution until the magnesium ions are sufficiently abundant to produce a precipitation of dolomite. In the case, again, of underground water bringing magnesium into a limestone, a solution may abruptly arise in which calcite is unstable and becomes replaced by dolomite. It will be seen that this view differs from the older one of the mere substitution of magnesium for part of the calcium present in a mass of calcium carbonate.

We have received from Prof. Eredia a pamphlet entitled "The Organisation of the Service of Weather Predictions in Italy," reprinted from the *Rivista Meteorico-Agraria* (vol. xxxv., 50 pp.). An experimental system of weather telegrams was instituted in the Papal States from July to December, 1855, and the observations were forwarded to Padre Secchi for examination. His report of the experiment was favourable, but practically the commencement of the service dates from April, 1866, when observations were telegraphed to the central office at Florence. After the removal of the latter to Rome the service was frequently improved, under the direction of Prof. Tacchini, and the daily weather report has latterly again been considerably enlarged. The present director is Prof. L. Palazzo, whose name is well known to many of our readers by the interest he takes in geophysics generally. Prof. Eredia also gives a brief sketch of the origin of the weather service in Europe. With reference to this country he remarks that in 1860 the Astronomer Royal informed M. Le Verrier (Paris) of the proposed establishment of a service on our coasts, and requested an exchange of bulletins. This is strictly true, but it might be explained that the communication was in reply to an inquiry by M. Le Verrier, which would naturally have been referred to Admiral FitzRoy before being dealt with. The latter issued daily weather reports to newspapers from September 3, 1860, and storm warnings from February 5, 1861. It may be worth while to direct attention to two apparent slips in the last paragraph but one on p. 7 of Prof. Eredia's laborious and useful compilation (with reference to a storm on December 1–2, 1863): Islanda should read Irlanda, and M. Davy is quoted as director of the English service.

In a review of Dr. Hobson's "Squaring the Circle" in the Bulletin of the American Mathematical Society for November, Prof. R. C. Archibald directs attention to the early use of the symbol π by William Oughtred (1574–1660) in his "Clavis Mathematica" of 1631 and in his "Theorematum in Libris Archimedes de Spheara et Cylindro Declaratio" (Oxford, 1652). Oughtred employs the symbols $\delta : \pi$ to represent the ratio of the semidiameter to the semiperiphery of the circle, although he does not use the symbol π separately. He states specifically that $\pi R/\delta$ is the semiperiphery of a circle of radius R. Prof. Archibald further directs attention to references to squaring the circle in the Birds of Aristophanes (produced 414 B.C.), lines 1004–5, and in the last canto of Dante's "Paradiso" (canto 33, lines 133–5, in Cary's translation), and he points out that Longfellow, in his translation, gives "to square the circle" as the equivalent of the Italian "Misurar lo cerchio."

In an article on "The Conic as a Space Element," in the Transactions of the American Mathematical Society, xv., 4, Mr. Roger A. Johnson develops a system of co-ordinates for the conic in three dimension space analogues to the line co-ordinates of Plücker, by treating the conic as a degenerate envelope. It is interesting to note that the problem of the conic in space has been studied for the last sixty years, and that in 1908 the Belgian Royal Academy announced the offer of a prize for a discussion of the subject. It may, however, be pointed out that the problem of the aeroplane in space is at the present time of a far more urgent character, and that the most pressing need is for pure mathematicians who find no difficulty in dealing with cumbersome formulæ as abstract as those which occur in connection with these harmless but unprofitable conics. Still, it is interesting to learn that the totality of conics of a T_4 that touch two fixed planes, the intersection of which does not meet the axis of the T_4, constitute a T_2 of the most general type.

OUR ASTRONOMICAL COLUMN.

The Approaching Maximum of *o* Ceti.—According to prediction, *o* Ceti or Mira will be at its maximum brightness on February 11 next, but it should be noted that both the star's period and brightness are not always the same at each return to its full brilliancy. As the star remains at its maximum brightness (2·0 mag.) for about fourteen days, it will be at a maximum on February 4 (approx.). At the present time it is a conspicuous ruddy object in a 4-in. telescope (mag. about 6·0), and its spectrum discloses the strikingly brilliant flutings and the bright hydrogen

lines. The variable is best situated for observation in the earlier part of the evening, and the following is its position:—

R.A.		Dec.
2h. 15m. 3s.	...	$-3^\circ\ 21'$

THE ANTWERP ASTRONOMICAL SOCIETY.—In this column references have been taken from time to time from the *Gazette Astronomique*, which was a monthly bulletin of the Antwerp Astronomical Society. The last issue (No. 81) appeared in the beginning of September, when the investment of Antwerp had already commenced. A certain number of the members of this society have taken refuge in this country, and many of their British friends have suggested the idea of continuing the publication of this bulletin in London. Many of the latter have already made an effort to solve the financial part of the scheme, and it is due to their initiative that General J. Lerissen (president) and M. Felix de Roy (hon. sec.), on behalf of the society, have issued a circular asking others to contribute. If sufficient support is forthcoming it it proposed to issue the bulletin in both French and English. It will contain, besides notes of observations and of scientific articles, ephemeral notes, reviews of publications likely to interest amateurs, and place at their disposal the working data provided by professional astronomers. Those wishing to help may obtain further information from the hon. secretary at 29 Stamford Street, London, S.E.

SOME RESULTS OF THE RECENT ECLIPSE EXPEDITIONS.—Last week reference was made to the results of the Spanish eclipse expedition to the Crimea during August last, and attention was directed to a red coronal radiation at λ 6373·87, which was discovered by M. Carrasco on his photographic plates. This radiation is a new addition to the spectrum of the corona, and, like some other coronal radiations, seems to vary in intensity with the state of solar activity at the time of eclipses. M. Iniguez, the director of the Madrid Observatory, has just forwarded an enlargement (paper) of the region, between Hα and D_3, the original of which was taken 13 sec. after second contact, and exposed for 10 sec. This print shows in the first place the sharpness of the images of the arcs, and in the second the clear and prominent arc due to the new coronal radiation. The wave-length is given as $6373{\cdot}87 \pm 0{\cdot}04$ Å. units. In the *Comptes rendus* (vol. clix., No. 23) for December 7 M. Deslandres presents a communication by MM. J. Bosler and H. G. Block with reference to the results of the Meudon eclipse expedition to Strömsund (Sweden). The note is restricted to the results of one part of their programme, namely, the spectrum of the corona. The continuous spectrum of the corona was perfectly regular, and indicated no signs of flutings or Fraunhofer lines, but only gradations due to the sensitiveness of the photographic plate. The well-known green radiation at λ 5303·7 was entirely absent. In the red part of the spectrum a brilliant and intense new radiation appeared. The wave-length is given as 6374·5 Å. units (to 0·2 Å.U. nearly), and agrees well with that determined by the Spanish observers.

GEMINID METEORIC SHOWER, 1914.—Mr. Denning writes:—"The weather greatly interfered with observations this year. The sky was, however, favourable on December 8, and a watch was kept at Bristol, but there were few Geminids. These exhibited a well-defined radiant at $106^\circ+31^\circ$. The following nights were cloudy and wet, but on December 12 the sky cleared for a few minutes about 10.35, and six Geminids were noticed. Later, through openings in the clouds, further meteors were recorded, all from the same shower. There were two very distinct radiants, viz., at $109^\circ+33^\circ$ and $119^\circ+32^\circ$. They appeared to be about equally active. In 1885 and 1892 the same pair of radiants were very rich, and seemed to prove that the shower is a double one. From a comparison of all my observations of the chief system near α Geminorum I conclude the radiant is distinctly a moving one like the Perseids. It seems visible during three weeks from November 25 to December 16, with a maximum on about December 12. This year I believe the display to have been a very rich one on that date, giving nearly forty meteors an hour, and I await observations from places where atmospheric conditions were more favourable than at Bristol. My positions for the radiant are as follow near the maximum:—

Dec. 5	...	$102^\circ+33^\circ$	Dec. 11	...	$109^\circ+33^\circ$
6	...	$104^\circ+33^\circ$	12	...	$110^\circ+32^\circ$
7	...	$105^\circ+33^\circ$	13	...	$112^\circ+32^\circ$
8	...	$106^\circ+33^\circ$	14	...	$114^\circ+32^\circ$
9	...	$107^\circ+33^\circ$	15	...	$115^\circ+32^\circ$
10	...	$108^\circ+33^\circ$	16	...	$116^\circ+32^\circ$

"From my observations in 1885 there is strong evidence that the companion shower at about $119^\circ+32^\circ$ also moves eastwards, but more data are required. Our weather is rarely suitable at this period of the year."

KASHMIR AS A SITE FOR A SOLAR OBSERVATORY.—Bulletin No. 42 of the Kodaikanal Observatory contains a very interesting report by Mr. J. Evershed on the seeing condition as studied by him in the valley of Kashmir. It may be remembered that last year he reported very favourably about this valley for solar observations during the months of August and October, and, contrary to all previous experience in other localities, he noticed that the definition of the sun was found to be of the best quality throughout the day and on all days that observations were made, there being apparently no marked variations depending on the height of the sun above the horizon, nor upon the type of weather prevailing. In order to test the conditions in this locality during other months of the year, and to make more critical observations both photographic and visual with larger instruments, an expedition was sanctioned by Government in April of the present year, and this report sums up the results obtained during the months of May, June, and July. A scheme of operations was arranged so that comparisons at Kashmir could be made with the experiences at Kodaikanal. For a detailed account of the results the reader must be referred to Mr. Evershed's report, but the following brief statement of the main result is as follows:—Taking a scale of seeing as very bad definition 1, bad 2, fairly good 3, good 4, and so perfect that no tremors can be perceived in the 8-in. solar image projected on a screen attached to a portable instrument as 5, then it may be stated approximately that the mean seeing at Kodaikanal for the whole year would hardly reach 2, whilst that in Kashmir valley would probably exceed 3·9. The number of days when the seeing ranged between 4 and 5 would be very much larger in Kashmir than in Kodaikanal. The photographic work was found entirely to confirm the visual observation, and, as he states, "indicates the enormous possibilities of progress in the study of solar physics which an observing station in Kashmir Valley would present." As the chief factor in solar research is the quality of the "seeing," the importance of the above conclusion cannot be put aside.

COLLIERY EXPLOSIONS AND COAL-DUST.

UNDER the title of "Great Colliery Explosions and their Means of Prevention" (London: The *Colliery Guardian* Co., Ltd.), Dr. W. Galloway has collected into a small volume a number of papers contributed by him between the years 1872 and 1908 to various publications; these were so scattered that their logical sequence was not always easy to trace, and they gain greatly by being presented in their order and gathered within the covers of a small volume.

The first two papers deal with the connection between colliery explosions and the state of the barometer, and showed, what no one probably doubts to-day, that there is a greater danger of firedamp explosions with a falling barometer than under any other atmospheric conditions. The next paper gives an account of a series of experiments which demonstrated that a violent atmospheric concussion, such as that produced by a shot, can force flame through the gauze of a safety-lamp, so that a lamp, which would be quite safe in a quiescent explosive atmosphere, may initiate an explosion if the same atmosphere is violently disturbed. This fact, like those above referred to, is a matter of such common knowledge to-day amongst miners that they are apt to forget that there ever was a time when it was not known, and it is as well that they should have at hand a reminder as to who it was that first discovered this very important fact.

The remaining papers are perhaps of higher interest than those already mentioned, as they all deal with the part that coal-dust plays in propagating colliery explosions. For a long time the coal-dust danger was either neglected or flatly denied even by the highest mining authorities, and Dr. Galloway deserves the greatest credit for the part he has played in forcing its recognition upon the mining community. It is evident from a perusal of the papers here collected that it was only gradually that the gravity of the danger of coal-dust explosions impressed itself upon Dr. Galloway himself, and that it was quite a long time before he could convince himself that coal-dust was dangerous in the entire absence of fire-damp. Thus in 1876 he disagrees with the opinions expressed by a French engineer, M. Vital, who held that finely divided coal-dust may of itself alone (*i.e.* without fire-damp) give rise to disasters, and he states his definite conclusion that "*a mixture of air and coal-dust is not inflammable at ordinary pressure and temperature*" (p. 57), and goes on to show that when as little as 0·892 per cent. by volume of fire-damp is added the mixture becomes inflammable. Already at this date, however, Dr. Galloway advocated the watering of the roadways in collieries so as to keep down the dust. In 1879 Dr. Galloway had apparently modified his views to some extent, for he then wrote: "It is probable, moreover, that some kinds of coal-dust require less fire-damp than others to render their mixture with air inflammable; and it is conceivable that still other kinds may form inflammable mixtures with pure air" (p. 73). In his first paper in 1882 he still seems to consider the presence of a minute proportion of fire-damp, too small to be detected by a safety-lamp in the ordinary way, which he calls the "*latent*" fire-damp, indispensable to the formation of a dust explosion, but he continued to experiment, and in his second 1882 paper he wrote that his experiments "show conclusively, I think, that fire-damp is altogether unnecessary, when the scale on which the experiments are made is large enough" (p. 111). It is important to note that Dr. Galloway reached this conclusion after six years of continuous experiments, in direct contradiction to his earlier views on the subject, and this fact should of itself have inspired confidence in the matured opinions that he expressed.

The remaining papers in this volume are devoted to an elaboration of this coal-dust theory, but though of undoubted importance, they are less so than the above-quoted series in which Dr. Galloway showed by direct experiment that coal-dust and air form an explosive mixture even in the absence of inflammable gas, and the fact that he was the first to furnish experimental proof of this has established his reputation as an original, accurate and painstaking investigator of colliery explosions; this little volume shows clearly enough the extent to which he has laid the coal-mining community not only of this but of all other countries under a deep debt of gratitude.

H. L.

THE EDUCATION IN LONDON OF REFUGEES FROM FOREIGN UNIVERSITIES.

A FEW weeks ago (NATURE, November 26) we gave an account of what is being done to establish an informal Belgian university at Cambridge, for students of the University of Louvain and other universities affected by existing military operations. Both the Universities of Oxford and Cambridge have, so far as we understand, offered a generous hospitality on a large scale to both the staff and students of Belgium universities, but while affording them every facility for quiet study, have not attempted to bring them systematically within their own system. The University of London, on the other hand, is putting at the service of refugee students not merely the teaching facilities of its two incorporated colleges, but also the right to enter its degree courses and to obtain its degrees on exceptionally favourable terms. It is allowing a partial or total remission of fees both for full teaching courses in expensive laboratory subjects, such as engineering and preliminary and intermediate medicine, and for entrance to examinations. It has further made special concessions as to both the matriculation and intermediate examinations, which will make it possible for the students to answer questions in French, and have their knowledge tested on the lines of education they have previously received in their own universities. If the Privy Council approve of the Amendment of Statutes which the Senate of the University is referring to them, a clever student who has come over to London from Belgian or French universities this autumn, will be able to pass the examinations in lieu of matriculation and intermediate by the early spring, and enter at once on his final course.

This interesting experiment to enable deserving students of the allied nations to obtain actual English degrees entails extraordinarily severe work on the administrative and teaching staff of the colleges. King's College has seventy-four of such students, University College sixty-seven, and the Imperial College a certain number. None of them knew English to start with, and special classes have had to be arranged to teach it them. The courses in foreign universities differ greatly from those of English universities, as well as from each other, and infinite care has had to be taken to discover the exact stage in each subject which a given student has reached. In engineering, for instance, in which King's College alone has forty-two such students, the standard of applied mathematics is much lower in the earlier stages in Belgium than in England, while that in pure mathematics is higher. Even allowing for the assistance of the Belgian professors who are being called into council, it is not above the mark to say that the time taken over each refugee student is as much as that over ten English students. Apart from the academic work, the hospitality which the senior common rooms of University and King's Colleges

have extended to these students, many of whom are for the present quite without funds, cannot be left out of account. In regard to the Jewish students, who form a large proportion of the whole, and who are mostly Russian subjects studying at Liège or Ghent, valuable help has been received from the Central Jewish Committee.

This effort, however great the tax it imposes on the colleges, is worth making. It will enable Belgians who are medically unfit to go on active service, and Russians whose military service begins at the end of their university career, to obtain their professional qualifications during the war, and thus fill the depleted ranks of doctors and engineers in their respective countries. It will also spread a knowledge of English university education on the Continent, and not improbably make the University of London an international, as it is already an Imperial, centre of university education.

THE PRODUCTION AT WILL OF EITHER FUNGUS-GERMS, FLAGELLATE MONADS, OR AMŒBÆ FROM THE ULTIMATE SEGMENTS OF SMALL MASSES OF ZOOGLŒA.

AN illustrated article dealing with this question of the heterogenetic origin from small Zooglœa masses of Fungus-germs, Monads, or Amœbæ, written by me, appeared in NATURE of November 24, 1904. That article was prepared at short notice in consequence of a short letter on "Archebiosis and Heterogenesis," which appeared a fortnight previously, and at a time when I was not specially working at this subject. Of late I have been doing much work in this direction, and have made out many very important new points, and can now speak with more precision concerning the changes generally, and the modes of obtaining them.

My results were received with great scepticism, and no bacteriologist has been induced to attempt either to confirm or refute them. The possibility of "infection" has so dominated them, that they have refused to consider the question. Of late, however, three bacteriologists have accepted my request that they should allow me to demonstrate to them my position by their examination of actual specimens. This they did, separately, and as a result neither of them was able to doubt that the Fungus-germs, the Monads, and the Amœbæ were, in truth, derived from the ultimate segments of the Zooglœal masses; nor did they suggest that the very similar developmental changes to be seen in hundreds of Zooglœal masses taken from their respective scums could possibly be accounted for by "infection."

Only one of my friends had any interpretation to suggest in opposition to my own. He started the supposition that what appeared to be bacterial aggregates might "possibly," in spite of their appearance, not actually be of that nature. He suggested that, though taking the guise of bacteria, and though all were similar in appearance, they might nevertheless be some hitherto unknown progenitors of Fungus-germs, of Monads, and of Amœbæ which had aggregated as Zooglœal masses, and subsequently given rise to their respective products.

This wild supposition may, at all events, be taken as an indication that its author could not doubt the fact of the different products coming from the ultimate segments, or imagine that "infection" could account for what he had seen. It was started by one who was absolutely opposed to the very notion of heterogenesis. He was subsequently able to find absolutely no support for his "possibilities," and after a futile search frankly admitted that only bacterial Zooglœas were known, apart possibly from others of an algoid type.

The current notion among bacteriologists concerning the nature and mode of origin of Zooglœas is that adopted by R. Muir in the article, "Bacteriology," in the last edition of the "Encyclopædia Britannica" (vol. iii., p. 161), in which he says:—"The Zooglœa is now known to be a sort of resting condition of the Schizomycetes, the various elements being glued together, as it were, by their enormously swollen and diffluent cell-walls becoming contiguous."

But bacteriologists do not seem ever to have examined the small masses that form in the scum on the surface of a hay infusion. I have been unable to find any reference to them, or of processes of segmentation occurring in any other Zooglœas. I cannot think that those with which we are now concerned are formed in the manner above indicated. All the evidence seems rather to show that as the bacteria rapidly multiply they also excrete the jelly-like glœal material in which they are subsequently found to be imbedded.

Preparation of the Infusions.

One of the important new points recently ascertained is that I can prepare two small infusions at the same time from the same sample of hay, and by allowing one to infuse for three hours at a temperature of 90° F., can feel confident that in the course of three to five days the ultimate products of segmentation of the Zooglœas that form can be made to yield Monads or Amœbæ; while if the other is infused for the same time at 98° F. no Monads or Amœbæ will appear, and the ultimate Zooglœal segments, though formed, and very similar in appearance, will remain apparently stationary for eight to thirteen days, and then begin to show themselves as multitudes of brown Fungus-germs.

It is best to use comparatively new hay, and not that of the previous season. I take a small portion and having cut it into ½-in. lengths, place it in 2-oz. beakers to which water is added just sufficient to cover it. The proportion of the two I have found to be a little more than 30 grains to the ounce of water. As soon as the infusions have been made they are filtered through No. 0 Swedish paper (so as to exclude encysted Kolpodæ and the great majority of Fungus spores) into common one-ounce porcelain pots, until they are about half-full—the depth of the infusion being then only a little more than half an inch. The scum which ultimately forms will be thin, and therefore much more favourable for examination than if it had been thick and formed over a greater depth of infusion. The covers are replaced on the pots, and the dates and temperatures at which the infusions have been made are marked thereon. These covered pots are then mostly kept at room temperature, 62°–64° F.

Examination of the Scum or Pellicle.

The pots are not usually opened until two days have elapsed, as it would be only during the last twelve hours that any very distinct scum begins to form, and that a few very small Zooglœas may be found scattered through it. By the end of the third day the Zooglœas may be very numerous, and will be found to vary much in size and shape. An example illustrating a rather later stage is shown in Fig. 1, in which the little masses are seen to be extremely numerous. Many of these early Zooglœas already show primary processes of segmentation.

In order to examine the scum a small portion is taken up on the point of a scalpel and rotated off on to a drop of distilled water. If thereafter it should be desired to preserve the specimen some 5 per cent.

formalin is run in, and the cover glass is ringed. But where there are brown Fungus-germs it is better to let the specimen remain in water, as the formalin, and also glycerin, would speedily remove their characteristic colour.

When some of these first-formed small Zooglœas are examined with a high power, it becomes obvious that they are simple aggregates of bacteria, such as may be seen in Figs. 2, A, and 3. Further, just the same kind of bacteria are to be seen within them as in the scum immediately around; and the bacteria from the scum of the infusion prepared at 90° F. do not differ morphologically from those of the scum on the infusion prepared at 98° F.

It must come to be a question whether the different products ultimately yielded by the two sets of Zooglœas can in part be attributed (*a*) to the fact that the constituent bacteria are actually different in the two cases, or (*b*) to the fact that the slightly different (and far from lethal) temperatures at which the two infusions have been prepared, have sufficed to modify the physiological attributes of the same set of bacteria. The latter seems to me to be by far the more probable explanation, looking in part to the seeming morphological identity, and also to the possibility that the exposure to the higher temperature of 98° F. for three hours may have somewhat degraded the molecular structure of the bacteria, so that these particular aggregates are only eventually capable of yielding vegetal rather than animal products, and that, too, after rather more than twice as long a period. Important facts in support of this conclusion will be reported later on.

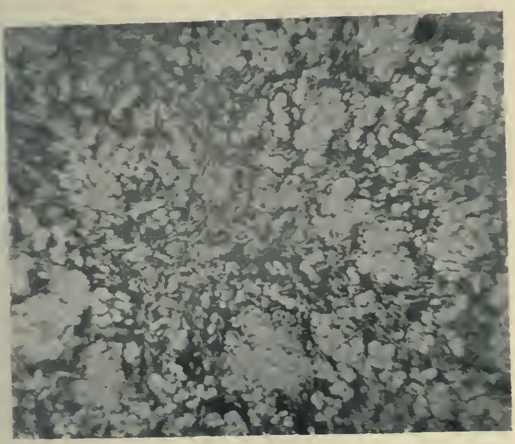

FIG. 1.—×200.

It is, moreover, a very remarkable circumstance that almost until the ultimate products of segmentation are reached there seems to be no means of distinguishing by mere microscopical examination whether the Zooglœal masses are going to yield brown Fungus-germs, Monads, or Amœbæ. As they grow and develop, they all tend to segment into smaller and smaller portions; and after a time the constituent bacteria become hidden owing to molecular changes in the glœal material. These are also shown by the segments becoming glistening and more refractive, and at the same time more receptive of logwood and other stains.

Conversion of Ultimate Segments of Zoogloeas into Brown Fungus-Germs.

In Figs. 2–5 are to be seen portions of some of the Zooglœas from pots containing an infusion that had been prepared at 98° F., and the scum on which subsequently yielded only Fungus-germs.

Fig. 2, A, shows a portion of one of the Zooglœas at an early stage, in which the bacteria are still very distinct, though later they often tend to become more or less enlarged and altered in appearance. In Fig. 2, B, a later stage is shown in which much segmentation has taken place, where the bacteria are no longer recognisable, and the segments have assumed the glistening appearance already referred to

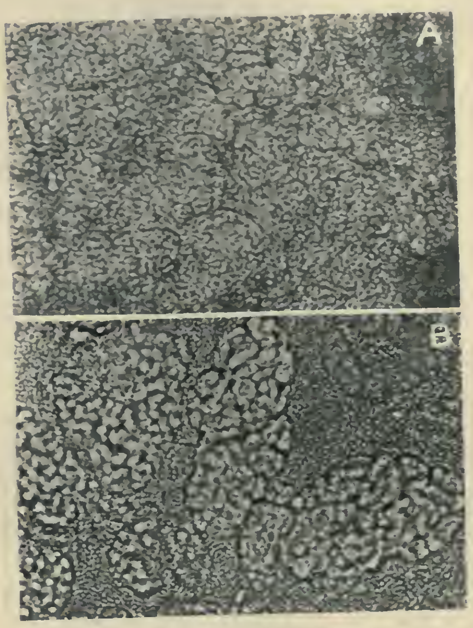

FIG. 2.—×500.

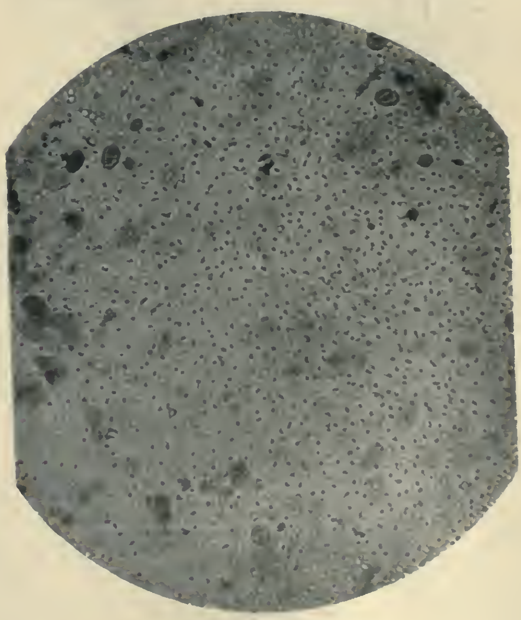

FIG. 3.—×500.

The date at which the change into brown Fungus-germs begins is subject to considerable variation, but this colour is rarely seen before the eighth or after the thirteenth day—the time needed being in part

dependent upon the temperatures at which the pots are kept.[1]

The actual mode of production of the Fungus-germs from the bacterial aggregates may be seen in Figs. 3-5. A portion of a Zooglœa lightly stained with *C. fuchsine* is shown in Fig. 3, in which the bacteria are remarkably distinct, and where here and there they are becoming enclosed within distinct cell-walls. We see, in fact, a free cell-formation going on, in which the bacteria become the nuclei, and these nuclei undergoing division. Fig. 4 shows other stained specimens illustrating the mode in which segmentation progresses from multibacterial aggregates in A to multinuclear masses in B, which lead on in C to separate ultimate products in the form of nucleated Fungus-germs.

In Fig. 5 we have to do with unstained specimens gradually assuming a brown colour. In A the three pale masses show early stages in which the Fungus-germs are forming, *in situ*, in fairly large segments; while the dark masses around are aggregates of

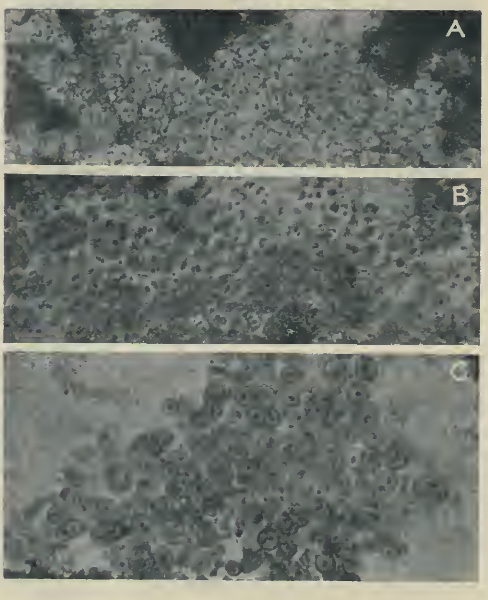

FIG. 4.—×500.

brown, fully formed Fungus-germs. In B we have a more ill-defined Zooglœa, in which careful examination will reveal portions becoming more and more distinct, until they end with groups of large well-defined brown Fungus-germs.

We have here then a direct free formation of cells, the existence of which has so long been doubted, where bacteria constitute the nuclei, and the altered glœal material the remaining portions of the cell-protoplasm. What is so plainly to be made out in Figs. 3 and 4 seems generally to occur when Fungus-germs are formed in and from Zooglœas; and the mode in which segmentation is so clearly shown to progress in Fig. 4 probably holds good for all other Zooglœas, even when the ultimate products are of a wholly different order

In all cases the Fungus-germs produced in the manner I have shown, though they multiply to some extent so as to form small heaps or short chains, remain as such for very many days, and require to be much coaxed in order to undergo further development with production of hyphæ.

Conversion of Ultimate Segments of Zoogloeas into Flagellate Monads.

Where the infusion has been prepared for three hours at 90° instead of at 98° F. the Zooglœas which form present no difference in appearance and in mode of segmentation from what has been represented in Fig. 2.

There is, however, this remarkable difference, that such masses never assume a brown colour, and their ultimate products of segmentation begin to be visibly transformed in three or four rather than in from eight to thirteen days, and then they reveal themselves as rapidly increasing swarms of flagellate Monads.

These ultimate segments appear at first as little spherical, motionless bodies, such as are shown dispersed at the edge of a portion of scum in Fig. 6, A, and also aggregated as ultimate products of a small

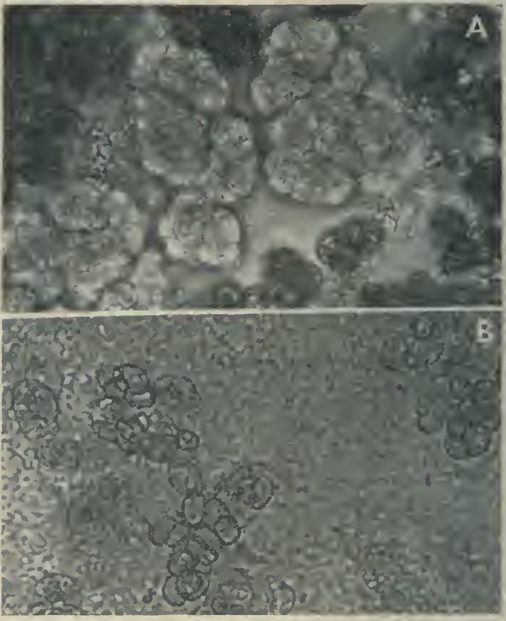

FIG. 5.—×700.

mass in 6, B, though they are there somewhat obscured by a few overlying bacteria. A smaller aggregate of motionless units is represented above, while below, before the running in of some formalin solution, some of the bodies shown were active Monads.

These Monads always contain a few granules, such as are shown in 6, C, in the lower body on the right, and a quite small nucleus is also frequently recognisable in such early units. Slight variations in size and shape of the Monads are met with from different samples of hay, just as different kinds of Fungus-germs are also produced. They have generally two flagella, though one of those that I succeeded in photographing (Fig. 6, C) has three. I have never previously been able to get any tolerable photograph of these Monads; this time I was to some extent successful with the aid of eosin. All other dyes or preservatives have proved useless, owing to the extremely delicate structure of the Monads. At times when a slide has been under examination for a rather long time, some of the Monads have become quiescent, and then I have often been able to recognise a contracting

[1] Where the infusion has been made at a higher temperature, such as 100°–102° F., the appearance of the brown Fungus-germs may be still further delayed. What I have to say in this communication refers only to the products from the Zooglœas that may be found within the first fourteen days.

vacuole near the posterior extremity, rhythmically opening, and sharply closing about every twenty seconds.

Flagella, nuclei, and contracting vacuoles appearing in animal units independently of heredity, and as derivatives from chance bacterial aggregates, such facts now revealed supply us with marvels far surpassing what was previously seen in the way of origin of nuclei and free-cell formation during the genesis of brown Fungus-germs—though even these latter changes give the death-blow to Virchow's celebrated dictum, *omnis cellula e cellula*.

Conversion of Ultimate Segments of Zoogloeas into Amoebae.

This is perhaps a more interesting and remarkable transformation than either of the other two. When I last wrote on this subject I was altogether unaware of the nature of the differential conditions favouring the conversion into Amœbæ rather than into Monads. Now I have found that this production of Amœbæ can almost always be brought about by preparing the infusion at a temperature of 85°, rather than at 90° F., and by subsequently keeping the pots at a temperature rather higher than that generally adopted. Sometimes, however, in such trials both Monads and Amœbæ are produced simultaneously.

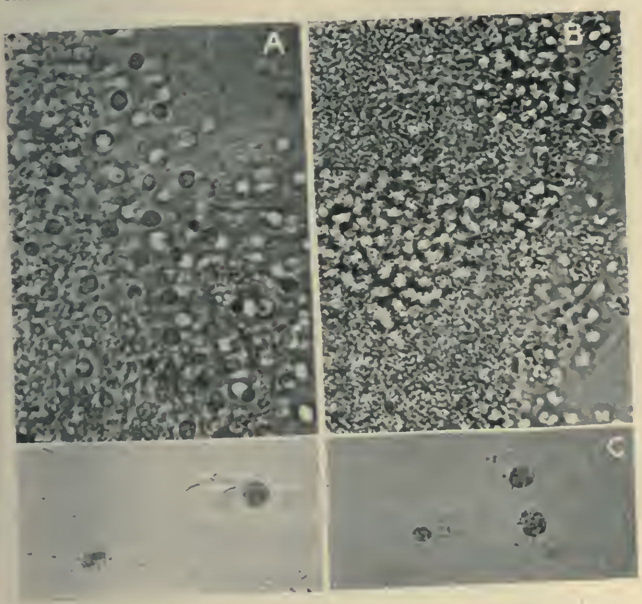

FIG. 6.—A and B × 500; C × 700.

The procedure mentioned generally leads to the production of a very large number of Zooglœas, which have essentially the same bacterial constitution and mode of segmentation as have been met with in the other Zooglœas, and which are represented in Fig. 2.

The transformed ultimate products of segmentation begin, as in the last case, to show themselves on or about the third day, while by the fourth and fifth days actual myriads of minute Amœbæ are to be seen in every portion of the scum taken up for examination, so that at last no traces of the very numerous Zooglœas from which they have been derived are to be found. These Amœbæ often at first have a single flagellum.

One of the final stages in such a resolution is shown in Fig 7, A, where the ultimate units, which are mixed with a few actual Amœbæ, are still pretty closely aggregated. In a few of them quite small nuclei are shown, though these are much smaller than what are generally to be seen in embryo Fungus-germs just separated from a parent mass. The latter are also usually more ovoid, and have much more well-defined outlines.

A few of the myriads of Amœbæ as they appear in the formalin solution are represented in 7, B. The great crowds of Amœbæ produced soon lead to conditions unfavourable for their existence, so that after another two days they will generally be found to have become encysted, as represented in Fig. 7, C.

Whether altered bacteria again furnish the nuclei of the finished products cannot be positively stated. The nuclei are always rather large in embryo Amœbæ, and distinctly larger than in young Monads.

A point of great importance in reference to what I have said concerning the comparatively sudden appearance of great swarms of small Amœbæ is the fact that such organisms can only rarely be seen to undergo division when immersed in fluids. I have long expressed this view, and now find it supported

FIG. 7.—× 500.

by the latest workers on these organisms, namely, J. W. Cropper and A. H. Drew, in their recently published "Researches into Induced Cell-Reproduction in Amœbæ." The rapid appearance, therefore, shown to occur of myriads of minute Amœbæ would be quite inexplicable by ordinary processes.

In what has been said details have been given which will almost certainly lead, at will, to the production either of Fungus-germs, of Monads, or of Amœbæ. I have already expressed the opinion (p. 462) that we have not necessarily to do with different bacteria in these cases, but rather with the same bacteria differently modified by the prolonged, though comparatively slight, differences of temperature maintained during the production of the infusions.

The recent access of cold weather has enabled me to confirm this, and has, moreover, shown that the temperature at which the pots are kept is only a little less important than the variations in temperature at

which the infusions are prepared. I have found, for instance, that infusions prepared at 90° and 85° F. respectively, will no longer yield Monads or Amœbæ if the pots are from the first kept at a temperature of 50°–54° F. Then, in each case, as a rule, only brown Fungus-germs begin to appear after eight or more days, instead of the Monads or Amœbæ which would have appeared had the pots been kept at the higher temperatures previously indicated.

Here then we have the revelation of still more astounding facts, since it seems to be shown that Amœbæ, Monads, and Fungus-germs are actually interchangeable products, capable of being derived from similar bacterial aggregates, under the influence of slight but well-defined differences of temperature.

A Few New Details Concerning Some Tube Experiments.

In a previous communication to NATURE for January 22 of this year I gave some account of my experiments with saline solutions in sterilised tubes, tending to show that living matter is still appearing *de novo* on the surface of the earth, seeing that under the very restrictive conditions necessitated by these experiments there was abundant evidence to show that Bacteria, Torulæ, and simple Moulds have repeatedly come into existence.

I stated that my experiments had been repeated in Paris with positive results by Albert and Alexandre Mary. They not only obtained organisms from their tubes, but caused them to multiply in different culture media.[2] My experiments were also repeated in New York by Drs. Jonathan Wright and MacNeal. After some negative and some doubtful results, they succeeded last year, among a few other successes, in producing crowds of organisms in every one of a set of twelve tubes, containing colloidal silica and other materials which I had sent them. At first they felt strongly of opinion that the results obtained from the first of these tubes, in which, as they said, unquestionable organisms were found in "enormous numbers," must have been due to the pre-existence of organisms in the materials used. But after careful examination of the materials they found no support for this supposition, admitted that they could not take refuge in any other, and added, "we have no suggestion to make other than your interpretation, and, indeed, we desire to be entirely non-committal as yet."

These experiments were undertaken by Dr. Wright, as he told me in his first letter asking to be supplied with some of the actual materials used by me, in consequence of his "sincere desire to ascertain the truth"; but only a few weeks after they had found unmistakable confirmation of my results, I received a letter informing me that he and his colleague were not intending to pursue the investigation. One reason alleged for their relinquishment of the investigation at this particular juncture was their non-success, in the few, and only slightly varied, attempts made to cause the organisms to grow in culture media.

Dr. Wright has, however, been good enough to send me some of their notes and unopened tubes, and amongst them I have received and opened three of the twelve tubes in question. On examination the organisms contained in each of them have been similar to those found in the first tube, specimens of which had been sent to me. In others, opened in New York, I am told the organisms have also been similar.

In Fig. 8, A and B, two of the many larger organisms found by me are shown. They are of a kind new to me, not corresponding quite either with *Streptothrix* or *Crenothrix* to which they seem most allied. In Fig. 9, A, one of the numerous early forms of such an organism, is shown; while in Fig. 9, B, we have a highly magnified reproduction of one of the many small masses which were found, similar to one which is to be seen in Fig. 8, A. In this mass,

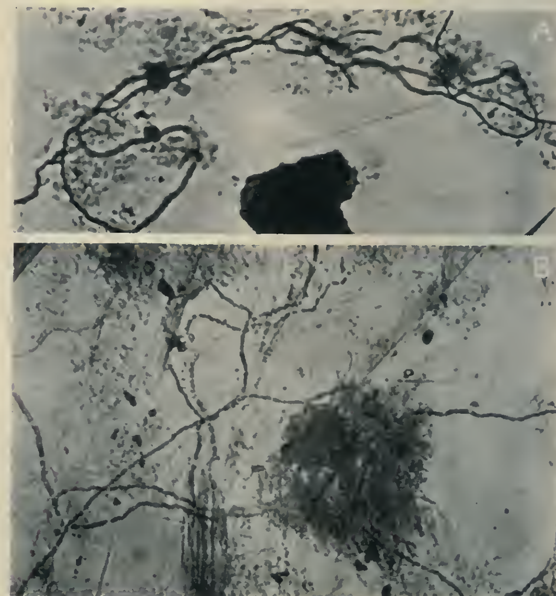

FIG. 8.—×350.

among crowds of bacilli, there seem to be also many embryonic forms of the large organism.

I handed the last of these tubes to Aubrey H. Drew,[3] as he kindly undertook to try to develop the organisms. He has been successful, with the aid

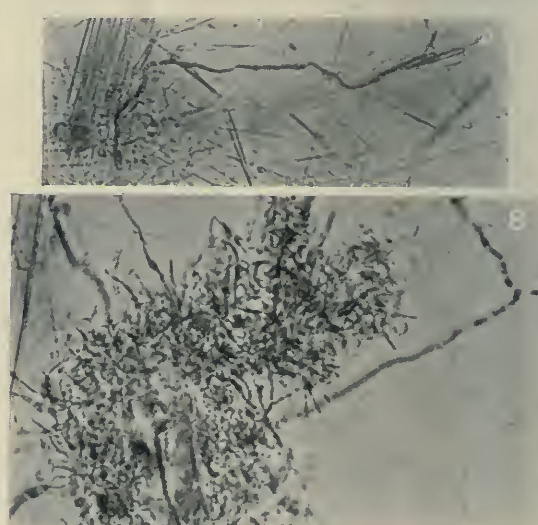

FIG. 9.—A×530; B×700.

of tyrosin and other auxetics, in cultivating the bacilli, more or less freely, in six different media, but not the large organism. The bacillus, too, seems to be strange; he has tested it in various ways and its

[2] See *Le Medecin* (Brussels), October 31, 1913, and January 15, 1914.

[3] Joint-author with Dr. J. W. Cropper of "Researches into Induced Cell-Reproduction." (Murray, 1914.)

behaviour, he tells me, is not in accord with any known form. He says: "It is large, 10 to 15 μ long, and shows a strong tendency in fluid cultures to grow into filaments, but I have not observed any branching." It is gram-positive, stains with difficulty, and "its most characteristic feature is a brilliant lemon yellow growth on auxietic agar."

I should like to refer to one other recent experience. In June 26–28, 1912, I prepared and sterilised six tubes containing a yellow solution composed of 3 drops of sodium silicate and 8 drops of liquor ferri pernetratis to the ounce of water. Five of these tubes were opened and their contents examined after periods ranging from six to nine months, and in each embryo Torulæ and other torula-like bodies, together with a few very minute mycelia of indeterminate types, are recorded by my notes to have been found. The sixth tube (No. 416) had been most of the time in the incubator, and was not opened till August 2 of this year—that is, more than two years after its preparation. Some previous experiences induced me to

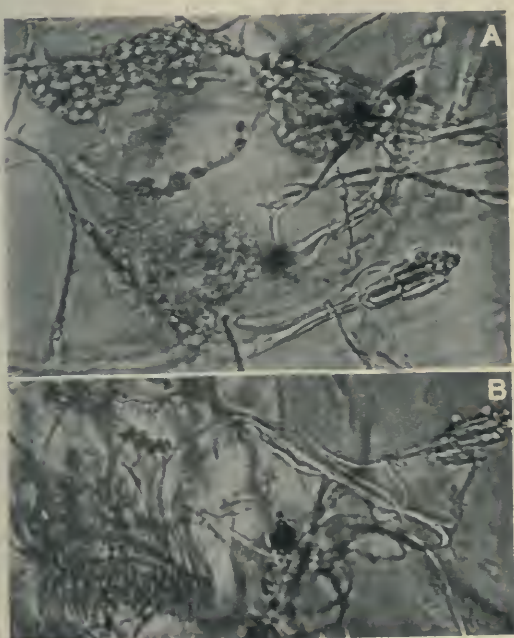

Fig. 10.—×700.

make such a trial. On opening the tube, in which there was only a very small amount of deposit, I obtained the whole of it in two dips with a pipette (the centrifuge used afterwards showed only a few shreds, granules, and minute glass splinters). The contents of the dips revealed many of the same torula-like bodies as had been found in the other tubes, and also "four masses of minute mycelium issuing from aggregates of minute spherical and ovoidal germs, together with granular matter, in part seemingly composed of typical cocci and short bacilli." With the Moulds, as shown in Fig. 10, A and B, there were masses of spherical spores with a central dot in each, together with small heads of fructification of Penicillium type bearing similar acrospores.

From a very similar solution contained in four other tubes, prepared on May 17–19, 1912, in three, which were opened at periods varying from seven to ten months, the spores and mycelium of a mould of Oospora type were found by myself and others. The fourth tube was kept for nearly seventeen months before it was opened, and two months before that date two obvious tufts of mould could be seen at the bottom of the tube, one of them nearly half an inch in diameter. When this tube was opened in Prof. Hewlett's laboratory, we saw that the growth was again a mass of Oospora[4] with the same characteristic spores as had been previously found. All this set of tubes had been exposed to light during the first six months, while the others had been in the incubator.

Concluding Remarks.

Many critics of my tube experiments have been incredulous either as to the organisms found in the tubes being really organisms, or else as to their being living and actually engendered within them. They found it difficult to reconcile with ordinarily entertained notions the idea that organisms like bacteria and Torulæ, to say nothing of Moulds, could be products of so-called "spontaneous generation."

Let such critics spend two or three weeks only in examining the developmental changes in the Zooglœas formed in a hay scum, and see how much many other cherished preconceptions will be upset. Are they ever likely to do it? Well, let them bear in mind that three bacteriologists to whom I have demonstrated these changes were unable to doubt that the Fungus-germs, the Monads, and the Amœbæ were actually derived from the ultimate products of segmentation; and, further, that they were unable to suggest "infection" as an hypothesis that could possibly account for the many hundreds of similar changes taking place simultaneously in each fragment containing the different sets of Zooglœa.

When they have seen similar results themselves, what attitude can the critics take? If they see animal products, such as Monads and Amœbæ, taking origin from aggregates of primordial vegetal units like bacteria, and are compelled to recognise that such Monads, altogether independently of any possible inheritance, are enabled to throw out flagella, to come into being provided with a nucleus, and to develop actively functioning contractile vacuoles, will they still adhere to all their preconceptions, or will they rather admit their previous ignorance of nature's potency in this as well as in many other directions?

In a recent able article[5] on "Science and the Limits of Belief," Sir Ray Lankester dwells very forcibly upon "the importance of knowledge based securely on experimental demonstration and the examination of actual things." As he says: "It is precisely by the refusal to discuss possibilities, and by being at the same time willing and anxious to receive and verify tangible demonstration of a fact, however improbable it may appear," that all progress in science has ever been made. With this I absolutely agree; and can only trust that critics generally will adopt a like opinion.

Archebiosis is a process that always takes place beyond our ken, seeing that it must begin with mere molecular collocations, gradually going on to the formation of particles of an ultra-microscopic order. And the only explanation that seems possible of the growth of such particles into organisms like those found in the tubes, as well as of the appearance of the heterogenetic products that we have seen proceeding from Zooglœal segments, is to fall back upon an explanation which is generally admitted to account for all the known forms of crystalline matter. Molecular constitution, combined with the influence of the environment, is what we have to appeal to there; and, as Herbert Spencer over and over again insisted, the forms and structures of organisms, under the influence

4 As shown by Fig. 4, in Nature for January 22, 1914.
5 In the R.P.A. Annual for 1915 (recently published

of what he termed "organic polarity," must be dependent upon like causes. In accounting for the lower forms of living matter, therefore, we may suppose, as he says,[6] that their "organic molecules of each kind, no matter how complex, have a form of equilibrium in which, when they aggregate, their complex forces are balanced."

H. Charlton Bastian.

SMITHSONIAN GEOLOGICAL EXPLORATIONS.

During the past year, the Smithsonian Institution was represented in the field by nineteen parties and individuals engaged in the collection of data relative to astrophysics, geology, biology, and anthropology, besides nine representatives of the Bureau of American Ethnology, who secured information relative to the American Indian. While most of the exploration occurred in the United States, considerable work was carried on in Canada, the West Indies, Peru, Switzerland, Borneo, Cashmere, Egypt, Greece, and Italy.

A recent publication of the institution describing the various explorations, includes a report on the Palæontological field-work of the secretary, Dr. C. D. Walcott, in the Canadian Rockies, near the Robson Peak district in British Columbia and Alberta, and in Field, British Columbia. The mountainous scenery in the former region is quite alpine in appearance, including snow-capped and glacier-covered peaks which tower 7500 to 9800 ft. above Lake Kinney, itself some 3000 ft. above sea-level. On this trip Dr. Walcott's party approached from the west in order to study the invertebrate fossils in this section, which he considers one of the finest in the world. At the base of the mountain at Lake Kinney, there exist fossil beds, 4000 ft. or more in thickness, where a number of important ancient Cambrian fossil fauna were secured, as well as many examples of the species found in 1912. At Field, work was carried on in the great Cambrian fossil quarry, where, after blasting out the solid beds to a depth of 22 ft., a fine collection for the U.S. National Museum was secured.

Another geological research party was also in the field for fossils, but, instead of the very early forms of life sought by Dr. Walcott, this second party, under the direction of Mr. J. W. Gidley, was in search of fossil mammals from a later epoch. In this connection, the party again excavated in the Pleistocene cave deposit near Cumberland, Maryland, discovered in 1912, and found many new forms of mammals, and more complete remains of several species represented in the first collection solely by jaw fragments. The collection now numbers about 300 specimens, which represent forty or more distinct types of hitherto undescribed animals, many of which are now extinct, including the bear, peccary, wolverine, badger, martin, porcupine, woodchuck, dog and the American eland-like antelope. Other specimens found in less complete form were the mastodon, tapir, horse, and beaver, besides several smaller rodents, shrews, and bats. All these different animal remains occur intermingled and comparatively thickly scattered through the deposits of this ancient limestone cave, which was exposed by a cut made by the Western Maryland Railroad, and reported to the museum by Mr. Armbruster. Mr. Gidley is pursuing his studies in identifying these different remains, and expects to continue his excavations from time to time.

Mr. C. W. Gilmore, of the National Museum, conducted explorations in the north-western part of Montana, where some vertebrate fossil bones were discovered by a member of the Geological Survey in 1912. A total of more than 500 separate fossil bones was collected, among them a nearly complete skeleton of a new Ceratopsian or horned dinosaur, the smallest known of the great horned reptiles, and the first to be found having a complete articulated tail and hindfoot. Another find was a partial skeleton of the new Trachodont or duck-billed dinosaur, recently described from specimens obtained in Canada.

Dr. R. S. Bassler spent some time in the Appalachian Valley of Maryland studying the post-Palæozoic geologic history of the region as indicated by the present surface conditions, under the auspices of the U.S. National Museum, and the Maryland Geological Survey.

Another field research party which concerned the collection of fossils was maintained in Illinois by Mr. F. Springer, in connection with the preparation of his monograph on the fossil crinoidea, and to add to the museum collections of these fossil invertebrate marine animals. The field-work was undertaken in co-operation with the geological work of the State of Illinois, in order that the horizons from which these fossils were taken might be definitely determined. This resulted in securing several large cases of material, among which were several very large slabs containing numbers of specimens.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Dr. E. G. Fearnsides, Miss F. M. G. Micklethwait, and Dr. E. P. Poulton have been elected to Beit Memorial Fellowships for Medical Research. Each fellowship is of the annual value of 250*l*.

The third annual conference of educational associations will be held from January 1 to January 9, 1915, at the University of London, South Kensington. The inaugural address on the principles of educational science will be given by Bishop Welldon. In addition to the addresses and discussions in connection with the meetings of the Geographical Association, to which attention was directed in our issue of last week, mention may be made of the following contributions to the conference. At the meeting of the Froebel Society on January 4 Prof. J. J. Findlay will speak on educative toys and apparatus. On January 5 the Rev. Canon Masterman's presidential address to the Teachers' Guild will be on education for national service. The Provisional Committee for the Development of Regional Survey will meet on January 6, and a number of speeches will be delivered on regional survey in relation to education. During the evening of this date the School Nature Study Union will meet, and Mr. E. E. Unwin will speak on nature-study and the teacher. On January 8 the Science Teachers' Association holds its meeting, and Miss Muriel Robertson will speak on some sleeping sickness problems in Uganda; and on the same day Dr. G. R. Parkin will address the Association of Assistant-mistresses on the responsibilities of Empire.

The annual Convocation of the Allahabad University for conferring degrees was held in November. The Chancellor, Sir James Meston, delivered an address which is reported in the issue of the *Pioneer Mail* for November 20. Towards the end of his remarks he said:—"My sole aim is the greater efficiency of our University. Now there are two kinds of efficiency. One kind, wrongly so called, seeks for a mechanical perfection, an official symmetry, a standardising of work and ideals with little thought

for human weakness and human reticences. Such is the Teutonic form of efficiency, against which the armies of England and India are battling in Europe at this moment. The efficiency which we want in the India of to-day is of a different and a better type. It seeks for a steady improvement of the conditions which stimulate self-development; it does not despise the feelings and frailties of mankind; and it moves through the portals of conviction towards the goal of the ideal. It is in this sense that efficiency must ever be the rally-cry of our University. We can never stand still but must always move forward, striving for the best, with a divine discontent for all the spurious imitations and the makeshifts which we may be asked to accept in its place. In the ordinary life of the world we have constantly to endure the second best or something still poorer, in art, in music, in literature, in our companionships. But let us not foist the second best, if we can help it, on our students. The temptations to be content with it will assail them soon enough. Be it our part to give them the best we can command, and to help them to enjoy and desire it. In this way shall we raise the true efficiency of our University and ensure for our graduates their proper place in the van of Indian progress."

SOCIETIES AND ACADEMIES.

Manchester.

Literary and Philosophical Society, December 1.—Mr. F. Nicholson, president, in the chair.—C. H. **Lander**: Graphical determination of the stresses in the main spars of monoplanes. One of the most complex problems connected with the design of beams continuous over several supports is presented by the main spars of monoplanes. The stresses are made up of direct compressions and those due to bending moments, the determinations of the latter being most complicated. The lift of a wing surface for small angles increases with the angle of incidence and with the square of the velocity: at a speed of about 60 miles per hour the lift of a certain type of curved wing varies from 5 lb. at 4° up to a maximum of 11·7 lb. at 17°; at 120 miles per hour these lifts would be four times as great. Most monoplanes are designed for a load of $0·007V^2$lb. per square foot, V being the designed speed in feet per second. From this the loading on the spar may be determined for different angles. The method of solution of the stresses then varies according to the manner in which the lift wires are attached to the spar. The direct application of Claxton Fidler's method of solution of continuous beams may be used when the lift wires are attached to the spar at the neutral axis. When these wires are attached at the lower side of the spar, the longitudinal moments induced may be assumed and their diagrams plotted as though the spars were discontinuous over the points of support, characteristic points obtained, and the true base line drawn by Fidler's method. A modification of Fidler's method can also be used in the case of wires badly adjusted or injured.—Prof. W. H. **Lang**: Studies in the morphology of Isoëtes. Pt. I.—The general morphology of the stock of Isoëtes. The external form and gross anatomy of the two-lobed stock of *Isoëtes lacustris* is described. The upper portion of the stock corresponds to the shoot, the lower portion behaves as a downwardly growing rhizophore, on which roots arise in acropetal succession. The position of the deeply-seated growing line of the rhizophoric region corresponds to that of the secondary meristem of the base of the stem, but its mode of growth is different. The growth proceeds, and the roots are brought to the surface, as if the lower apex were not only drawn out and deeply sunken, but the opposed sides of the depression were congenitally united. When the roots are exposed by the splitting process at the groove they stand exogenously on the surface. This mode of interpreting the morphology of Isoëtes proves satisfactory when applied either to the explanation of the growth of the stock itself or in comparisons with Lepidodendreæ and Pleuromeia. The rhizophoric region of the stock of Isoëtes is regarded as the structure in existing plants most closely comparable to the stigmarian base of the Lepidodendreæ.

December 15.—Mr. F. Nicholson, president, in the chair.—F. R. **Lankshear**: Quantitative absorption spectra. Part ii.—A new ultra-violet photometer. A new ultra-violet photometer was described, in which, by a system of condensers and prisms, two equal beams of light are obtained. One beam passes through the absorbing liquid and the other through a central adjustable sector. Corrections due to the intermittent nature of light thus become unnecessary.—W. C. **Jenkins** and E. L. **Rhead**: Some notes on aerolites: the Appley Bridge aerolite of October 13, 1914. A summary of observations made on the mass found at Appley Bridge, and the results of preliminary analyses of its chemical composition.

Paris.

Academy of Sciences, December 7.—M. P. Appell in the chair.—Haton de la **Goupillière**: A property of arithmetical progressions.—J. **Bosler** and H. G. **Block**: Observations of the eclipse of the sun of August 21, 1914, made at Strömsund (Sweden) by the expedition from Meudon Observatory. The main object of the expedition was to photograph the spectrum of the corona in the whole visible field, including the red, and, if possible, obtain some indications of its velocity of rotation. The weather conditions proved extremely favourable. The results of the observations are summarised on p. 460.—M. **Skossarewsky**: The electrolytic dissociation of acetylene and its metallic derivatives. The electrolytic dissociation of acetylene and its monosodium derivative has been proved by measurements of conductivity in solution in liquid ammonia. The dissociation increases with the dilution of the solution. The temperature coefficient of the specific conductivity is about 2 per cent. for 1° C., and is nearly independent of the concentration.—M. **Tiffenau**: Molecular transposition in the *cyclo*hexane series: passage to the *cyclo*pentane series. Orthoiodo-hydroxy*cyclo*hexane, treated with silver nitrate, gives the aldehyde of *cyclo*pentane-carboxylic acid. The removal of hydriodic acid causes the opening of the ring, and passing from a *cyclo*-hexane to a *cyclo*pentane derivative. Homologues of the *cyclo*hexane alcohol behave in a similar manner.—Marcel Le **Brazidec**: Molecular transposition in the phenyl*cyclo*hexane series: migration of a phenyl group without passage to the *cyclo*pentane series. Iodo-phenyl*cyclo*hexanol, on elimination of hydriodic acid with silver nitrate gives phenyl*cyclo*hexanone, a *cyclo*-pentane derivative not being formed.—C. **Grossmann**: The uranium minerals of Fiadanana, Madagascar. Externally the mineral resembles euxenite and contains from 12 to 40 per cent. of Ur_3O_4. The mineral with the higher proportion of uranium possesses a radio-activity nearly double that of pure black uranium oxide, and may prove a possible source of radium compounds.—Maurice **Lugeon**: Some consequences of the presence of crystalline sheets underlying the Niesen zone (Switzerland).—Fernand **Guéguen**: The alteration termed "piqûre" of sail and tent canvas. The loss of strength of canvas in certain spots after exposure to the open air is shown to be due to the

development in the tissue of various moulds. It does not seem to be due to accidental contamination of the fabric, but is caused by the development, under the influence of moist heat, of filaments of mould present in the new material. Sterilisation by steam is suggested as the most practical means of dealing with the trouble.

CALCULATING DEVICES.

Modern Instruments and Methods of Calculation. A handbook of the Napier Tercentenary Exhibition. Edited by E. M. Horsburgh. Pp. vii+343. (London: G. Bell and Sons, Ltd., and The Royal Society of Edinburgh, n.d.) Price 6s. net.

ALL who are interested in the history or the methods of calculation owe a debt of gratitude to the editor and the committee who have produced this valuable book. It is in the recollection of everyone concerned in mathematical operations that the Royal Society of Edinburgh held a great celebration in July last, three hundred years after the publication, by John Napier, of his admirable Canon of Logarithms. This was attended by learned delegates from many distant countries, as well as by a number of our own countrymen. Greatly as many must have regretted their inability to be present on account of duties elsewhere, this regret will not be lessened by a perusal of the book now under review, for from it they will learn what a magnificent collection was available for inspection and discussion. This collection of tables, books, portraits, and instruments of various kinds, which must have appealed to the historic as well as the utilitarian and mechanical instincts of those who were fortunate to be able to attend the celebration, form the basis upon which the present work is constructed, for it is in minor part catalogue and in major part a series of descriptive articles by experts in the several branches.

Seeing that the price asked for a large octavo book of 343 pages and containing a very large number of excellent illustrations is only six shillings, those who are interested should feel that, like the Nautical Almanack, the work is in effect a gift, the price doubtfully covering the cost of production.

The first section, by Prof. G. A. Gibson, deals with the life of Napier, of his great invention of logarithms, of his meeting with Briggs, and matters mainly of personal and historical interest. Here we read how Napier formulated his ideas of the logarithm which was derived, not from algebraic methods, as is now found to be most convenient, but upon the relative values of the portions of two lines determined by the motion of two points, one moving uniformly and the other, starting at the same, but moving with diminishing velocity such as to be proportional in amount to the length of the part untraversed. He thus made his logarithms without reference to a base, and the logarithm of "the whole sine" (the sine of 90°) becomes zero, the logarithm of positive quantities less than unity is positive, and of quantities greater than unity is negative. Curiously, hyperbolic logarithms to the base e are not those that Napier calculated, but logarithms to the base $1/e$. It is difficult to realise now that highly convergent series for logarithms are universally understood how Napier could have calculated as he did the logarithmic series and tangents of all angles from 0° to 90° by intervals of one minute of arc, and this long before the days of the binomial theorem. In this chapter we learn incidentally that Napier invented the decimal point, and we find also a description of the well-known "bones."

The next two sections are very largely in the nature of catalogues of the articles in the loan collection and of the collection of mathematical tables, but descriptive articles are included, of which one on portable sun-dials, by J. R. Findlay, and an account, written by Dr. Knott, of the great manuscripts by Dr. Sang, given by his daughters to the Royal Society of Edinburgh, may in particular be mentioned, as also the concluding article, by W. G. Smith, on the special development of calculating ability in prodigies or "calculating boys."

The further chapters are as follows: "Calculating Machines," by F. J. W. Whipple, but including special articles by P. E. Ludgate and T. C. Hudson; "The Abacus," by Dr. Knott; "Slide Rules," by G. D. C. Stokes; "Other Mathematical Laboratory Instruments," by a number of specialists. As this chapter includes such varied and elaborate instruments as integraphs, planimeters and their use in naval architecture, harmonic analysers, tide predictors, machines for drawing conic sections, for solving equations and precision plotting, many of which are well illustrated and explained by a number of authors having special knowledge, it will be evident that this is one of the most technically difficult and illuminating in the book. Among remaining chapters may be mentioned that on ruled papers and nomograms, which latter are graphical devices by means of which numerical solutions may be found for equations involving several variables. For instance, in the general equation for a spherical triangle showing the relationship between any angle and the three sides, Prof. D'Ocagne has given a nomogram from which, if three of the six quantities are given, the other three can be determined by the aid of a stretched thread.

The chapters relating to calculating mechanism contain descriptions of numerous recent additions

to our resources in this direction which as yet are but little known, and interesting to many as a discussion of the novelty and advantages of these would be, it would be impossible to do justice to the subject without occupying far more space than is available. Dr. Knott's chapter on the abacus, also, is one which it would be delightful to follow if only space allowed, for the description of the mental process followed by the Japanese when making their lightning speed calculations with the abacus, of their inverse way of effecting division, and, in general, of the manner in which they work off figure by figure the problem set upon the abacus as it is done with to make room for the new figure in the result; all are full of interest, and a careful study of this chapter would be likely to modify the complacency with which the European in general contemplates the Asiatic as a computer with wires and beads.

C. V. BOYS.

OIL OF VITRIOL AS AN AGENT OF "CULTURE."

The Manufacture of Sulphuric Acid and Alkali with the Collateral Branches: a Theoretical and Practical Treatise. By Prof. G. Lunge. Fourth edition. Vol. i.: Sulphuric Acid. Part i., pp. xxiv+582. Part ii., pp. xii+583–1078. Part iii., pp. xii+1079–1617. (Gurney and Jackson, 1913.) Price, vol. i. (in 3 parts), 3*l*. 3*s*. net.

PROF. LUNGE'S monumental work on the manufacture of sulphuric acid is one of the acknowledged classics of chemical technology, and the soundest proof of its continued merit and widespread appreciation is seen in the circumstance that it has now reached its fourth edition. The subject is admittedly of great complexity. The manufacture is one of the great staples of chemical industry, and lies, in fact, at the basis of that industry in general.

Indeed, it is impossible to conceive of the position of chemical industry, and of the industries dependent upon it, if the world were suddenly bereft of sulphuric acid. If we could deprive Germany, for example, of all means of manufacturing or otherwise procuring oil of vitriol, not only would her chemical industries languish, but even her capacity for military offence or defence would be effectually checked since the use of this acid is indirectly, but nevertheless absolutely, necessary for the manufacture of those high explosives upon which her artillery, the strongest arm of her service, wholly depends. She has, of course, internal means of supply, but these are by no means limitless, and there are already signs that she is within measurable distance of the end of her resources as regards the provision of the raw materials needed for the manufacture. Liebig once said that we might gauge the civilisation of a country by the amount of this acid it consumed. It would appear, therefore, that the continued forcible dissemination of German "culture" is largely dependent upon a German supply of oil of vitriol.

But, of course, it is the arts of peace that mainly consume the oil of vitriol the world requires, and there is scarcely a process of manufacture that could be named that does not need it either directly or indirectly.

It is difficult to obtain a trustworthy estimate of the aggregate output at the present time, but from the statistics referred to by Dr. Lunge it is probably not fewer than five million tons, of which not less than a fifth, and probably more, were, prior to the outbreak of war, made in Germany, mainly from imported iron pyrites.

In addition, Germany has hitherto imported a gradually increasing quantity of oil of vitriol, amounting in 1911 to 99,653 tons. At the present time, therefore, she is almost wholly dependent upon the employment of zinc-blende, the relatively poor German pyrites, the mixed ores from Freiberg, and Mansfeld, and the small quantity from gas-oxide. It may be anticipated, therefore, that the serious economic disturbance consequent upon the invasion of her eastern frontier will very largely affect her ability to maintain her supply.

In the case of a substance of such world-wide application as sulphuric acid it need scarcely be said that there is a very strenuous industrial competition, and there is probably no branch of chemical technology which has been more thoroughly developed than its manufacture, and to-day its production is studied, watched, and controlled with all the precision of a vast scientific experiment in which all the resources of modern chemical, physical, mechanical, and engineering knowledge are brought to bear. The main principles of its manufacture are in all probability definitely established, but so fierce is the competition and so bountiful the trained skill and intelligence concentrated upon its economic production, that each succeeding decade sees some new departure, often of fundamental or far-reaching importance. It is a duty which the veteran author has imposed upon himself in the days of his retirement from the active work of his professorship, to take note of these changes, and to embody them in successive editions of the great work with which his memory will always be associated. That he may long be spared to continue this self-imposed task is the sincere hope of every well-wisher to the progress of that great branch of technology of which Dr. Lunge has been for so many years so distinguished an exponent.

T.

TWO MATHEMATICAL COURSES.

(1) *The Theory of Numbers.* By Prof. R. D. Carmichael. Pp. 94. (Mathematical Monographs, No. 13.) (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 4*s.* 6*d.* net.

(2) *Lectures Introductory to the Theory of Functions of Two Complex Variables.* Delivered to the University of Calcutta during January and February, 1913, by Prof. A. R. Forsyth. Pp. xvi+281. (Cambridge: University Press, 1914.) Price 10*s.* net.

THESE works are mainly interesting as examples of the trend of instruction given to university students who are just beginning to specialise. One is based upon two years' teaching in Indiana University; the other is the substance of a course delivered, by invitation, at the University of Calcutta, with, presumably, a number of Indian students in the audience. Both courses agree in the endeavour to trace the main outlines of the argument, to give really illustrative examples, and to avoid excessive detail on particular points of minor importance.

(1) Prof. Carmichael does not advance beyond well-beaten and classical ground, so that he has little opportunity of introducing really modern ideas. All but one of his six chapters deal with such things as ordinary factorisation of integers, elementary congruences, Fermat's theorem, and primitive roots. Chapter vi. is a miscellany in which there is a statement, without proof, of the law of quadratic reciprocity for two odd primers; a very brief account (with references, fortunately) of some special Galois imaginaries, and some interesting samples of the true Diophantine analysis. Some of the harder examples are novel and interesting, *e.g.* "The number of divisions to be effected in finding the G.C.M. of two numbers by the Euclidean algorithm does not exceed five times the number of digits in the smaller number (supposed written in the decimal scale)."

Without advising any improper and premature specialisation, it may be fairly urged that some of the work contained in this course might be done at school; the G.C.M. theory, and that of linear congruences, at any rate. Familiarity with the congruence notation is so important that its introduction ought not to be deferred.

(2) Prof. Forsyth has undertaken the difficult task of giving an outline of the known theory of functions of two independent (complex) variables, together with an account of what he calls "triple theta-functions." Everyone who has studied this theory at all is aware that it suggests theorems similar to those of Gauss, Green, Cauchy, etc., for functions of one variable, but that it is very difficult to prove them in an analogous, so to speak, geometrical way, mainly because while a plane or a sphere gives us a graphic picture of the field of one complex variable, we cannot at present realise a convenient image of the field of two independent complex variables. It is easy enough to make images of a sort; for instance, take two planes, plot off the independent variables, x, y, in the usual way on each, and now associate with a given pair (x', y'), the line joining the point which is the image of x' to that which is the image of y'. An obvious objection to this is that the meet of the planes does not correspond to a unique pair x', y', and there are other inconveniences connected with the difficulty of visualising linear complexes and congruences. After reviewing various proposals, Prof. Forsyth concludes that the only practicable way at present is the purely analytical one, following the methods of Weierstrass and his school. It is to be hoped that this is not the final word on the question; at any rate, there are papers by Picard, Appell, and Poincaré which ought to stimulate those whose ideas naturally clothe themselves in geometrical forms.

Features of the course which should be noted are: (1) the introduction of *two* dependent variables, now and then, as functions of two independent variables; the use of this is analogous to that of one-one transformations of plane curves; (2) in the chapter on integrals, where we have *two* algebraic functions introduced, so that the independent variables are arbitrary; (3) the theory of the so-called "triple theta-functions." The characteristic equations of these functions are given in the form:

$$\vartheta(z+1, z') = \vartheta(z, z'+1) = \vartheta(z, z')$$
$$\vartheta(z+\mu, z'+\mu') = \exp.\{-2\pi i(2z+2z') - 2\pi i(\mu+\mu')\}\,.\,\vartheta(z, z').$$

Hence the author derives double Fourier expansions for the functions, which fall into a co-ordinate set of sixteen; various tables and formulæ relating to them are given. The course concludes with a sketch of the theory of quadruply periodic (double) theta-functions, and their algebraic relations.

It seems to us that this course is not quite so well-proportioned or up-to-date as that of Prof. Osgood, recently published, on the same subject; but the difference of object and of audience must be allowed for. At any rate, we have a useful guide to the work of Weierstrass and Picard, a certain amount of new, although not very fundamental, theory; some instructive and original examples; and, it need scarcely be said, an elegant analytical presentation of the subjects treated.

G. B. M.

THE LONDON HOSPITALS AND THEIR FUTURE.

Historical Account of Charing Cross Hospital and Medical School (University of London) Original Plan and Statutes, Rise and Progress. Founded 1818. With which is included some Account of the Origin of the other Hospitals and Schools in London. By Dr. W. Hunter. Pp. xx + 309. (London: John Murray, 1914.) Price 21*s.*

THE rise and development of the "teaching" hospitals of London is intimately associated with the progress of medical science in England; besides being the homes of medical education, much excellent research work, particularly on the clinical side, has emanated from their walls.

In a sumptuous volume, embellished with a wealth of illustrations and reproductions of old prints, Dr. William Hunter, its "Dean," reviews the history of Charing Cross Hospital. He classifies the modes and motives of origin of the London hospitals as follows:—(1) The *Monastic* (afterwards charitable), *e.g.* St. Thomas's and St. Bartholomew's; (2) the *Charitable, e.g.* Westminster, the London, St. George's, etc.; (3) the combined *Charitable* and *Educational,* for which Charing Cross Hospital was founded; and (4) the *Educational,* University and King's College Hospitals.

Founded by Dr. Benjamin Golding in 1818, the fortunes of Charing Cross Hospital were directed by him for a period of well-nigh fifty years. Of its many distinguished students, the name of Huxley is the most prominent, and his memory is perpetuated in the biennial Huxley Lecture delivered at the school.

The Charing Cross Medical School has continued to progress, and one of the latest developments is the housing of the Public Health Department of King's College within its walls—a form of concentration in one branch of medical education which to some extent falls into line with the conceptions of the Royal Commission on University Education in London.

Although the report of this Royal Commission foreshadows many changes in medical education, there seems little prospect of State control of the hospitals—indeed, the voluntary system of support appears to be in a stronger position than ever. When the first Employers' Liability Bill came into force many came to the conclusion that this was the thin end of the wedge for State control, and the second and more far-reaching Act seemed to confirm this opinion. As a matter of fact, however, the voluntary hospital system has gone on, and as the public became accustomed to these Acts, the hospitals continued not only as well as before, but most of them with improving revenues. Even the appearance of the National Insurance Act upon the scene has made no difference—most of the hospitals receive better support than ever from the public, and the King Edward's and other funds are thriving beyond all expectation. On one hand, it is true, the voluntary system has disadvantages. It is the generous and sympathetic portion of the public that supports the hospitals, and others shirk their responsibilities. On the other hand, the poor obtain better treatment than they could probably obtain in State supported hospitals. There is a blaze of light on the British voluntary system that is entirely absent from the continental State hospitals and in hospitals under the Poor Law. Even if the present voluntary hospitals were taken over by the State, it is almost certain that new ones would immediately be founded, as has been the case in Paris (*e.g.* the Hertford Hospital).

There might well be some modification of the hospital system in London. The sick should so far as possible be removed from the densely populated centres more into the country. That large blocks of wards should be erected on costly sites in the heart of London is a mistake—both financially and from the medical point of view. All that is required at the centre is accommodation for receiving rooms and for a sufficiency of beds for the reception of accidents and emergencies and for the treatment of the very ill. All the other cases, and the serious cases as they convalesce, should be removed to hospital wards erected more in the country. In these days of motor transport and improved road surfaces this would be an easy matter, and the staff by the same means could minister to the sick almost as readily on the slopes of Hampstead as at Hyde Park Corner.

R. T. HEWLETT.

SCIENCE AND METAPHYSICS.

(1) *Henri Bergson: An Account of his Life and Philosophy.* By A. Ruhe and N. M. Paul. Pp. vii + 245. (London: Macmillan and Co., Ltd., 1914.) Price 5*s.* net.

(2) *The Idealistic Reaction against Science.* By Prof. Aliotta. Translated by A. McCaskill. Pp. xxii + 483. (London: Macmillan and Co., Ltd., 1914.) Price 12*s.* net.

(3) *Berkeley and Percival.* By Benjamin Rand. The Correspondence of George Berkeley afterwards Bishop of Cloyne, and Sir John Percival afterwards Earl of Egmont. Pp. x + 302.

(Cambridge University Press, 1914.) Price 9*s*. net.

(1) IF a layman may presume to criticise the professional metaphysician, one may say that the merit of M. Bergson is to have freshened up philosophy. His point of view is *nullius addictus jurare in verba magistri*, and he has successfully cast off all the trammels not only of the old cut and dried philosophy of the schools, but even the gaseous mysticism of Neo-Hegelianism. Yet some style him a Neo-Hegelian. Philosophy, he says, should be moulded on experience, and experience both changes and grows with human development. There is something of most philosophies in M. Bergson's attitude to the universe, for his philosophy is simply this : it is everything but a system. He is neither monist nor pantheist, but, as it were, a layman trying to understand. This attitude of his is optimistic; he has confidence in the universe. It may seem that he, like other exponents of "the new philosophy," has a quarrel with monism and materialism, but he himself has deprecated all philosophical quarrels, for after all philosophy is only our attitude to and conception of the Absolute, and the wise man simply absorbs the positive results of all philosophies.

M. Bergson has given movement to metaphysics; he has charmed it with change. Change is "the very basis of all reality." To drive home his dynamic idea of reality, he employs phrases. In such a subject nothing else can be employed, for metaphysics is not science. It is at its best and it is most useful when it does not aim at being a science. The French philosopher is akin to the Greek Heraclitus, who preached eternal flux, and Heraclitus coined some great phrases. M. Bergson observes that "the animal is a specialist." It is a well-known truth, but has never been put so neatly. M. Bergson's demerit perhaps is his animism. He has studied most branches of science, but the only positive hint he derives from them is a "creative evolution," which is simply vitalism writ large. He speaks of "the idea of a God, Creator and free, the generator of both matter and life, whose work of creation is continued on the side of life by the evolution of species and the building up of human personalities." This may be pragmatic (though he would resent the imputation), but it amounts to very little. Equally *a priori* is his observation that "the brain apart from its sensorial functions has no other office than to exhibit in pantomime the mental life." It is scarcely fair, again, to credit the parallelist with supposing "that memories are somehow hung on the brain, as though a telephone conversation should remain on the wire." On the whole, M. Bergson strikes one as a brilliant epigrammatist, illuminating with modern flashes of insight the ancient and permanent text of Aristotle, "the principle of life is a God; for energy of mind constitutes life, and God is this energy. He, the first mover, imparts motion and pursues the work of creation as something that is loved." The phrase is worthy of Bergson, but the argument is in a circle.

(2) Signor Aliotta criticises with some volume the idealistic reaction against science in modern thought. He himself holds "a spiritualistic realism" by means of which he can defend scientific method and natural reality against the irrationalism of Neo-Hegelianism. His volume is remarkable as including criticism of every scientific and philosophic hypothesis and method of the last hundred years. Both Aliotta and Bergson show how modern philosophy aligns itself with science. All its deductions are based on some scientific theory. Signor Aliotta is at one with M. Bergson and other moderns in having done with scholasticism and systematism. "Concrete thought is not a cold abstract conception, but experience seen in the glow of the idea which breathes the warmth of feeling, and is moved by the energetic impulse of spontaneous volition, which inspires it with the enthusiasm of faith." "We must replace the static conception of the object which regards it as complete in itself in an inaccessible sphere by a dynamic view which beholds it in its progressive ascent to a higher form of knowledge and reality." He attempts to effect a *rapprochement* between idealism and realism, a laudable effort. Whereas Bergson finds in "intuition" the crucible of nature, Aliotta regards reason as "the final goal at which an experience aims and to which by its means all the beings in the world tend." This is teleology and presumes an Absolute Consciousness. "Nature does not exist only in the mind of man, but also outside our thought." "He who believes in the objective value of his science must then also believe in God. If an Absolute Thought does not exist, nature cannot be rational, and if there is no rationality in things, the reconstruction which we make of them with the categories and principles of our mind is an arbitrary projection of no value whatsoever."

(3) Such critical reflections would have interested Berkeley, the theorist of vision and the theistic idealist, who argued for the non-existence of matter. Existence and reality are terms which have borne the burden and heat of philosophers' tongues. Why not admit everything to be real? Berkeley's letters, hitherto unpublished, contain nothing of scientific or philosophic interest. They

only show concern as to the reception of his books, and a general interest, as of a man of the world who was also a prelate, in the doings of great personages. His famous excursions into science and metaphysics seem to have been such *tours de force* as have always been executed by brilliant public men.

In a sense Berkeley was an eighteenth-century Bergson. His naïve development of the thesis that judgment is involved in every act of vision was consonant with the then state of psychology. In his metaphysics he turned out matter, in order to introduce the living God. The being of the sense-world consists in its being perceived. The remark of Clarke and Whiston, themselves professional metaphysicians, deserves immortalisation; they expressed, when invited to criticise Berkeley, regret for "the waste of his extraordinary genius on metaphysics."

A. E. CRAWLEY.

OUR BOOKSHELF.

Modern Tunneling: with Special Reference to Mine and Water-supply Tunnels. By D. W. Brunton and J. A. Davis. Pp. vi+450. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1914.) Price 15*s*. net.

THE matter in this book is confined chiefly to tunnels and adits for mining purposes, and includes also those used to carry water for power, irrigation, and domestic use. Such tunnels are driven generally through fairly hard rock. Some cross-sections of typical tunnels are given, and extensive bibliographies are supplied which will be of assistance to the engineer responsible for the design of a tunnel. The bulk of the book, however, is taken up with descriptions of methods of executing tunnels. The authors are evidently experts in such work, and give capital discussions on such subjects as the choice of power for tunnel work, air compressors, ventilation, rock-drills, haulage, blasting, and timbering.

The section dealing with precautions which should be taken by the manager in order to ensure the safety of the workmen is of particular interest. In 1911 an average of nearly four men per 1000 employed in and about the metal mines of the United States were killed; 3·8 per 1000 in coal-mining were killed in the same period. These accidents are not entirely preventable, but much of the present mortality and injury is the result of ignorance or gross carelessness, and can be avoided. When, for instance, a man sees fit to thaw frozen dynamite in a frying-pan, or by a candle flame, there is nothing accidental about the explosion which ensues. Many managers also are either ignorant of ordinary precautions or most negligent in seeing that they are properly and consistently carried out. The fall of a slab of rock weighing anything less than one ton should be charged at once to carelessness.

The authors give a long list of don'ts, and include notes of warning regarding intoxication, which, as a contributory cause of accidents, is too little appreciated. Even a slight degree of intoxication is dangerous underground, where it is very apt to be greatly aggravated by lack of fresh air and by heat. Most of the processes described relate to American practice, but British engineers will find much to interest them in this volume.

Jute and Linen Weaving. By T. Woodhouse and T. Milne. Second edition. Pp. xxvii+590. (London: Macmillan and Co., Ltd.; New York: The Macmillan Company, 1914.) Price 12*s*. net.

THIS book must be ranked among the classics in technical literature. There is a thoroughness and completeness about it that appeals equally to the elementary student of weaving, to the experienced textile engineer, and to all those occupying responsible positions in the weaving departments of the textile industry.

Whilst the book is written around the title and deals with the subject of jute and linen weaving, a very considerable portion is equally valuable to the cotton and other sections of the trade; in fact, it may be looked upon as a very comprehensive exposition of the subject of weaving in general, for most of the problems and mechanism connected with weaving are fully treated.

For a book of this character to require a second edition is clear evidence of the very high appreciation in which it is held. The authors have taken advantage of this issue to add considerably to its value by the inclusion of some 108 new illustrations with their corresponding explanations, and much new matter has been incorporated. The 582 pages are divided up into twenty-two chapters ranging from an explanation of counts, through a very complete description of preparing machinery of almost all types, arrangements and details of looms, and their special purposes with minute particulars of their functions and products.

The newest chapters include automatic weft supply mechanisms, the chain linking machine, terry or turkish towel motions, warp stop motions, the latest box motions and jacquards, and an interesting chapter on electric driving of individual looms.

To all who are interested in jute and linen weaving and even to those who are chiefly concerned in other sections of manufacture, this book can be recommended as an unusually valuable text-book, and the authors are to be complimented on attaining such a high level in their treatment of the subject.

The Indian Museum, 1814–1914. Pp. xi+136+appendixes. (Calcutta: Trustees of the Indian Museum, 1914.)

ONLY Anglo-Indians who, like the present writer, can recall the days when—in the early middle 'seventies—the natural history and antiquarian collections of the Asiatic Society of Bengal were crammed into an ordinary-sized dwelling-house in Park Street, while those of the Geological Survey, together with its offices, were housed in a business

tenement near the river, are capable of realising and appreciating the contrast between the present and the past in respect to the status of science and art in the City of Palaces. The change was great enough when the Chowringhi "jadu-gahr" (home of magic), as the Indian Museum is invariably termed by Bengalis, was first opened during the later 'seventies, but the present enlarged building, as photographed in the volume before me, with its additional upper storey and doubled frontage, renders the original structure almost a doll's house in comparison, magnificent and spacious as it was thought to be at the time when the present writer assisted in arranging the galleries.

In housing in this magnificent and lavish style the valuable collections illustrating the natural history, geology, archæology, and ethnology of British India, the Indian Government has done its duty in a manner worthy of all praise. Whether, however, the attempt to make the museum a great centre of educational instruction in biology will ever be realised, seems, to quote from the admirable account of the rise and history of the collections given by the Hon. Justice Sir A. Mookerjee in the introduction to the volume, more than doubtful. The introduction is followed by accounts of the various departments of the museum, all written in a style which renders the volume a model of what a work of this nature should be, and a credit to all those concerned in its production. R. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Colon as a Symbol for Ratio and Division.

IN 1902 Prof. W. W. Beman, of the University of Michigan, pointed out ("L'Intermédiaire des mathématiciens," T.9, Paris, p. 229, question 2424), that the colon (:) occurs as a designation of geometric ratio at the end of the trigonometric and logarithmic tables published, together with William Oughtred's "Trigonometria" of 1657. Beman inquires whether this symbol for geometric ratio has a still earlier date.

Before answering this question we remark that it is highly improbable that the colon occurring in those tables was inserted by Oughtred himself; in the "Trigonometria" proper the colon does not occur, and Oughtred's regular notation for ratio and proportion, A . B ∷ C . D, is followed throughout.

In the English edition of Oughtred's "Trigonometrie," printed in the same year, 1657, but subsequent to the Latin edition, the passage of the Latin edition containing the : is recast, the new notation for ratio is abandoned and Oughtred's regular notation introduced.

In Oughtred's posthumous "Opuscula mathematica hactenus inedita" (Oxford, 1677), the colon (:) is used frequently, but it may have been introduced by the editor of the book.

In answer to Beman's inquiry, we remark that the colon (:) was used to designate geometric ratio some years before 1657 by at least two authors, Vincent Wing, the astronomer, and a schoolmaster who hides himself behind the initials "R. B." Wing wrote several works. In 1649 he published in London his "Urania Practica," which, however, exhibits no special symbolism for proportion. But his "Harmonicon Coeleste" (London, 1651) contains many times Oughtred's notation A . B ∷ C . D, and many times also the new notation, A : B ∷ C : D, the two notations being used interchangeably. Later there appeared from his pen, in London, three books in one volume, the "Logistica astronomica" (1656), "Doctrina spherica" (1655), and "Doctrina theorica" (1655), each of which uses the notation, A : B ∷ C : D.

The book by the second author is entitled "An Idea of Arithmetick at first designed for the use of the Free Schoole at Thurlow in Suffolk . . . by R. B., Schoolmaster there" (London, 1655). One finds in this text 1 . 6 ∷ 4 . 24, and also A : a ∷ C : c.

It is worthy of notice also, that in a text entitled "Johnsons Arithmetick, in Two Bookes" (second edition, London, 1633), the colon (:) is used to designate a *fraction*. Thus, $\frac{3}{4}$ is written 3 : 4. If a fraction be considered as an indicated division, then we have here the use of : for division, at a period fifty-one years before Leibniz first employed it for that purpose. However, division dissociated from the idea of a fraction is not designated by any symbol in Johnson's text. In dividing 8976 by 15, he writes the quotient 598 6 : 15.

FLORIAN CAJORI.

London, December 23, 1914.

Is "Atikokania lawsoni" a Concretion?

HAS a mistake not been made in Memoir No. 28 of the Geological Survey of Canada? Dr. C. D. Walcott therein describes certain silicified structures in the Steeprock Limestone of Lake Ontario which he names *Atikokania lawsoni*. He considers they represent "a group of organisms related to the sponges," or else corals like the Archæocyathinæ.

He appears to have relied on three of their features: (1) a central cavity; (2) the general form, including an

Coralloid mass from the 17-in. "Flag" bed. Fulwell Hill Quarry. × ½.

inner and outer wall, with (3) radiating tubes with septæ. Unfortunately they possess "no structural details." I suppose the author was unacquainted with the characters met with in the Magnesian Limestone of Fulwell Hill, Sunderland, where the forms are entirely due to segregation or to osmotic influence. His illustrations have a remarkable resemblance to much seen there in what I designate coralloid—a specimen of which is shown in the accompanying figure.

These have often solid centres like those in his Fig. 5, plate 1; the bands also resemble the irregular septa in his Atikokania. Without any traces of spicules it seems to me very doubtful indeed that these bodies have any organic origin, especially as it seems clear that changes in rocks after deposition lead sometimes to the formation of tubes. If my conclusions are correct, this in the Fulwell coralloids is certainly a very common development in the almost universal rod formation there. The change appears to be the result of the adherence of small circular groups of rods around a central canal; with so much of such material—there are at least two square miles of it some 130 ft. thick—the cause, whatever it may be, seems unconnected with either erosion, hydration, dolomitisation, metasomatosis, or organic remains.

I have also seen tubes of this kind in a few other calcareous rocks, but the most common banded formation (probably allied to the septæ in Dr. Walcott's specimens) is seen in weathered mortar found in the shady parts of old buildings, especially those situated near the coast. GEORGE ABBOTT.

2 Rusthall Park, Tunbridge Wells, November 18.

WHEN your letter of November 23, 1914, enclosing a note by Mr. George Abbott on the silicified structures described in Memoir No. 28 of the Geological Survey of Canada as *Atikokania lawsoni*, reached me on December 8, I had on my table a copy of NATURE of January 29, 1914, containing the note on "Zonal Structure in Colloids," by Mr. Abbott. Prior to meeting with this article, I did not know of the remarkable structure of the Sunderland Magnesian Limestone, or I should have certainly directed attention to it.

During the past summer I made large collections of supposed algal remains from the pre-Cambrian rocks in the Rocky Mountains of Montana. Some of these appear to be of undoubted organic origin. Others appear to be a combination of algal deposits in connection with concretionary consolidation.

The subject is now under investigation, and in this connection I shall take up the forms that I called Atikokania. With present information I should *not* be inclined to refer the latter to the sponges or to the Archæocyathinæ. CHARLES D. WALCOTT.

Smithsonian Institution, Washington, U.S.A., December 9.

A HISTORY OF BRITISH BIRDS.[1]

WE have already noticed the first four parts of this comprehensive publication, and the general scope of the work and the plan on which it is carried out need not be more than briefly referred to here. We now welcome the twelfth and concluding section of the work and the last of its attractive and fascinating pages.

The book claims to be the only existing work which gives an adequate account of the habits of all our species of birds, except those so rare that they cannot be said to have, as British birds, any habits worth describing. These latter are treated shortly at the end of the last volume. It claims also that it brings together from every source, British and foreign, the whole available information on the subject, and presents it in a form interesting alike to the specialist and the general reader. In showing what is known and what has yet to be found out about the habits of our birds, and in laying stress on the scientific problems which underlie the facts, the work stands alone in giving to the serious student of bird-life starting-points for further research. Though not professing to do more than supply summaries of the geographical distribution of all the species, the work claims to give recent information under this head which is not to be found in any other book on British birds.

It would be unjust to the contributors to these volumes if the impression arose that they had been merely content to compile the observations of others. For while it is true that in more than one case contributors to this book have found

Photo.] [*W. Farren.*
FIG. 1.—Lapwing's nest. From "The British Bird Book."

themselves in the very unsatisfactory position of having to write about species of which they had little personal knowledge, there is much information in the book that is the result of direct personal observation, and much, again, of this information could have been supplied only by the contributors and by no one else. Among them we have only to name the Rev. F. C. R. Jourdain, who, in search of eggs, has travelled over so much of Europe and the adjacent countries, and Mr. William Farren, to show how much valuable original observation the editor has had to draw upon among his various contributors. As the editor points out, too, though the bird-man who has concentrated his attention on a few species

[1] "The British Bird Book." Edited by F. B. Kirkman. Sections V—XII. (London and Edinburgh: T. C. and E. C. Jack, n.d.) Price 10s. 6*d*. net, per section.

—the specialist in field ornithology—cannot afford to ignore the experience of others in his own field, and must to some extent be a compiler if he is to be thorough, it is obvious that he has a great advantage over the non-specialist in that his knowledge enables him to value and select the evidence with a confidence that cannot be felt by one who is dealing with the relatively unfamiliar.

These conditions and circumstances, and what naturally follows from them, doubtless account for the somewhat uneven quality of the various accounts of the different families or groups of birds which go to make up this very readable work. It is pointed out that in a work to which there are several contributors, it becomes necessary to bring into harmony the claim of the individual writer to express himself in the way he thinks best, and the claim of the editor to subordinate individual treatment to the general plan. To strike the just balance between the two is far from easy—perhaps impossible. The tendency in the present work has favoured the individual. The gain has been a vigour and freshness of treatment that are not always conspicuous in works of this kind; the loss a certain weakening of methodical arrangement which is more particularly apparent in the earlier part of the work, owing partly, however, to circumstances that were neither contemplated nor desired, nor, at the time, capable of remedy. The loss, it is hoped, will be practically made good by the completeness of the index. Be this as it may, although some of the articles may be somewhat weak, and perhaps in parts fanciful, we have here, on the whole, a series of excellent life-histories of our birds; many of them written by experienced and accurate naturalists from their personal and recent experience and observations. There are statements to be found with which we do not agree; and it would not be difficult to criticise parts of the book. But it is a great and a novel work; and, if anything, it improved as it went on.

The coloured illustrations have been drawn from life, not from stuffed specimens; in many cases long special journeys have been made to distant localities to study little-known birds for the purpose of this book. Photographs of nests, nesting sites, etc. (two of which are reproduced here), as well as a series of coloured plates of eggs of British birds, are given.

If the scheme of the work is new, that of the larger illustrations is in keeping with it. The coloured plates are not merely figures of the birds, but they also tell part of their life-history. We may instance those of the sand grouse, crested grebe, the arctic tern pursued (as is its wont) by a skua, and the red-legged partridge struck down by a peregrine. Where it is the habit of the bird to congregate, it is so represented, *e.g.* the gannet, of which twenty-seven individuals appear in the plate. Mr. Seaby's delightful coloured studies alone are enough to give everyone interested in our birds an overpowering desire to put these volumes on their book-shelves. Many of them will recall to the naturalist scenes which he has witnessed, but, alas! has not had the power to preserve except in memory. For in their illustration of bird-life no photograph will vie with the coloured drawing of the skilled artist *who really knows his birds*. Apart from the all-importance

Photo.] [*F. B. Kirkman.*
FIG. 2.—Nesting ground of lesser blackbacked-gull (Farne Islands). From "The British Bird Book."

of correct and delicate colour, the camera undoubtedly does not see things just as the human eye sees them. To name only one, Mr. Seaby's pied flycatchers, as an example of the sort of picture of bird-life we really desire. The female is about to feed the young, the male looking on. Here we have a bit of life-history shown in just the spot in the deeply shaded June woods where the nesting birds will be found—perfect in its facts and details. The birds are alive, the expression in their eyes quite wonderful.

The coloured plates of eggs (some by Mr. Grönvold), carefully prepared, cannot fail to be useful for identification purposes. Since the eggs of the great bustard and the avocet (not to mention the wood sandpiper, only once known to nest in Britain) are figured, we are at a loss to know why that of the black-tailed godwit is omitted. All three birds have ceased to breed with us, but the godwit was the last to survive as a breeding bird, and, moreover, is the most likely of the three to resume that status. There is a useful plate illustrating the down and *nest feathers* found in the nests of the different species of wild duck, the eggs of which are often very much alike. It is only by means of these feathers that the identity of ducks' eggs can be made sure of.

The final section of the work comprises classified notes on the rare British birds (including all species not described in the body of the book), extending to nearly a hundred pages. Chapters on structural characters; migratory movements, by Mr. T. A. Coward; the study of bird behaviour; and bird photography. Also a list of works consulted and a good and full index.

SUPERSTITION AND DISEASE.[1]

THIS volume represents the Fitzpatrick lectures for 1912 delivered at the Royal College of Physicians. Dr. Crawford has treated his subject as much in its mental and moral aspects as in its physical, and the result is a wise and very interesting book. In a few chapters he gives us a vivid presentment of the long series of epidemics which devastated Europe and the Levant between the days of Moses in Egypt and those of Napoleon at Jaffa. Painting, sculpture, and architecture have all been pressed into the service, and the thirty-one plates in the book testify to the frequency with which the world's great artists have found inspiration in the terrible scenes of a plague-stricken city.

Many writers, too, from Thucydides to Pepys have been laid under contribution, and bear witness to the magnitude of the catastrophes. We read of Rome in the thirteenth century shaken by twelve visitations of plague, each one extending over several years. We read of the Black Death when one-fourth of the entire population of Europe perishes. Half England is wiped out in this pandemic, and towns and villages are stripped of inhabitants.

Sometimes the epidemic runs its course with appalling rapidity. The destruction by plague of Sennacherib's army in one night may be legendary, but there is no reason to doubt that in Byzantium during a four months' visitation the daily mortality often reached the total of ten thousand.

Dr. Crawford directs attention to the identity through the ages of the "portents" of plague. For example, the angel with drawn sword is seen to hover over London in 1665, as over Rome in 590, and over Jerusalem centuries before Christ.

From century to century, too, similar theories of its causation are rife. It is the work of malig-

Dress of a Marseilles doctor, 1720. (From "Plague and Pestilence in Literature and Art."

nant demons; it is sent from heaven in punishment for sin; it is the result of evil magic exercised by man on man; it is engendered in the clouds; it is caused by earthquakes which liberate the poisons from the earth; by dust which irritates the skin; by impure air, or unsuitable food. Of all the speculations, the most mischievous because productive of such hideous cruelty is the surmise that it is caused by water which has been poisoned by our enemies, the Jews—or by our enemies, the Christians.

Dr. Crawford points out that the contagious

[1] "Plague and Pestilence in Literature and Art." By Dr. Raymond Crawford. Pp. viii+222. (Oxford: Clarendon Press, 1914.) Price 12*s.* 6*d* net.

character of the disease was recognised by lay observers long before it was accepted by science. The mental myopia which is, he says, apt to afflict science when untempered by letters is indeed apparent in this connection, and it is chastening to professional complacency to note the long list of lay writers from Thucydides onward who accept the truth of contagion from man to man, while the doctors agree in rejecting it.

The methods of cure vary little throughout the long period with which Dr. Crawford deals. The plague may be stayed by offerings of prayer and sacrifice. In this belief Marcus Curtius hurls himself into the abyss, or Solomon Eagle prays in the streets, naked, and bearing on his head a brazier of burning coals. Or scenic plays are performed with the double purpose of propitiating the angry gods, and of distracting men's minds. It is true that Livy notes when this treatment is first applied :—"The plays neither distract men's minds from religious awe, nor their bodies from disease"; but, for all that, the practice continues far down into the Middle Ages, when mystery and miracle plays are used as instruments of intercession with the saints.

Among the more material methods of treatment the kindling of huge fires is ordered by Hippocrates by way of curing the "distempered" atmosphere, which the Father of Medicine conceived to be the chief cause of disease in man. His example is scrupulously followed in the plague of London in 1666, and in that of Marseilles in 1720. Some physicians throughout the centuries advocate temperance in all things—especially in food and drink; others, again, see safety in intemperance. Dr. Nathaniel Hodges, for instance, holds firm belief in double doses of sack whenever exposure to infection is inevitable.

But for the most part medicine confesses herself helpless, and owns that the only prophylactic treatment likely to be successful is instant flight—tempered, perhaps, by purgatives or by "Armenian bole." This is the prescription of Galen, and it is only too faithfully adopted by himself and by the majority of physicians in plague-times after his day.

Many names, however, in the arenas of both medicine and religion shine out with radiance across this sombre background of ignorance and error. One of the most noteworthy is that of the intrepid Gregorius, who dissects three dead bodies in the vain hope of finding the cause of the scourge.

Science does move, moreover, even though it be but slowly, slowly. Little by little a code of sanitary precautions grows up, and superstition wanes as the true nature of the disease is recognised, and the right precautions adopted. Plague, exorcised by knowledge, vanishes almost entirely from western Europe before the end of the eighteenth century.

Dr. Crawford is, as we have indicated, specially interested in the beliefs and the behaviour of man under the stress and strain of plague-epidemics. In the history of the disease he finds striking evidence of the inherent tendency of the human mind to revert to savage instincts in face of crushing calamity.

But that, after all, is only one aspect of our more than Janus-faced mentality to which Dr. Crawford is, perhaps, a little less than kind. For, turned in another direction, it is our mentality which leads us away from the panics, despairs, and barbarities of ignorance, into the sanity and efficiency of exact knowledge.

E. H. MARTIN.

HISTORY AND ETHNOLOGY OF ASSAM.[1]

THIS book is intended to supply a popular account of northern Assam and its borderland, the details of which are scattered through a wide and not easily accessible literature. The sword of the gallant author is mightier than his pen, and it is a subject of regret that the manuscript was not revised by someone with a keener sense of style. In dealing with the more obscure questions of archæology and ethnology he does not profess to write as a specialist, and if the book had been confined to an account of the savage tribes of the borderland and their relations with the British Government, the local experience of the author would have found ampler scope. With these reservations the book is an interesting account of a country of which, be it said to our shame, the average Englishman knows little.

FIG. 1.—The remarkable "Stonehenge" at Togwema, Naga Hills. From "History of Upper Assam, Upper Burmah, and North-Eastern Frontier."

The best part of the book is the account of the tribes. Much has recently been done to extend our knowledge of these races by the admirable series of tribal monographs now in process

[1] "History of Upper Assam, Upper Burmah and North-Eastern Frontier." By Col. L. W. Shakespear. Pp. xix+272. (London: Macmillan and Co., Ltd., 1914.) Price, 10s. net.

of publication by the Government of Assam. Of these and of the valuable "Gazetteer of Upper Burma and the Shan States," by Sir J. G. Scott and Mr. J. P. Hardiman, Colonel Shakespear has made much use. But his own experiences have enabled him to add interesting material, and the large collection of photographs and drawings adds to the value of the book. It has passed the censor attached to the Headquarters staff in India, and it is creditable to that department that they have not suppressed the outspoken criticisms on our methods in the past of dealing with these troublesome neighbours. We have been too prone to delay action for the punishment of raids, to impose inadequate penalties on the guilty tribes, to use

FIG. 2.—Angāmi Nagas. From "History of Upper Assam, Upper Burmah, and North-Eastern Frontier."

large and expensive expeditions to effect what might have been, and has been, done by smaller detachments. Hence, we have met with many regrettable incidents which by prescience and better management might have been avoided.

The publication of the book is timely because it impresses the need of a firm policy on this frontier, particularly as China is beginning to show her power. If the new Republic succeeds in organising an army capable of meeting disciplined troops we may have trouble before us. To meet this emergency the extension of our railway system to the strategical points on the frontier is an obvious necessity.

COLLOIDAL CHEMISTRY IN RELATION TO INDUSTRIES.[1]

II.

PRACTICALLY the only inorganic colloidal preparation made on a large scale at present is the colloidal graphite manufactured by Acheson and used as a lubricant under the name of "Aquadag." Colloidal tungsten was at one time employed in the manufacture of squirted filaments for incandescent lamps, but these have been superseded by drawn wire. The use of colloidal sulphur as spray for hops and vines has been patented and seems likely to be more efficacious than the coarser suspensions of flowers or milk of sulphur.

Of far greater technical importance, however, than these colloidal preparations of inorganic substances are the bodies which, to the layman, are exclusively suggested by the terms "Colloids" or the colloids of Graham. This class comprises such important constituents of organic raw materials as albumen, hide substance, starch, and cellulose; also the various derivatives of the latter, india rubber, gutta percha, and, finally, many manufactured products, among which glue and gelatin may be mentioned as typical. These various substances naturally exhibit a somewhat bewildering variety of individual behaviours, and it is therefore impossible to do more than refer to some properties they possess in common.

Most of them in contact with water—or, in the case of india rubber and nitrocellulose, in contact with certain organic solvents—exhibit the phenomenon of swelling, *i.e.* they imbibe the liquid with increase in volume. The process may either come to an end without solution or dispersion, as with cellulose, or it may proceed as far as the latter either at ordinary or higher temperature, as with albumen and gelatin respectively. This swelling is obviously an inevitable concomitant or antecedent of any treatment with liquids, and therefore of importance in processes differing as widely as tanning and malting. It is well known empirically that the amount of water taken up is affected by even small concentrations of acid, alkali, and neutral salts. The important fact brought out by colloidal research is that this action, particularly in the case of neutral salts, is in no sense chemical, since it is the same on substances differing as widely as gelatin and agar. This knowledge has already been of great value in elucidating the *rationale* of many empirical processes, and its systematic application is likely to be far-reaching. Particularly interesting is the effect of iodides and thiocyanates, which promote the absorption of water to such an extent that, for instance, gelatin dissolves in *cold* solutions of such salts, and that cellulose (as has been shown by v. Weimarn) can be dissolved in hot solutions of calcium iodide or thiocyanate.

A further general rule is that solutions of all these bodies, whatever their nature or that of the solvent, exhibit two peculiarities: the physical

[1] Continued from p. 422.

properties do not depend simply on the concentration, but on the whole previous treatment, especially as regards temperature, and they are not in any event stable, but vary with the age of the solution, although no chemical change whatever may be demonstrable. It is therefore of the utmost importance that a solution, such as the cellulose or nitrocellulose solutions used in making artificial silk, should possess identical properties at a given moment, and research has shown that the most sensitive and most easily measured "indicator" constant is the viscosity. Viscosity measurements accordingly form a recognised means of control in these and other industries. The theoretical study of viscosity is also gradually throwing light on the mechanism of the changes which colloidal solutions undergo in ageing.

A very general property of finely divided matter, and therefore of colloids *par excellence*, is the power of taking dissolved substances out of solution. This phenomenon, so far as it consists in a concentration of such dissolved substance on the surface of the colloid, is called adsorption, and is of the greatest importance in nature and in the arts. The use of Fuller's earth and of gelatin or isinglass for decolouring and clarifying liquids is one of the familiar applications: other instances are so numerous that the difficulty is one of selection. Thus the processes of dyeing and of tanning begin with adsorption, which may be followed by chemical reaction or by diffusion of the substance, concentrated in the first instance on the surface, into the body of the fibre. According to the personal bias of investigators each of the factors involved has been credited with preponderating importance, and it will require much patient work to settle their relative share in processes so complicated. Adsorption, as distinct from chemical combination, has also been advanced as the explanation of certain peculiarities in the vulcanisation of rubber, and forms a subject of rather acute controversy. The adsorptive action of various constituents of the soil on the salts necessary to plant life, a line of investigation first pursued by van Bemmelen, is gradually becoming clear, and light is thereby thrown on a subject of extraordinary intricacy. The so-called humus substances, in particular, have received attention recently, and there seems to be sound evidence in favour of the view that their effect is largely due to their adsorbent action rather than to their somewhat indefinite acid character. In photographic chemistry the proof that the photohaloids, *i.e.* the coloured products obtained by exposing certain forms of silver halogen salts to light, are adsorption compounds of silver and silver salt, has been established experimentally by preparing these products from silver salt and colloidal silver. Incidentally, it may be remarked that the connection between degree of dispersity, mentioned in the last article, and colour has provided the explanation for the great range of shades of the silver image which can be obtained by varying the exposure and the concentration of the developer.

We have so far considered colloids chiefly in a state of suspension or solution, and have now to refer briefly to the equally important "gel" condition, *i.e.* the more or less solid form they assume when solutions of sufficient concentration are allowed to set by cooling, *e.g.* gelatin and agar, or when the solvent is removed by some means. The most familiar example is the gelatin jelly. These gels possess a number of properties of great technical importance. Many of them retain their cohesion and elastic properties when the greatest part of the solvent is removed, so as to yield elastic filaments or films; cellulose and several of its derivatives are thus used in the manufacture of artificial silk and of photographic films. The elastic properties can be varied considerably by the addition of other soluble substances to the solvent: one of the most important instances is celluloid, consisting of nitrocellulose and camphor or various related bodies. Another important feature of certain gels is that of being rendered insoluble and also incapable of absorbing water by various agents: thus casein treated with formaldehyde becomes a very stable plasmic mass, used industrially as "galalith," while gelatin, to which a small amount of a bichromate has been added, becomes insoluble on exposure to light—a property utilised in the "carbon" process of photographic printing and other methods of photographic reproduction.

Since gels contain very large percentages of liquid the diffusion of dissolved substances in them is very little impeded, as was known already to Graham. Solutions of two reacting substances may, therefore, easily be brought into contact in a gel, and reactions carried out in these conditions exhibit a number of very striking and important peculiarities, of which space permits us to mention only one. By a suitable choice of concentrations the reaction may be slowed and may be arrested at an intermediate stage, which in aqueous solutions would be quite transitory. Perhaps the most striking instance is the extremely sensitive silver bromide of the photographic dry plate, which cannot be produced at all in aqueous solution. It is very probable that this effect of gels may become of technical importance in many other directions, and it deserves careful consideration.

Although the survey here given has necessarily been very brief and incomplete, it is probably adequate to show in how many directions industry is likely to profit by research in colloidal chemistry. To sum up briefly, the latter has demonstrated the bearing on chemical processes and their results of a number of factors which are in no sense of the word "chemical," such as the degree of dispersity; the electrical properties of finely divided matter and the possibility of modifying them by the reaction of the medium; the effect of the latter on such universally important phenomena as swelling of organic substances and on their elastic properties and, finally, the in-

numerable manifestations of adsorption. The recognition of all these factors will naturally be a somewhat arduous task, but will furnish at the very least a new method of attacking problems which cannot be solved by chemistry—in its narrower sense—alone. E. HATSCHEK.

PROF. J. W. HITTORF.

THE death of Johann Wilhelm Hittorf, at the age of ninety years, removes an eminent and honoured leader from the ranks of German physicists. Born and brought up in Bonn, Hittorf devoted himself to the study of mathematics and natural science at the Universities of Bonn and Berlin, and became Doctor of Philosophy in 1846. Shortly afterwards he attached himself, as privatdocent, to the Academy (later the University) of Münster in Westphalia, the institution with which he was to be associated during his lifetime. Appointed "ausserordentlicher" professor in 1852, Hittorf became full professor of physics and chemistry four years later, and this post he held till 1879. On the reorganisation of the institution in that year, the chair of physics and chemistry was divided, and Hittorf continued as director of the physical laboratories until serious illness compelled him, in 1889, to seek relief from active teaching work. With rest came recovery and renewed activity, to such good purpose that between his seventieth and eightieth years Hittorf published some half-dozen memoirs. He died on November 28 last, as professor emeritus of the University of Münster, full of years and honour.

Hittorf's investigations dealt with a number of problems on the borderland of physics and chemistry, and the results are embodied in about thirty communications to scientific journals. In appraising this output of original work, it must be borne in mind that the earlier researches were carried on under serious disadvantages in respect of laboratory equipment, and that he himself was personally responsible for all the experimental work described in these memoirs.

Some of the first researches were concerned with the allotropy of selenium and phosphorus, and the discovery of the so-called "metallic" variety of the latter element was made by Hittorf. This work, however, is quite overshadowed by the remarkable series of investigations (published 1853–9) on the migration of the ions during electrolysis. Whilst Faraday had studied mainly the nature and the quantity of the substances produced at the electrodes by electrolytic decomposition, Hittorf investigated the more subtle changes of concentration that take place in the electrolyte itself. From these concentration changes, the relative rates at which the ions of an electrolyte move during the passage of a current, and their relative share in the transport of the electricity, were deduced.

This work met with practically no recognition from Hittorf's contemporaries, and indeed was vigorously attacked by the leading German physicists of the time. Twenty years later the significance of these investigations began to be appreciated, and fortunately Hittorf lived to see his great work accepted as a fundamental part of the science of electrochemistry.

A prominent place among Hittorf's researches must be assigned also to investigations, carried out at the suggestion of his master Plücker, on the spectra of ignited gases and vapours. The memoir embodying this work, which was published in the Philosophical Transactions for 1865, deals with the plurality of spectra, and shows, more especially for the case of nitrogen, that the same substance can give two different spectra. Hittorf's association with Plücker may be further traced in a series of important papers on the passage of electricity through gases; the foundation of what is known regarding kathode rays, discovered by Plücker in 1859, was laid in these investigations.

The remarkable activity of Hittorf's later years, already referred to, was shown chiefly in a study of the passivity of metals, more especially chromium; it was found that this phenomenon cannot be attributed to the presence of a film of oxide on the surface of the metal. It is a striking fact that in his last published memoirs Hittorf returns to the transport of electricity in electrolytes, the field of research in which he laboured fifty years before, and with which his name will be inseparably associated.

J. C. P.

DR. N. C. DUNÉR.

THE death of Nils Christoffer Dunér has deprived Sweden of one of her most distinguished men of science, and astronomy of an active and devoted student. Born on May 21, 1839, Dunér entered the University of Lund in 1855, and took his doctor's degree in 1862. He became a member of the staff of the Lund Observatory in 1864, and occupied that position until his appointment, in 1888, as Professor in the University and Director of the Observatory of Upsala. He died at Stockholm on November 10, after a brief illness following his return from a journey to observe the solar eclipse of last August.

Dunér made notable contributions to many departments of astronomy, and his name will be especially remembered in connection with his work on double stars, variable stars, the spectra of red stars, and the investigation of the sun's rotation by the spectroscopic method. His work on double stars during the years 1867 to 1875 at once placed him in the front rank of double-star observers and computers.

Several variable stars were discovered or investigated by Dunér. Two of them—Y Cygni and Z Herculis—have proved to be of exceptional interest. Dunér not only found that the light-changes of these stars could be completely explained by supposing them to be eclipsing variables of the Algol type, with the difference that both components are bright, but was able to determine the elements and dimensions of the two systems.

In 1878 Dunér turned his attention to stellar spectra, and with only a 10-inch refractor at his disposal, courageously entered upon a systematic survey of the red stars. His classical memoir, "Sur les étoiles à spectres de la troisième classe," 1884, gives details of his eminently successful observations of the spectra of 352 stars. Further observations were made with the Upsala 36 cm. refractor in 1893. The interest of such observations is now largely discounted by the entry of the giant telescopes and spectrographs of America into this field of research, but Dunér rightly considered that comparative observations of a large number of stars by a single observer might have a special value.

Another important investigation by Dunér was that on the sun's rotation, carried out at Lund, and later at Upsala, with a powerful grating spectroscope which he designed for this purpose. His memoir, "Recherches sur la Rotation du Soleil" (1891), is a model report on a scientific investigation, and a lasting tribute to the skill of its author. The observations were extended to solar latitude 70°, and showed that the polar retardation indicated by spots was continued far beyond the sun-spot zones.

Dunér was an inspiring teacher, and his amiability and self-sacrificing devotion to their interests gained for him the affection and gratitude of his pupils and fellow-workers. His scientific achievements brought him many distinctions, among which may be mentioned the award of the Rumford medal by the Royal Society in 1892, and election as an Associate of the Royal Astronomical Society in 1889.

NOTES.

INQUIRIES which reach us from time to time suggest that many people would find it a convenience to be able to examine books received from publishers abroad and reviewed in NATURE. These volumes are usually not readily accessible, and often the only copies existing in this country are the few sent to scientific journals for review. We have therefore made arrangements to retain at NATURE office, St. Martin's Street, W.C., for a period of six months after the issues in which the reviews have appeared, all volumes published in countries outside the United Kingdom. Every volume from abroad reviewed in our columns will thus be on view freely to anyone who cares to call to see it. This arrangement will begin with our first issue in the New Year, and we believe that many men of science will welcome the opportunity which it will afford them of inspecting American and foreign books of which reviews have been printed in NATURE.

AFTER a long period of service in that capacity, Mr. W. L. Distant is resigning the editorship of the *Zoologist*.

THE Rome correspondent of the *Times* reports that among the Italian Senators who are to be nominated on New Year's Day is Signor Marconi.

THE death is announced at Los Angeles, in his seventy-sixth year, of Dr. John Muir, member of the Washington Academy of Sciences, and distinguished as an explorer and naturalist, as well as by his work for many years in the cause of forest preservation.

IT is announced in *Science* that in the will of the late Miss Dessie Greer, the American Museum of Natural History is designated as the ultimate beneficiary of a fund of 18,000*l.* By the will of the late Mr. W. Endicott, of Boston, a bequest of 5000*l.* for cancer research is made to Harvard University.

THE death is announced, at sixty-four years of age, of Sir Robert Simon, professor of therapeutics in the University of Birmingham since 1910, and author of a book on "Disease of Brass Workers" and other works; also of Mr. D. Balfour, member of the Institution of Civil Engineers, and a fellow of the Geological and the Royal Meteorological Societies.

WE regret to announce the death, in his seventy-second year, of Dr. Leon Lereboullet, president of the French Medical Association, and associate member of the Academy of Medicine. An obituary notice in the *British Medical Journal* points out that he collaborated with Dechambre on the *Gazette Hebdomadaire de Chirurgie*, and was editor of the "Dictionnaire Encyclopédique des Sciences Médicales." He was also the author of several works on medicine, and of a series of articles on the health service which attracted the attention of Jules Ferry and other leading statesmen.

THE Governor of Bombay unveiled on November 30 a simple marble memorial tablet in Bombay Cathedral to Lieutenant Bowers, Royal Indian Marine, who lost his life with Captain Scott and his comrades in the Antarctic. We learn from the *Times* that the memorial at Finse, in Norway, in honour of Captain Scott and his companions was unveiled on December 28 by Dr. Skattum, vice-president of the Norwegian Geographical Society. The memorial has taken the form of a monument about 20 ft. high bearing the names of the explorers—Captain R. F. Scott, Dr. Wilson, Captain L. E. G. Oates, Lieutenant H. R. Bowers, and Petty Officer Evans—and an inscription reading:—"Erected by Norwegians in honour of Antarctic research and heroic courage."

A MEETING of the Imperial Advisory Council of the Institute of Industry and Commerce was held on December 22 at the offices of the institute on Aldwych Site, Strand, for the purpose of considering, among other matters, the best means of bringing about the standardisation of company law throughout Great Britain, the Dominions and Colonies in order to facilitate commerce within the Empire. The council decided that a memorandum should be drawn up by the institute after consulting with the leading specialised trade organisations, and that this memorandum be submitted to the Agents General of the Dominions and Colonies for submission to their respective Governments. The policy of the institute is to develop a set of satisfactory working conditions

within the Empire in which industry can operate, and if this is accomplished satisfactorily a considerable increase of trade should follow.

A CENTRAL NEWS telegram from Amsterdam, published in the *Times* of December 21, announced that Prof. Otto Sackur was blown to pieces by an explosion which occurred in the laboratory of the Kaiser-Wilhelm Institute at Dahlem, near Berlin, where experiments in high explosives were being conducted. The Kaiser-Wilhelm Institute was founded in 1911 by the Kaiser-Wilhelm Association for the Advancement of Science, and the first volume of results of researches issued by it was described in NATURE of May 28 (vol. xciii., p. 322). Prof. Sackur was one of the ablest of the younger physical chemists in Germany. A pupil of Richard Abegg, he became a Privat-dozent in the University of Breslau, and on Abegg's appointment to the Technische Hochschule there, succeeded him as extraordinary professor in the University. He later received an appointment in the Kaiser-Wilhelm Institute. Sackur was more distinguished as a theorist than as a practical worker. His papers cover a wide range, and are characterised by considerable independence of thought. In 1912 he published a "Lehrbuch der Thermochemie und Thermodynamik," which is an admirable modern introduction to the subject, and is, we understand, being translated into English.

THE Duke of Bedford presided at the general monthly meeting of the Zoological Society on December 23, 1914; twenty-two new fellows were elected, the honorary membership of the society was conferred on Field-Marshal Earl Kitchener of Khartum, and eight new names were added to the list of corresponding members. During November fifty additions were made to the menagerie, of which forty-two were presented; among the latter particular interest attaches to a pair of South African elands presented by Mr. A. H. Wingfield, of Ampthill House. During the same month the number of visitors to the gardens was 26,403, or 15,166 fewer than in November, 1913. From January 1 to November 30 the total number of visitors was 1,037,929, representing a decrease of 90,225, as compared with the corresponding period in 1913.

IN a letter to the *Times* of December 26, and in an article in the *Strand Magazine* for January, 1915, Sir E. Ray Lankester disputes the idea that Germans are entitled to special pre-eminence in the domain of physical sciences. On the contrary, with the exception of the work in spectrum analysis in the middle portion of last century, their claims to original discoveries of importance, more especially during the reign of the present Kaiser, are comparatively insignificant. Their real line of success lies in their capacity for adopting and developing the discoveries made in other countries for their own interest and benefit, more especially when large profits are to be made, as in the case of the artificial synthesis of indigo and other organic products, by such means. In their voluminous treatises on the history of science published during the last forty years they have in many instances deliberately ignored the claims of investigators in other countries to discoveries and ideas upon which their own work is based.

THE Committees on Food and Hygiene of the Paris Academy of Sciences have presented reports dealing with the conservation of cattle during the war and with the alcohol question. In view of the meat supply required for the troops and the necessity of reserving the best animals for reproduction, it is recommended that all young animals and calves should be preserved and that importations of meat from Australia, New Zealand, the Argentine Republic, and the French colonies should be encouraged. It is also suggested that animals should be killed in the place where they were raised, as the transport of live cattle is attended with many disadvantages. The installation of large cold storage depôts is recommended. Recommendations were also made with regard to the consumption of alcohol. It is proposed that the number of places open for the sale of alcoholic drinks should be limited, that absinthe and similar liqueurs should be absolutely prohibited, and that the privilege of the *bouilleurs de cru* should be suppressed. These conclusions were unanimously adopted by the academy, and forwarded to the Government.

A NOTICE recently appeared in *Science* that the late Dr. Albert Günther's collection of pamphlets relating to fishes, amphibia, and reptiles has been secured by the Carnegie Museum at Pittsburgh. As a matter of fact, some years have elapsed since Dr. Günther, finding that through failing eyesight he could no longer make full use of this portion of his scientific library, and being naturally loathe to break up an unrivalled collection of separate papers and monographs gathered from the scientific periodicals of the eighteenth and nineteenth centuries, and knowing of no purchaser in this country, determined to sell the collection as a whole to Prof. C. H. Eigenmann, of Indiana University, who also held the post of curator of ichthyology in the Carnegie Museum. The collection shipped to America in August, 1910, comprised nearly 7000 octavo and 600 quarto and folio pamphlets, by some 1200 authors. The possession of so complete a literature in so compact a form enabled Dr. Günther to identify and describe collections of fish at home without always having to visit public libraries. He often said that so complete a series of the smaller monographs on the ichthyology and herpetology of the time would probably never be accumulated again. May their value be as great in the New world as it has been in the Old!

As announced with regret last week, Mr. A. R. Hunt, who was well known in the British geological world, died at his residence, Southwood, Torquay, on December 19, aged seventy-one years. Son of a chief of an old firm of wine shippers, he was born and lived his earliest years in Portugal. After taking his M.A. degree at Trinity College, Cambridge, he read for the Bar, and was enrolled a barrister of the Inner Temple, not, however, to follow the profession. His family settling in Torquay, brought him into association with Pengelly, and the stirring revelations of

Kent's Cavern, and under these influences he found his interests and attention directed towards natural science. In 1872 he was elected a member of the Torquay Natural History Society, and for the rest of his life he gave that institution his enthusiastic support, serving for long on the committee and as president for the years 1879–81. He was closely associated with the Kent's Cavern explorations, and his familiarity with details and parts rendered him the best fitted man then living to conduct the Geologist's Association through the cavern on its visit to Torquay in 1901. Mr. Hunt's fondness for sailing led to his striking out a line of investigation that put his yacht to scientific use by exploring the inshore sea bottom with dredges and studying the action of shore waves and currents. This he followed up by constructing experimental tanks, and his researches were recognised by practical engineers dealing with the problems. His literary contributions to science are mainly included in the Transactions of the Devonshire Association, which contain thirty papers by him. More communications in number are contained in the *Geological Magazine*, and he also contributed to the Linnean Society's Journal.

M. ROMAIN ROLLAND's eloquent appeal now appears in pamphlet form—"Above the Battlefield" (Cambridge: Bowes and Bowes; price 6*d.* net). Its main thesis should be interesting to scientific readers, since it is an indictment of European leaders of thought for their attitude to war in general and the present war in particular. War, he assumes, is a catastrophic calamity to civilisation and the race; "it is always the octopus sucking the best blood of Europe"; "is there no end to this bloody and puerile sport, in which the partners change about from century to century—no end, until the whole of humanity is exhausted thereby?" Many who might protest are apt to listen to "the old refrain of the herd that makes a god of its feebleness . . . 'the fatality of war is stronger than our wills.'" But "there is no fatality! The only fatality is what we desire; and, more often, too, what we do not desire enough." Leaders of thought, guardians of the pillars of knowledge which support the fabric of culture, "did not desire war. . . . What then did they do to prevent it? What are they doing to put an end to it?" Some are passive, but the majority are active, "stirring up the bonfire, each one bringing his faggot." In this "epidemic of homicidal fury . . . all the forces of the spirit, of reason, of faith, of poetry, and of science, all have placed themselves at the disposal of the armies in every State. There is not one amongst the leaders of thought in each country who does not proclaim with conviction that the cause of his people is the cause of God, the cause of liberty, and of human progress. And I, too, proclaim it."

THE great photographic collections of the National Geographic Society of Washington have again been utilised for a valuable topical issue of the *National Geographic Magazine* for November, which is occupied by a paper under the title of "Young Russia—The Land of Unlimited Possibilities," by Mr. G. H. Grosvenor. The sketch of Russian history, ethnology, geography, and industrial resources is slight, but pleasantly written. The feature of the number is one hundred admirable photographs, of which seventeen are in colour, which represent various phases of city and village types, religion, art, and scenery, with groups of the many races included in the empire.

OF the two chief articles in the December issue of the *American Naturalist*, one, by Prof. J. H. Morgan, relates to the failure to produce mutations in Drosophila by means of ether, while the other, by Prof. J. S. Dexter, is devoted to the analysis of a case of continuous variation in the same genus.

A THIRD contribution to the account of the Long Island fauna and flora, now in course of publication in the Science Bulletin of the Brooklyn Institute, forms the contents of vol. ii., No. 3, of that serial. In this part Dr. F. Overton treats of the frogs and toads, which include ten species, referable to five genera and four families.

THE December number of the *Irish Naturalist* is a very thin one; containing, in addition to notes, reviews, etc., only an article by Mr. E. M. Barrington on the migration of wrens, in which it is shown that numbers of these apparently poor flyers regularly cross the Channel twice a year. The fact being established that the species is a constant migrant leads the author to ask how it comes about that local races have been established in St. Kilda and the Faröes.

Wild Life continues to appear regularly, albeit with a certain reduction in the number of pages, despite the fact that both the editor, Mr. Douglas English, and his collaborator, Mr. W. R. Knight, are serving their King and country, the former as a subaltern in the 1st Surrey Rifles, and the latter as a private in the 1st Batt. H.A.C. In the December issue Mr. Russell Roberts concludes his realistic account of the black rhinoceros; among bird-photographs the most striking is one of a flock of black-headed gulls on the wing, by Mr. H. B. Macpherson.

FOR some time past, as we learn from the report of the council for 1913–14, the Natural History Society of Northumberland, Durham, and Newcastle-on-Tyne has been endeavouring to raise a sum of 25,000*l.*, to form an endowment for the upkeep of the Hancock Museum, which is at present a heavy drain on the general fund. Between 3000*l.* and 4000*l.* (including 1000*l.* from Lord Joicey, the president) had been raised, when the outbreak of the war put a stop to the project, at any rate for the present. The most important addition to the museum during the period under review is a magnificent collection of tropical and subtropical butterflies, made by Dr. Eltringham, with special reference to mimicry. A part of this series has been placed on exhibition, and the rest retained in the original cabinets.

To the first half of the Bergens Museum *Aarbok* for 1914–15 Dr. A. Brinkmann communicates the description of a new genus and species of nemertine annelids, based on a male and female dredged in May, 1914, in the North Sea, at a depth of between 1000 and 1200 metres. The new genus belongs to the

family Drepanophoridæ, but is peculiar in the circumstance that the rhynchocœlom and the œsophagus open by a common aperture, this feature being recorded in the name Uniporus. The typical *U. hyalinus* is characterised by the total absence of pigment; but in two other members of the genus, one of which was described in 1901 as *Drepanophorus borealis*, the upper surface is well pigmented. The paper concludes with remarks on the affinities and systematic position of the Drepanophoridæ. In another article Mr. B. Tyvold discusses the structure and relations of the parasitic "zoophytes" of the genus Sphyrion, which are found on the fins of lumpsuckers and gurnards, and, although described by Cuvier, have hitherto remained a puzzle to naturalists. It is now decided that their true position is in the family Chondracanthidæ. Whaling at Durban and Saldanha Bay and the various species of whales taken there, form the subject of a third article, by Mr. O. Olsen, who recently described a new species of finwhale from these waters.

IT is not surprising that the presidential address of Mr. A. D. Hall to the Agricultural Section of the British Association in Australia has excited considerable interest in the Colonies. The *Agricultural News* (Barbadoes) of November 21 discusses the problems of bringing into cultivation land hitherto allowed to run to waste, in its bearings on West Indian agriculture and conditions. Two phases of winning new land are in progress simultaneously in the West Indian islands—the clearing of fertile soils as yet untilled and the reclaiming of land hitherto regarded as unprofitable to farm. Efforts are also being made to regenerate areas once under cultivation, which have been robbed of their fertility by defective methods of farming. Since loss of water from the soil surface is one of the most important factors in determining fertility under tropical conditions, any methods of reducing this loss have especial significance. Mr. Hall suggests that evaporation can be checked by the provision of screens or hedges that will break the sweep of the wind across the land. Screens of this kind have long been used in the islands to protect such crops as cacao and limes from the persistent sweep of the trade winds, but their use for the conservation of moisture in the soil has received little consideration, and experiments in this direction might profitably be made.

A "NOTE on the preparation of Indian forest floras and descriptive lists," issued as Forest Bulletin, No. 23 (Calcutta, 1914), by Mr. R. S. Hole, will be found interesting and useful to botanists generally as well as to those concerned with forestry. The author emphasises the importance of taking a comprehensive view of the entire forest vegetation instead of confining attention to the large timber trees, and points out that numerous minor products, some of them of considerable value, are obtained in India from trees and shrubs as yet unidentified, besides the revenue obtainable from insignificant herbs and grasses which form the forest undergrowth or occur in open places in the forest areas. His paper is intended as a first step towards the preparation of simplified floras and descriptive lists and schedules suitable for officials who cannot be expected to have the leisure or the botanical knowledge necessary for the successful identification of species by the floras now in existence. He draws a sharp distinction between the scope and function of a flora and a descriptive list respectively, and gives a summary of the information which it is proposed to include in the latter, together with an admirably planned schedule which includes the ecological as well as systematic characters.

IN a valuable paper on the development of the Trinidad oilfields, contributed to the last meeting of the Institution of Petroleum Technologists, Prof. J. Cadman traced briefly but clearly the history of this little-known oilfield, which properly commences, as the paper shows, with the prospecting operations of Mr. Randolph Rust at Guayaguayare in 1902. The mere fact that within thirteen years this oilfield has produced more than seventy-two million gallons of oil, and that the annual output is already more than twenty-two million gallons, in quite sufficient evidence that this field has attained a position of decided importance amongst the sources of supply of petroleum of the British Empire. As Prof. Cadman points out, it is not yet possible to predict what the life of the wells is likely to be, but so far there seems to be no good reason to fear any abnormally rapid rate of exhaustion of the oilfield. There are numerous interesting problems, both technical and geological, presented by this field, which is remarkable for the high pressures existing in the oil-sands and for the considerable proportion of sand carried up by the crude oil. The author has shown how these difficulties have hindered the more rapid development of the oilfield, and gives an interesting account of the methods used to overcome them.

THE *Philippine Journal of Science* for June last (vol. ix., sec. A., No. 3) contains an interesting account of an occurrence of iron ore in the province of Bulacan, Island of Luzon, as also of a somewhat special industry of iron smelting that has been developed therefrom. The ores consist of magnetite and hematite, and these are smelted by the natives in small blast furnaces, the iron produced being cast direct into moulds for the production of ploughshares and ploughpoints. The furnaces are built of soft clay bricks set in clay, and cased with bamboos, and are about 7 ft. 6 in. in height, and 5 ft. in external diameter; the inner cavity is 5 ft. 9 in. deep, and is conical, tapering from 40 in. at the top to 20 in. at the bottom. It is fitted with a single clay tuyere, and is blown with the usual Chinese double-acting hand-blower, made from a hollow tree trunk, and fitted with a wooden piston packed with feathers; the blower is 11 ft. 6 in. long and 14 in. in diameter. The furnace is charged with ore and charcoal at intervals, an average charge consisting of 55 lb. of ore and 95 lb. of charcoal; no flux is used. Such a furnace produces about 5 cwt. of castings daily, the iron being a hard white iron, low in silicon, but containing a fair percentage of carbon. The extraction of iron is only 68 per cent. of that present in the ore, most of the loss being due to prill of iron entangled in the viscous slag. The

process is particularly interesting, as detailed records of the production of cast-iron in furnaces of such a primitive type are not numerous. The industry is very evidently Chinese in its origin, and it seems obvious that it owes little or nothing to European influences.

DURING the forced rest from his usual busy, scientific work Dr. H. R. Mill recently spent three and a half months in New Zealand, and visited the meteorological stations between Stewart Island, in the south, and the Bay of Islands, in the north, in which he was assisted in every way by Mr. D. C. Bates (Dominion Meteorologist) and others. He has embodied his impressions and notes obtained of the climate in an interesting article, untrammelled by tables or diagrams, in *Symons's Meteorological Magazine* for December. Among many other matters, he points out that although Great Britain lies nearer the pole than any part of New Zealand, the climates are much alike, summer in the South Island being apparently no warmer than in England; the lower latitude, however, ensures a greater intensity of sunlight, and vegetation proves that the mean temperature of winter is much higher than Great Britain. The prevailing wind being westerly, the mountains receive a rainfall exceeding 100 in. in many places, while on the east much of the area has an average of less than 20 in. The climate of the North Island is decidedly warm in summer, and there is a marked contrast between the two seasons. Great faith is attached to the weather forecasts; weather conditions being simpler the prognostics are less liable to misinterpretation than in Western Europe. Changes and movements of clouds appear to be more expressive of weather changes than in this country, and much use is made of them in filling up the gaps in telegraphic reports.

IN the *Comptes rendus* of the Paris Academy of Sciences for November 30 M. Colardeau describes an X-ray method of localising foreign bodies imbedded in the tissues. The matter is of special importance at the present time on account of the war, and during the past few months many suggestions have been made. The Röntgen Society, under the presidency of Sir Alfred Pearce Gould, has already devoted its December meeting to the question, and a further discussion is arranged for January. M. Colardeau's method differs but slightly from the plan introduced some years ago, and now almost universally adopted with the addition of minor improvements, by Sir James Mackenzie Davidson.

THE Journal of the Washington Academy of Sciences for December 1 contains an abstract of a paper by Mr. L. W. Austin, of the Naval Radio-telegraphic Laboratory, on quantitative experiments in radio-telegraphic transmission. The signals were sent from the station at Arlington, Virginia, which uses the Fessenden rotary gap giving an antenna current of 100 amperes and a wave-length of 3800 metres. The aerial is triangular with a mean height of 400 ft. Short-range experiments showed that owing to insufficient conductivity of the soil the effective height of the antenna was only 200 ft. The strength of the signals was determined by the shunted telephone method on board the U.S.S. *Birmingham* on a voyage to Gibraltar and back. The effective height of the receiving antenna was 114 ft., and the effective resistance 50 ohms. For distances between 300 and 2000 miles the strength, I_R, of the received signals could be expressed by the equation $I_R = (120\pi h_s h_R I_s / \lambda d R)$ exp. $(-0.0015 d/\sqrt{\lambda})$, where h_s and h_R are the effective heights of sending and receiving antennæ, I_s the sending antenna current, λ the wave-length, d the distance of the stations apart, and R the resistance of the receiving system. This is a slight modification of the theoretical expression given by Sommerfeld. The complete paper will be published in the Bulletin of the Bureau of Standards.

MESSRS. BURROUGHS WELLCOME AND Co., Snow Hill Buildings, have sent us a copy of the Wellcome Photographic Exposure Record and Diary for 1915, which is a neat little pocket-book with a strong canvas cover. Having been issued for several years, and each year revised and brought up to date, it is now the most compact essence of photographic information —a veritable "tabloid." If you want to know how to tone bromides green, how much flashlight powder to use, about night photography, about speeds of papers and plates, and about a host of other requirements of the photographer, whether amateur or professional, you have only to look into this pocket-book where the information is dealt with clearly, tersely, and accurately. Practical experience of practical men is embodied in these pages, and the experience culled by experiments and long practice is analysed and set forth in simple formulæ and precise directions, not only helping the beginner, but saving him time, trouble, and material. The Wellcome Exposure Calculator, fitted ingeniously in the inside of the back cover, has only to be used once to be used always. By one turn of the scale the correct exposure for any plate or film is immediately given for any time of day or year. Blank forms are given for the entry of all details about each photograph taken, and these are followed by a diary for entry of ordinary daily memoranda. The book is issued in wallet form, complete with pencil, and three editions are published, suitable for the northern hemisphere, the southern hemisphere, and the United States. It is a cheap shillingsworth, and every photographer should invest in one.

FIVE short papers on audible and other cab signals on British railways were read and discussed at the Institution of Mechanical Engineers on December 18. These papers express the opinions of engineers connected with, and describe experiments which have been in progress on, the Midland, Caledonian, North-Eastern, Great Western, and Metropolitan Railways. It is generally admitted that the present system of semaphores and lamps is not entirely trustworthy, and it is hoped that some standard system of cab signalling which will be effective may be evolved soon. As was pointed out by Mr. Blackall, of the Great Western Railway, it is very important that some standard should be conformed to, so that the engines belonging to one railway passing over to the system of another may be able to pick up the signals which would ordinarily be given to the engines belonging to the latter system.

A new Diesel marine engine, built by Messrs. Doxford and Sons, of Sunderland, is described in the *Engineer* for December 25. In this engine the complicated cylinder cover casting with its valve arrangements is got rid of by having two pistons in the cylinder working in opposite directions. The upper piston is attached by a piston rod to a compensating arm, which is connected by two rods, one on each side of the cylinder, to two cranks placed at 180° to a central crank; the lower piston is connected in the usual manner to the central crank. The various operations in the cycle take place between the two pistons. The exhaust escapes through ports in the top end of the cylinder; these are uncovered by the upper piston when near the top of its travel. Scavenging air is admitted through corresponding ports at the bottom end of the cylinder; these are uncovered by the lower piston, and ensure a capital flow of scavenging air throughout the whole cylinder. The admission valves are placed at the middle zone of the cylinder. Cooling water is supplied to the lower piston through a rocker arm, and to the upper piston through a telescopic tube; the latter arrangement is open to some criticism on account of the difficulty of preventing leakage.

The issue of "Hazell's Annual for 1915" is now ready. This is the thirtieth year in which this useful "record of the movements of the time" has been published. Some idea of the number of topics dealt with may be formed from the fact that the index to the volume contains close upon 20,000 entries. As is natural, great prominence is given to facts in connection with the war, but this engrossing subject is not allowed to overwhelm the other matters of importance dealt with in previous issues. A section entitled "The March of Science," runs to about thirty-four pages, and includes a summary of the proceedings at the British Association meeting in Australia, and a *résumé* of progress in scientific research during 1914. We are glad of the opportunity to extend the praise offered in these columns to the trustworthiness and completeness of previous editions of the annual to the present issue, the price of which is 3*s.* 6*d.*

Mr. C. Baker, 244 High Holborn, London, has issued his January list of second-hand scientific instruments which he has on sale or for hire. Particulars are given of more than 1500 pieces of apparatus, prominent among which are numerous microscopes and telescopes and their accessories. Every instrument is guaranteed to be in adjustment, and arrangements can be made for workers in the country to have pieces of apparatus on approval.

OUR ASTRONOMICAL COLUMN.

A Remarkable Meteor.—On Tuesday, December 15, at 6h. 25m. p.m., an extremely slow-moving meteor was seen by Mr. W. F. Denning at Bristol, and by Mrs. Wilson at Bexley Heath. It had rather a long flight, and was much brighter than a first magnitude star. The meteor was curious as belonging to a radiant point in Aquarius at about 336°–12°, and at the same position as the July Aquarids. No meteors have hitherto been recorded, so far as is known, from this radiant so late in the year. The object of December 15 last had a height of from sixty-seven to forty miles, its luminous course extended more than seventy miles, and its velocity was fourteen miles per second. The meteor must have been observed by many persons, the night being very clear and the object a very conspicuous one with an extensive trajectory. At the middle of December a well-defined shower of slow meteors from between α and β Persei at 48°+44° was prominently active. This same radiant has been observed at many other times of the year, but never before on December 15 and 16.

Parabolic Orbits of Meteor Swarms.—In the Publications of the Leander McCormick Observatory (vol. ii., part 4) a paper on 126 parabolic orbits of meteor swarms is published by Mr. Charles P. Olivier, these deductions being made by him from more than 2800 observations of meteors, the combined work of the American Meteor Society. Mr. Olivier directs particular attention to the excellent work carried on by this society in spite of its youth, and hopes for more ideal methods of work in the future. It may be remembered that the author previously (1911) published a paper entitled "175 Parabolic Orbits and other Results Deduced from over 6200 Meteors," which appeared in the Transactions of the American Philosophical Society, N.S. (vol. xxii., part 1), and the present contribution may be considered practically a continuation of the above, the first radiant here numbered, namely, 177, following serially the radiants given in the 1911 publication.

One of the chief problems of meteoric astronomy is that of stationary radiants, and in many quarters it is considered that many of them exist, while other workers on theoretical grounds look upon them as mathematically impossible except in a few cases. Mr. Olivier attacks the problem by inquiring into the method of the reduction of the radiant points, and concludes that the usual process of combining observations of many successive dates, and radiants which lie sometimes as much as 10° from one another, etc., tend to influence greatly the result. His results, reduced separately for each date, "show almost no evidence of stationary radiation, and so far as they go may be considered to disprove its existence." Numerous interesting tables accompany this paper, among which may be mentioned that containing the 126 parabolic orbits; elements based on eight radiants suggesting these meteors were originally intimately connected with Halley's comet; ten orbits belonging to the main Perseid stream, confirming their connection with comet 1862 III., or Tuttle's comet, and other tables giving the magnitudes of the meteors seen, percentages of meteors of a given magnitude to the totals seen, and their colour and duration.

The Spectrum of 10 Lacertæ.—The star 10 Lacertæ (R.A. 22h. 35m., declination +38° 32′, magnitude 5·0) displays a spectrum which is conspicuous for the sharpness of the important line at wave-length 4686 and of the other lines of hydrogen and helium. This star is therefore not only suitable for a good determination of its radial velocity, but affords an opportunity of obtaining an accurate measure of the stellar wave-length of the line at 4686 and other lines. Both these objects have been investigated by Messrs. E. B. Frost and Francis Lowater, and the results are described in the *Astrophysical Journal* for October (vol. xl., No. 3, 1914, p. 268). The line 4686 is now generally regarded as a line in the principal series of helium, and the laboratory work of Prof. Fowler has consigned to it the wave-length 4685·90. The line is recorded in the spectrum of the chromo-

sphere with the following wave-lengths:—Lockyer λ 4685·90, Dyson λ 4685·86, and Mitchell λ 4686·00. The wave-lengths which the authors have now deduced from fifteen plates of the star are as follows:—

Frost: 4685·897 ± 0·016 (15 plates).
Lowater: 4685·903 ± 0·018 (15 plates).
Mean: 4685·90.

Other important lines, the stellar wave-lengths of which are here deduced, are $\lambda\lambda$ 4116·33, 4097·55, and 4089·12, closely approximating to the wave-lengths given by Lockyer in ϵ Orionis, namely, 4116·54, 4097·59, and 4089·14. With regard to the radial motion of the star, the motion of the system is given as probably −12 km., almost wholly due to the solar motion. From one plate they give the velocities of the two components, but state that the data are insufficient for indicating the period of the star, but "there seems to be little to suggest a period of less than several days."

THE ORBITS OF δ ORIONIS, R.Z. CASSIOPEIÆ AND R.X. HERCULIS.—Nos. 15 and 16 of vol. iii. of the Publications of the Allegheny Observatory describe the researches by Mr. Frank C. Jordan on the orbits of δ Orionis and R.Z. Cassiopeiæ. In the case of the former, thirty-six spectrograms of the star were secured with the Mellon spectrograph during the period 1908 to 1912, and these were used for the determination of the orbit and at the same time to rediscuss Hartmann's results. A comparison of the elements derived shows that the shape and size of the two orbits are practically identical. The radial velocity of the system has different values in the two derived orbits, but this difference is stated to be apparent rather than real. If, however, it should be proved to exist, the author states that "it would imply a third body, making the system similar to that of Algol." R.Z. Cassiopeiæ exhibits a light variation of an Algol-type star, and Mr. Jordan summarises the various values of the period derived by previous workers. The earliest spectrographic observations of the star were made in 1906 by Hartmann, and while he found a velocity range from +33 to −112 kilometres, this agrees well with the range of the definitive curve here given, namely +28 to −111 kilometres. For the present discussion seventy-one plates were employed, taken during the years 1910 to 1913, and tables are given showing the velocities deduced from each plate, the wave-lengths and origins of the line employed, etc.

Mr. Harold Shapley, in the *Astrophysical Journal* for November (vol. xl., No. 4, p. 399) contributes a paper entitled "The Spectroscopic Orbit of R.X. Herculis Determined from Three Plates with a New Photometric Orbit and Absolute Dimensions." He shows that the solution for the elements of the spectroscopic orbit of a faint star is possible when only a few measures of the radial velocity have been determined, provided that the system is an eclipsing binary and that the period, epoch of minimum, eccentricity, and longitude of periastron have been derived from the light curve. In his summary he states that the new photometric orbit of R.X. Herculis has been computed from unpublished observations obtained at Harvard and Princeton. The alternate minima are found to differ in depth by nearly a tenth of a magnitude. The stars are nearly equal in size, and are sensibly spherical. Their surfaces are separated by three times the radius of the larger star. From measures of lines on three plates it has been possible to derive very satisfactory spectroscopic orbits of both components. The combination of elements from the photometric and spectroscopic orbits gives the actual dimensions of the stars. The parallax of the system is found to be 0·006″.

AGRICULTURE AND THE WAR.

AT the half-yearly meeting of the Agricultural Education Association, just held in London, a discussion was held upon "Agricultural Products Deflected by the War." The chairman of the association, Prof. Somerville (Oxford University), presided, and there was present a large gathering of members, including Sir Patrick Wright (Board of Agriculture for Scotland), Mr. J. F. Blackshaw (Board of Agriculture), Prof. Barker (Bristol University), Profs. Seton and Crowther (Leeds University), Prof. Gilchrist (Armstrong College, Newcastle-on-Tyne), Dr. Goodwin (Midland Agricultural College), Drs. Russell and Hutchinson (Rothamsted), Prof. Hendrick (Aberdeen University), Prof. Bryner Jones (Aberstwyth), the hon. secretary, Mr. P. Hedworth Foulkes (Harper Adams Agricultural College), and others.

We give a summary of the remarks made by Dr. Russell, director of the Rothamsted Experimental Station, in opening the discussion:—

The object of to-day's discussion is to see how agriculturists are likely to be affected by the dislocation caused by the war, and what line we, as expert advisers to the farmer, ought to take. There can be no doubt about the main duty of the farmer in the present crisis. He must by all means in his power increase the saleable output from his farm, particularly of those things which the community needs most—a need which is expressed by an increase in price. In framing this advice it must be remembered that the ordinary unit of time for the farmer is the length of the rotation, but in these special circumstances the unit might well be altered to the duration of the war. Thus a scheme which would usually be condemned as bad husbandry from the ordinary rotation point of view might nevertheless be advantageous in the new conditions.

Roughly speaking we may classify the agricultural products affected by the war into two groups: those which are permanently affected, and those which are only temporarily affected. Correspondingly there must be two methods of ascertaining their value to the farmer: careful investigations for permanent purposes, and more rapid and necessarily less accurate trials for temporary purposes.

Palm nuts are fortunate in coming within the purview of the West African Committee, under the guidance of Sir Owen Phillips, and thanks to their enterprise all of us here have been duly informed of the character of this product, while a number of experiments have been put in hand to test its possibilities for British agriculture. For permanent purposes a full investigation is required, and will, of course, be given. Continental experience has shown that the material is good; at the same time we know that it has been put on the market before, and it did not take permanent hold. Apparently no serious fault was found with it, yet it never became part of our regular concentrated food for stock. There must be a reason for this, and the object of the investigation will be to ascertain what it is.

Other products of like nature are no doubt available or will become so—and will probably form the subjects for investigation. But there is an emergency problem that is quite different in nature and wants altogether different treatment. We have seen during the last five months a marked rise in the price of cereals. This is an expression of the fact that the community wants these particular goods, and the farmer must do his best to supply them. Now many farmers do not grow their winter oats entirely for sale. Part—often the greater part—of the stock is kept back for their own horses. Much food also is produced for stock. The important emergency

problem arises: Can we recommend any ration in which imported or other products, cheap in price because they are not now needed by the community, can replace and liberate from the farm home-grown produce that is wanted elsewhere? Time will not allow of a full investigation, and the advice must often be based on foreign work or on past experience elsewhere. Short, rapid trials alone will meet the case. It is not necessary that the whole stock should be liberated; an increased sale of only 10 per cent. from every farm would add very materially to the quantity available for the community.

The replacement, of course, must be done without prejudicing the total food supply; thus we must not advise the production of grain at the expense of milk or of meat; our main concern will be to increase the saleable output.

Another type of product is only temporarily affected. A certain amount of guano which used to go to Belgium is now available. Shoddy or wool waste may be confidently expected in quantity whilst the Yorkshire mills are kept going so busily. There are also considerable amounts of sulphate of ammonia obtainable.

In time of peace cereals are often grown simply on residues of previous crops. Probably in every district the agricultural adviser knows of some manurial scheme that would make use of these products and increase the yield. It cannot be too strongly urged that demonstrations should be put in hand as speedily as possible to show how this can be done. The cost of the manurial scheme should not be too high; these are not times when speculative propositions can be undertaken, but only those that are likely to prove successful. It is certain that the area under wheat has been increased this year; the efforts of the agricultural adviser should be extended now to an increase in the yield per acre. Potash must remain a difficulty until the present search for new supplies is rewarded with success.

A third problem of importance is this:—Are any rearrangements possible whereby products not likely to be in much demand shall cease to be produced? This applies more particularly to horticulturists and market gardeners than to agriculturists. Early cucumbers, for example, have hitherto gone almost entirely to Germany, and this fact was realised in time to prevent growers from trying to raise them. The production of certain fruit and other market garden produce may require similar readjustment.

In conclusion, the time is appropriate to urge on all our farmers the need for reducing all waste to a minimum. The ordinary farm compares badly with modern manufacturing concerns in this respect; considerable amounts of material are left to waste on the plea that it is not worth while doing anything better. It can never be too strongly urged that waste is a sign of bad farming, and the present is a good time for reform.

NEW CANADIAN DINOSAURS.

TWO very remarkable new types of Canadian Cretaceous dinosaurs are described by Mr. Barnum Brown in the first and last of a consecutive series of three papers published in vol. xxxiii., pp. 539–65, of the Bull. Amer. Mus. Nat. Hist. The first of the triad is devoted to Anchiceratops, a member of the horned group (Ceratopsia) from the Edmonton beds of Alberta, characterised by the great size of the knobs bordering the nuchal flange, and the pair of large oval vacuities by which the latter is pierced. Special interest attaches to this type from the fact that it serves to explain the mode of origin of the ceratopsian flange. In the smaller and less specialised type represented by Monoclonius the supra-occipitals form a pair of hook-like opposing processes on the hind border of the upper surface of the skull, leaving a mushroom-shaped interval between them, and a pair of very large vacuities in the skull-roof. In Anchiceratops the supra-occipital processes have united in the middle line, where only a remnant of a central fontanelle is left, while the vacuities in the lateral portion of the cranial roof are very much smaller. Finally, in Triceratops, which is both the largest and latest member of the whole group, all vacuities have disappeared from the cranial roof and the nuchal flange attains its maximum development.

In the second paper the author describes and illustrates a nearly complete skull of the aforesaid Monoclonius from the Belly River beds of Alberta, which exhibits very clearly the features just referred to. But by far the most interesting of all is the skull (associated with the skeleton) of a trachodont dinosaur from the formation last mentioned, remarkable for the elevation of the cranial region into a tall, helmet-like crest, formed by the nasals, prefontals, and frontals. This unique conformation recalls the skull of the helmeted cassowary—a feature commemorated in the specific portion of the name (*Corythosaurus*

Skull of *Corythosaurus casuarinus*. About one-tenth natural size. *Den*, dentary; *Ex.O*, exoccipital; *Fr*, frontal; *Ju* jugal; *La*, lachrymal; *Mx*, maxilla; *Na*. nasal; *Pmx*, premaxilla. *Po.f*, postfrontal; *Pr.den*, predentary; *Pr.f* prefrontal, *Qu*, quadrate; *Sur*, surangular; *Sq*, squamosal.

casuarinus) proposed for this new type. As minor features of the skull (the figure of which is herewith reproduced on a reduced scale) may be mentioned its relative shortness, the narrow beak, and the small size of the narial aperture.

At the close of this paper Mr. Brown proposes a revised classification of the Trachodontidæ, which he divides into the two families Trachodontinæ and Saurolophinæ, the latter characterised by the presence of a cranial crest which is lacking in the former. The first group is represented by the genera Trachodon, Kritosaurus, Hadrosaurus, and Claosaurus, and the second by Saurolophus, Hypacrosaurus, and Corythosaurus.

R. L.

GEOLOGY IN AUSTRIA-HUNGARY.

THE widely representative character of the work of the Geologische Reichsanstalt of Vienna is fully maintained in recent issues of the *Jahrbuch*. One of the most notable publications from the point of view of students and teachers of geology is that by O. Ampferer and W. Hammer, entitled "Geologischer

Querschnitt durch die Ostalpen vom Allgäu zum Gardasee" (lxi. Bd., 3 u. 4 Heft, p. 513). This includes a critical description, district by district, of a coloured section drawn on the horizontal and vertical scale of 1 : 75,000, and published with this double part of the *Jahrbuch* as a folded illustration three and a half metres in length. The authors acknowledge their indebtedness to the administration by the Reichsanstalt of the Urban Schlönbach travelling-fund. Bibliographies are appended to each division of the description, and the whole may be regarded as a development and replacement of the remarkable single-handed work of Rothpletz, published in 1894. The authors point out (p. 535) that Rothpletz recognised the influence of great overthrusts, being in this matter a pioneer well ahead of most of his contemporaries.

The geological section includes subsidiary profiles in the overfolded limestone Alps of the Lechtal area, which have since provoked some criticism in the *Verhandlungen* of the institute; a traverse of the upper Inntal under the Piz Lischanna; the Trias of the Ortler, with schists overlying it on the north; the injection-gneisses of Monte Tonale; the huge masses of tonalite in the Adamello mountains; and, finally, the contorted Triassic series of the Val Sabbia, leading down to the Lake of Garda. Numerous detailed sections are added in the 180 pages of text. The systematic exposition that characterises Ampferer's work is recognisable in the account of the structure of the northern limestone Alps (pp. 669–83), accompanied by diagrams that would have delighted the heart of G. P. Scrope, and in the general summary (pp. 697–709), in which stress is laid on the absorption of masses of rock into the depths as a source of mountain-folding. It is urged that the structures now visible are based on much that is invisible, and that the folded matter is not merely superficial, but represents the crests of masses which have sunk deeply into the crust. The complete alteration, largely by thermal processes, of these sunken masses, renders the discovery of root-regions for the folded upper layers impossible. These upper layers assume anomalous positions in regard to one another through fracture and overthrusting, and not through the formation of flattened and continuous overfolds. While a localised region of the deeper crust is softened and gives way, the more rigid masses on either side close in and crumple the weakened portion, pressing a large part downward, but leaving the superficial layers above it contorted and even upthrust above the general surface. "Der grosze Massenüberschusz an der Oberfläche ensteht durch Einsaugung tieferer Zonen erdeinwarts." The authors argue that the visible crystalline masses beneath the strata that are overthrust, or, on the Decken theory, overfolded, form far too narrow saddles, and could not have underlain the broad region that would be occupied by the upper rocks if these were spread out in their original positions. Hence something has disappeared from the lower zones by absorption into the unseen regions of the crust.

O. Ampferer is also concerned (lxii. Bd., p. 183) with a scheme for the representation of far more detail than is usual on geological maps. He indicates the actual strike of outcropping strata by continuous coloured lines on the contoured topographical sheet, so that we can see at once how the edges of the rocks lie on mountain-slopes or across valley-floors. He also proposes to show, by a scheme of dots of various shapes and colours, the character of detritus on the surface and its origin from the several rocks that enter into the structure of the district.

R. v. Klebelsberg (lxii. Bd., p. 461) reviews the marine fauna of the Ostrau Beds of Moravia and Silesia, and concludes that the marine intercalations represent transgressions, in Middle Carboniferous and Lower Coal-Measure times, from the sea that lay continuously over Russia in the Carboniferous period. He hopes for a correlation of these overflows with those of Britain, Belgium, and Westphalia, since they may record events of wide significance, though of short duration. The positions of these marine bands in the Ostrau Beds is shown in sections by W. Petrascheck (lxiii. Bd., plate 14). The marked folding of the Upper Silesian coalfield occurred in Permian times.

E. Hartmann, of Munich, inspired by Rothpletz, furnishes a detailed study of "Der Schuppenbau der Tarntaler Berge am Westende der Hohen Tauern" (lxiii. Bd., pp. 207–388). Numerous types of rock are described that are due to deformation and mylonitisation during overthrusting, and the glaucophane-schists (p. 332) are referred to a mixture of diallage-hornblende rock with the slates into which it has intruded. The three flake-like sheets that have been piled on one another by the Alpine overthrusting are held to have been folded later (p. 376) by earth-movements from north-west to south-east, and, to a less degree, from east to west. The author, like many workers in the eastern Alps, finds that the phenomena are explicable by overthrusting, rather than by a transference of material from a distance as part of a great overfolded sheet.

Franz Kossmat (lxiii. Bd., p. 171) deals with the folded structure of the interesting region of potash salts in the Miocene system of East Galicia. Franz Toula (*ibid.*, p. 621) continues his work in western Bosnia, and describes a number of Triassic cephalopods, which appear to differ little from species established by Mojsisovics. G. Schlesinger (lxii. Bd., p. 87) discusses the ancestry of the proboscideans in the light of an unexpected discovery of *Elephas planifrons* in Lower Austria. The remains come from strata that are at the latest Middle Pliocene, though younger than the Pontian, with its Pikermi type of fauna (p. 93), and the occurrence in Europe of this typical Siwalik species leads the author to trace the known species of elephants from their source in the Fayûm to Europe and North America. He regards *E. planifrons* as passing from India through Europe to Africa, and as the direct ancestor of *E. meridionalis* (p. 150). The dwarf elephants of the Mediterranean islands are referred to a double origin, both the ancestors, *E. planifrons* and *E. antiquus*, being, however, normally large forms (p. 171), and Schlesinger adopts Abel's view that their degeneration in teeth and size arose from the close interbreeding necessitated by geographical changes.

Franz Kretschmer's studies on the "Kalksilikatfelse" in the gneiss of Moravia (lxii. Bd., p. 359) form an important addition to the literature of eclogites and amphibolites. It is now well recognised that these rocks, which are so common as inclusions in fluidal gneiss, are, in a great number of cases, residues of calcareous strata invaded by a granite magma.

The series of papers published in the *Verhandlungen* of the Reichsanstalt often contain new stratigraphical conclusions, new records of fossils, and at times illuminating criticisms. The controversy as to the structure of the imposing limestone mass of the Wetterstein, which forms the northern wall of Tyrol above Partenkirchen, is sustained by O. Ampferer (1912, p. 197) and O. Schlagintweit (1912, p. 313). The former demolishes, with accompanying diagrams, certain impossible readings of the local structure; the latter opposes Ampferer's view that the mass has been thrust from east to west, and continues to connect it with the overthrust sheet of the Inntal, and not with the underlying Lechtal sheet. The Cainozoic

beds north of the Carpathians are studied by W. Petrascheck (1912, p. 75), who indicates (p. 92) an interesting groove, parallel with the range, in which they assume an unexpected thickness above the Coal-Measures. The problem of their faulting-down, infolding, or original deposition in a hollow of erosion, reminds us on a smaller scale of that of the Indo-Gangetic plain (see NATURE, vol. xciv., 1914, p. 347). W. von Friedberg, of Lemberg (1912, p. 367) compares the fossil contents of the Polish Miocene with those of Miocene beds in Austria, North Italy, and France, and concludes that the Burdigalian is absent, that the salt-series is Helvetian, and that the Tortonian extends below and also above the gypsum-bearing strata of Podolia. The beds with the brackish-water mollusc Oncophora are held to be somewhat younger than those of Bavaria, and to represent (p. 387) the first arrival of the Miocene sea in Podolia in Upper Helvetian times. References to these beds in Moravia will be found in a note by A. Rzehak (1912, p. 344).

An interesting feature in mountain-structure is shown in sections by G. Geyer (1913, p. 293) of the Toten Gebirge on the border of Styria and Upper Austria, where gypsum-bearing beds have been squeezed up like dykes into limestones of much later date. As an example of critical reviewing, we may cite the extremely valuable summary by F. Katzer (1911, p. 387) of Cvijić's researches in Macedonia and the Balkan peninsula as far as the Dardanelles, which have been mostly published in the Servian language. The origin of the Bosporus-Dardanelles river-cut comes in question (p. 417). We have kept until the last a mention of a discussion by O. Ampferer of Penck's well-known association of terminal moraines and outwash-plains (1912, p. 237). While we think that Ampferer distinctly underestimates the amount of water that may escape from an ice-front of continental magnitude through a loosely piled block-moraine, his citation of the filtering effect of a terminal moraine is distinctly useful. He thus cannot admit the association of a large terminal moraine with an extensive "apron." The two structures, for him, should be in inverse proportion. Ampferer does good service (p. 238) in pointing out an anomaly in Penck's diagram of a double moraine-wall enclosing a "Zungenbecken." This figure has been extensively reproduced, but has puzzled other geologists. How was the outer moraine piled up if the inner one was not destroyed? On the other hand, if it is the older of the two, why do its outwash-products overlie those of the inner wall?

G. A. J. C.

ON SALTS COLOURED BY KATHODE RAYS.[1]

PERHAPS a part of the phenomena which I am about to discuss is already familiar to you all. I shall not bring forward many hypotheses. So you will perhaps ask why I should speak at all. And, in fact, apart from reference to certain facts not published hitherto, my intention is mainly to invite the interest of men younger and abler than myself in a class of phenomena which seem to constitute a new condition of matter, but on which very few have yet worked.

If kathode rays fall on certain salts—for example, common salt, or chloride of potassium, or potassium bromide—vivid colours are produced immediately on these salts.[2] Thus common salt becomes yellow-brown (like amber), potassium chloride turns into a beautiful violet, potassium bromide becomes a deep blue colour quite like copper sulphate. Here you see a specimen of common salt transformed in this way on the surface of the single crystals into a yellow-brown substance. I show also sodium fluoride, which takes a fine rosy colour.

The colours so acquired in a very small fraction of a second may be preserved for a long time, even for many years, if the coloured substances are kept in the dark and at low temperatures. But in the daylight, and also under heat, the colours will gradually disappear until the original white condition is reached again.

The colours of different salts are sensitive to heating in a very different degree. I could show you the yellow sodium chloride, prepared some months ago in Europe, but I cannot show you here the violet KCl and the blue KBr, because these colours, even in the dark, do not stand the heat of the equator. The same salt, if dissolved, may keep very different colours, according to the medium in which it has been dissolved, even when the pure medium itself cannot be coloured at all by kathode rays. I am speaking of *solid solutions,* produced by fusing a small quantity—for instance, of common salt or of certain other alkali salts—together with a great mass of a salt which remains itself colourless in the kathode rays, as, for example, the pure potassium sulphate. Lithium chloride acquires a bright yellow colour in the kathode rays; but if dissolved in potassium sulphate a lilac hue is produced, as you may see in this specimen. Likewise the pure carbonate of potassium acquires a reddish tint, but after dissolving it in the potassium sulphate it becomes a vivid *green* in the kathode rays, as you see here.

Very small admixtures are sufficient to produce intense colours. So 1/25,000 of carbonate will produce the green colour in the potassium sulphate; even 1/100,000 gives a marked colour, and an amount of certain admixtures, which I estimated as 1/1,000,000 only, may produce a slight but quite perceptible coloration in some salts. So if you work with potassium sulphate which you obtain from chemical factories guaranteed as chemically pure, you may observe a set of different colours in these preparations under the kathode rays, by which you will detect the nature of the different small admixtures which adhere to the pretended pure preparations of the different factories. In this way a new analytical proof, much more sensitive than the ordinary chemical methods, is obtained, and impurities may be detected even when a certain specimen of salt contains more than a single impurity, because the colours produced by different admixtures generally disappear with different speed in the daylight or under rise of temperature. For instance, the ordinary potassium sulphate turns to a dark grey with a slight greenish tint at first. After a short while the very sensitive grey will disappear, simply under the ordinary temperature of the laboratory room, and a vivid green comes out. The grey hue indicates a very small amount of sodium chloride, 1/100,000 or so, and the remaining green indicates the admixture of a carbonate. Here are some preparations of potassium sulphate each containing a single small admixture (K_2CO_3, Li_2CO_3, LiCl, KCl, KBr). You will notice how different are the colours of the originally white substance, varying from green to bluish-grey, ash-grey, greyish-blue, and violet.

By fractional crystallisation one may finally get a really pure preparation of potassium sulphate, which

[1] By Prof. E. Goldstein. A paper read before Section A of the British Association at the Australian meeting, and ordered by the General Committee of the Association to be printed *in extenso.*

[2] E. Goldstein, *Wiedem. Ann.*, liv., 371; lx., 491; *Phys. Zeitschr.*, iii., 149; *Sitzungsber. Ber. Akad. d. Wiss.*, 1901, 222.

is no longer coloured by kathode rays (or only in a very slight degree, indicating minimal traces of sodium chloride). But there are other preparations which, so far as I know, cannot be acquired in pure condition by any means, not even by fractional crystallisation. I never came across a pure sodium sulphate—the purity exists only on the manufacturers' labels. Even the best preparations of this salt contain an amount of sodium carbonate which up to the present cannot be separated from it, not even by frequent fractional crystallisation. The colour produced by the small admixture, which always remains, is a very marked ash-grey. By an intentional further addition of sodium carbonate the colour becomes nearly black.

The question arises: What may be the cause of these colorations in pure salts and also in solid solutions of them? Shortly after the colours of the alkali salts had been discovered, an explanation was given,[3] according to which the phenomenon mainly consists in a chemical reduction. For instance, in the case of potassium chloride the chlorine would be set free, while the remaining potassium is dissolved in the unaltered main quantity of the salt, colouring it at the same time. And it seemed a convincing proof for this theory when Giesel[4] and also Kreutz, simply by heating rock salt in the vapours of sodium or of potassium, produced colours in this rock salt quite similar to those produced by kathode rays. It seemed that the problem was settled finally. However, it was soon discovered that the coloured Giesel salts, although they look to the eye quite like the kathode-ray salts, in all other respects behave quite differently. For instance:—

(1) The kathode-ray salts, as I mentioned before, are very sensitive to daylight: after an exposure to diffuse daylight of a few minutes—or in some salts even of several seconds only—the coloration diminishes, whilst the Giesel salts remain unaltered even when they are kept in full sunshine for days or even weeks.

(2) The kathode-ray salts, if dissolved in distilled water, show absolute neutral reaction; the Giesel salts are strongly alkaline.

(3) The kathode-ray salts give very marked photo-electric effects (as Elster and Geitel[5] observed); the Giesel salts are quite ineffective.

(4) In certain circumstances, which will be mentioned further on, the kathode-ray salts may emit a phosphorescent light, the Giesel salts none at all. Therefore the question arose again, Whether there is not a marked internal difference between the kathode-ray salts and the Giesel salts, and what is the nature of the latter?

I have succeeded in settling this question, having produced salts *by kathode rays*, the behaviour of which is in every respect *absolutely identical with that of the Giesel salts.* You may produce such substances if you allow the kathode rays to fall on the original salts not for a short moment only, but for a somewhat prolonged time, *until the salts are strongly heated.* Produced in this way the salts will keep colours; but the substances coloured in this way are *not* sensitive to light; they show no photo-electric effect; they give *strong alkaline* reaction, and they are not suited for phosphorescence—all like the Giesel salts. It is quite sure, and you may test it also directly by spectroscopic proof, that in this case, if for instance you have worked on sodium chloride, *the chlorine is set free.* Then, of course, an amount of free sodium is left, which dissolves itself in a deeper layer of unaltered sodium chloride, to which the kathode rays could not penetrate. I call these non-sensitive colours *the after-colours of the second* class, while the ordinary sensitive after-colours, produced in a short time on cool salts, are called after-colours of the first class.

Now, if the after-colours of the second class are identical with those of the Giesel salts, then, of course, the very different substances of the first class cannot be also identical with the Giesel salts. Therefore the question arises anew what is the nature of the first-class after-colours?

One observes with regard to solid solutions that the first-class colours depend not only upon the *metal* contained in the small admixture, but they vary greatly, for instance, in the case of the admixture consisting of potassium chloride or bromide or iodide. This indicates that the metals alone do not cause the after-colours. It becomes much more clear when we expose some ammonium salts to the kathode rays. (The ammonium salts are cooled by liquid air in the discharge-tube to prevent their evaporation.) Then you get strongly marked after-colours likewise; for instance, ammonium chloride becomes yellow-greenish, the bromide becomes yellow-brown, the iodide becomes brown, and the fluoride a deep blue. In the daylight these colours are gradually destroyed, quite like other after-colours of the first class. The colours themselves—yellow-greenish for the chloride, yellow-brown for the bromide, and so on—induce us to presume that the after-colours in this case are produced by the haloids, and not by the hypothetical ammonium radicle. This presumption becomes a strong conviction when we observe that also a great number of organic preparations which contain no metal at all (and not any metal-like radicle) acquire marked after-colours of the first class in the kathode rays also. (The part of the discharge-tube which contains the organic substances is cooled by liquid air.)

Then you may observe that solid acetic acid ($C_2H_4O_2$) remains quite colourless in the kathode rays; but if you substitute a hydrogen atom by chlorine, the substance thus produced (the monochloro-acetic acid) acquires a marked yellow-green after-colour. If you introduce an atom of bromine instead of chlorine, you get $C_2H_3BrO_2$, and the after-colour is of a marked yellow. Bromoform ($CHBr_3$) turns into the colour of loam, and chloral (C_2HCl_3O) becomes a deep yellow. In this way we see that not only salts, but likewise substituted acids, substituted hydrocarbons, and substituted aldehydes acquire after-colours if they contain any haloid.

Now, it seems highly improbable that in the case of alkali salts the electro-positive component is absorbed only (producing the after-colour), and that, on the other hand, in the ammonium salts and in the organic substances the electro-negative component is efficient only. The most probable inference is that in each case *both* components remain and that both are efficient, but that under the same conditions the haloids produce a slighter colour than the metals, so that in the case of the salts the haloid colour is overwhelmed by the metal colour.

Therefore we are compelled to suppose that we have not to deal with a decomposition in the ordinary form, by which the different components are finally separated from each other and at least one of them is set entirely free, but that the components detained by absorption remain at a quite short distance from each other, so that they may easily meet again. I realise that—for instance, in the case of sodium chloride—at every point of the coloured layer there is an atom (or perhaps a molecule) of chlorine and an atom (or a molecule) of sodium; but they cannot combine, because they are fixed by absorption and distended from each other by the absorptive power, which in this case surpasses the chemical affinity. But the absorptive power may be

[3] E. Wiedemann and G. C. Schmidt, *Wied. Ann.*, liv., 618.
[4] F. Giesel, *Ber. D. Chem. Ges.*, xxx., 156.
[5] J. Elster and H. Geitel, *Wied. Ann.*, lix., 487.

weakened by heating and the chemical affinity or the amplitude of the molecular vibrations may be strengthened by the energy of daylight.

If we grant these assumptions, it is immediately evident why the reaction of all dissolved colour substances of the first class is a neutral one, for the two components may combine again and re-establish the original substance. The other special qualities of the first-class colours, and especially their differences from the Giesel salts, which contain the electro-positive component only, may be deduced likewise from this retention of both components and their opportunity of meeting each other again when the absorptive power is weakened or the chemical affinity is strengthened. Now, the two components in the coloured substances being distended in some degree, I propose for this special condition of matter the name of *distension*. If we accept this, have we created a new name only, or does matter in this condition really show new qualities? It seems to me that we have to deal with a peculiar condition of matter, which deserves a more elaborate study than it has met until now. I will not enter again into some special qualities, which have already been mentioned—the photo-electric effect and so on—but I should like to point out that matter in the distension state shows a strongly strengthened absorption of light.

We noticed with regard to ammonium chloride the yellow-greenish after-colour of the chlorine. Now, kathode rays, as used in these experiments, will not penetrate any deeper than one-hundredth of a millimetre into the salt. In such a thin layer even pure liquefied chlorine would not show any perceptible colour. But besides this it must be noticed that we observe this after-colour at the temperature of liquid air, and that chlorine at this temperature, as Dewar and Moissan observed, is snow-white, even in thick layers. In a similar degree the brown colour of bromine is weakened at low temperatures. Now, if nevertheless we observe at this very low temperature the marked characteristic colours of chlorine and bromine, we must conclude that the absorptive power of these substances has become a multiple of its ordinary value. One may observe this strengthening of the absorptive power directly in the pure sulphur. Sulphur likewise turns into a snow-white substance if cooled by liquid air. But when the kathode rays fall on the white sulphur it takes immediately a yellow-reddish colour. It is a real after-colour, because at constant low temperature the colour is destroyed by daylight.

Now, since the strengthening of light absorption occurs in this elementary substance, it becomes evident that the cause cannot be any chemical process, but only a physical allotropy. The special character of this allotropy (which may be connected with an absorption of electrons) will not be entered on in a discussion here. Probably we have to deal with a polymerisation, so that, for instance, the yellow-reddish sulphur would be analogous to polymerised oxygen—to ozone.

I have mentioned already that the first-class after-colours are gradually destroyed by incident daylight. A peculiar phenomenon is connected with this destruction of colour. I found that after the daylight had fallen on the coloured substances, even for the shortest time, most of them showed a marked phosphorescence of long duration. I have observed this phosphorescence even in substances which had been coloured twelve years ago and had been kept in the dark since that time. The diffused dim light of a gloomy November day, when falling through a window on the coloured substance for one or two seconds only, is sufficient for the production of this phosphorescence in a marked degree. If you allow the daylight to fall several times on the same spot, then the colour is weakened at this spot, and we come to the presumption that the loss of coloration is generally attended by the emission of phosphorescent light. This is in accordance with the experience of Wiedemann and Schmidt that if the destruction of the colour is produced by heating, likewise a phosphorescent light is produced, which in this case is strong but of a short duration, corresponding to the quick destruction of the after-colours by strong heating.

If the salts, after having been coloured in the condition of a fine powder and then having been put between two glass plates (in order to obtain a plane surface), are placed in a photographic camera instead of the photographic plate, you may get a fine phosphorescent picture of a landscape or of architecture after a very short exposure.

Time does not allow me to mention in detail several other peculiarities which are shown by matter in the distension state. In one direction only I may be allowed to make some remarks.

The first-class after-colours may be produced not only by kathode rays but also by the β rays of radioactive substances, as you probably know But they may also be produced by *ultra-violet light,* for instance, by ultra-violet spark light, even when a quartz plate is interposed between the spark and the salt. More than thirty years ago I brought forward a hypothesis, according to which in every point where kathode rays strike a solid body a thin layer of ultra-violet light-radiating molecules is produced in the gas, to which ultra-violet light of very short wave-lengths, for instance, the phosphorescence of the glass walls in the kathode rays, is due. But I came further to the assumption that nearly all effects which are commonly ascribed to special qualities of the kathode rays, and likewise of β rays and X-rays, are mere effects of the ultra-violet light which is produced by the stopping of these rays. I have been guided by this assumption during many years, and have very often been aided by it in foreseeing new phenomena. For instance, in this way I was induced to expect that the after-colours would be produced not only by kathode rays but also by the ordinary ultra-violet light; further I could guess that also the X-rays would produce after-colours (which in this case have been observed by Holzknecht), and in recent times I could foresee that solid aromatic substances (the benzene derivatives) in the ultra-violet light must change their spectra of ordinary phosphorescence, composed of broad bands, and turn to peculiar spectra composed of narrow stripes, the wave-lengths of which are characteristic of the single aromatic substances.[6] So I believe also that the after-colours are produced not directly by the kathode rays or by β rays, but by the aforesaid ultra-violet light which is connected with the stopping of the other rays.

In this way the after-colours enter at once into a great class of phenomena known as *reversible effects of light*. You know that certain effects of the visible spectral rays are destroyed by rays of longer wave-lengths, by the infra-red rays. And the analogy to this phenomenon is in my opinion the destruction of the after-colours: they are produced by the ultra-violet light of the stopped kathode rays and are annihilated by the longer visible wave-lengths of daylight. In this way you may likewise understand, for instance, that the coloured spots, produced by X-rays on the luminescent screens after long exposure, may be destroyed again by exposure of the screens to day-

[6] E. Goldstein, *Verhandl. d D. Physik. Ges.*, xii.

light. You may also explain the peculiar medical observation that therapeutic radium effects in parts of the human body not covered, specially in the face, are often not of long duration—for the face is exposed to the counteracting visible rays of daylight.

We notice here a connection of our subject with a department of great practical importance. For all therapeutic effects of X-rays, radium rays, and mesothorium rays would, according to this view, be effects only of ultra-violet light produced by the stopping of these rays in the human body, and the special character of the radium- and mesothorium- and X-ray treatment would consist mainly in the carriage into the interior of the body, by the rays, of the ultra-violet light, which is not confined to the surface of the body, but is produced at every place where any of the entering rays are stopped. You may notice further that this view of the medical ray-effects presents a heuristic method for the treatment itself, which up to the present followed quite fortuitous and merely empirical paths. For it may be hoped that treatment by radio-active substances will be useful in every disease in which ultra-violet light has been proved to be efficient in some degree; you will avoid such treatment in the well-known cases in which light of short wave-lengths is noxious, and you may be justified in substituting an ultra-violet light treatment where radium or mesothorium is not obtainable. At the same time it becomes evident why the treatment of certain diseases by the β rays has effects very similar to those produced by *fulguration*—that is, by the light of very strong sparks; the efficient agent is in both cases the ultra-violet light.

But it cannot be a physicist's task to enter too far in medical questions: it was only my intention to show how interesting are some of the problems which are connected with the salts coloured by kathode rays.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

By the will of the late Dr. T. Bell, head of the firm of Messrs. Pyman, Bell, and Co., coal exporters and shipowners, of Newcastle, the sum of 3000*l.* is bequeathed to the Armstrong College, Newcastle.

THE report of the proceedings of the general committee for promoting the establishment of an Imperial College of Tropical Agriculture is referred to in the *Pioneer Mail* of December 4. It is stated that Mr. R. N. Lyne, Director of Agriculture, Ceylon, says he thinks that the West Indies will now support Ceylon's claims to be the home of the college. The committee resolved to take steps to raise 40,000*l.* for building and endowing the college, of which 20,000*l.* should be asked from the Governments concerned, including India, and the remainder be raised by public subscriptions, provided Government contribute the share stated. It was also resolved to collect 5000*l.* for the erection of a hotel for European students. The committee has not committed Ceylon for the site; at the same time it favoured that country.

SEVERAL bequests for higher education in the United States are announced in the issue of *Science* for December 18 last. Two gifts of 20,000*l.* each have been made for the development of a graduate course in preparation for business and business administration at the Sheffield Scientific School of Yale University. The two donors are graduates of the University. 2000*l.* has been given to Smith College by Mr. and Mrs. A. J. White, of Brooklyn. Half of the money is to be applied toward payment for recent improvements on the Lyman Plant House. A bequest of 2000*l.* to St. Lawrence University at Canton, N.Y., is made under the will of Mrs. Kate A. L. Chapin, of Meriden, Conn. Prof. and Mrs. Frederic S. Lee have given to Columbia University the sum of 4000*l.* to establish a fund for the use of the department of physiology.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Meteorological Society, December 16.—W. F. **Stacey**: The distribution of relative humidity in England and Wales. The author has prepared mean monthly and annual maps of relative humidity based on the 9 a.m. observations made at more than ninety stations during the ten years 1901–1910. An examination of these maps shows that in winter the air over the interior of the country is more moist than that over the coastal regions; that the minimum relative humidity occurs earlier in the year in the western parts of the country than in the eastern; that in summer the air over the interior of the country is drier than that over the coastal regions; and that the smallest range of humidity is found in the west and the greatest in the interior towards the east. The distribution of temperature is the chief determining factor in the distribution of relative humidity; while sea influence, the direction and character of prevailing winds, the configuration of the country all have important effects on temperature, and therefore on relative humidity.

Geological Society, December 16.—Dr. A. Smith Woodward, president, in the chair.—Prof. W. M. Flinders **Petrie**: The Palæolithic age and its climate in Egypt. The classes of worked flints peculiar in Egypt are:—(1) Irregular, with broad unregulated fractures. (2) Rounders, flaked in all directions to an edged disc. (3) Hoofs, very thick, rudely domed with an obtuse edge. (4) Lunes, with obtuse edges. (5) Crescent scrapers. Irregular flints, similar to those from St. Acheul, are found in high Nile gravels. The regular European types occur exactly like those classed as Chellean and Acheulian. The Mousterian forms are so often found in various periods, that they cannot be assigned without evidence of age. The Aurignacian survive into the early civilisation. The large class of flints from the Fayum desert comprises all the Solutrean types, and also Robenhausian forms. The flakes of the early civilisation (8000 to 6000 B.C.) are identical with Magdalenian. Views of the Nile cliffs show the general nature of the country and conditions. Successive changes of level are indicated by (1) the collapse of immense drainage-caverns far below present level; (2) the filling of valleys with débris up to 650 ft. above the present sea-level; (3) the gouging-out of fresh drainage-lines through the filling; and (4) rolled gravels on the top of cliffs 800 ft. above sea-level, since when there has been no perceptible denudation by rain. The great extent of these elevations and depressions is likely to be connected with similar movements at Gibraltar, which are believed to synchronise with the movements of glacial periods in northern Europe. The evidence of the flint ages agrees with this connection.

PARIS.

Academy of Sciences, December 14.—M. P Appell in the chair.—E. **Branly**: Intermittent conductivity of thin dielectric plates. A study of the conductivity of a thin plate of dielectric induced by the passage of a rapidly alternating current.—P. **Duhem**: The hydrodynamical paradox of M. Brillouin.—M. C. Jordan was elected vice-president for the year 1915.—M. **Bazy**: Statistical note on tetanus. A study of 129

cases of tetanus occurring in 10,896 wounded. In eight cases, the disease appeared fourteen or more days after the wound, one as late as twenty-seven days. Stress is laid on the valuable preventative action of the anti-tetanus serum. In hospitals where preventative injections have been made systematically the tetanus mortality is 0·42 per cent.; in hospitals where the injection is made in suspected cases only the mortality is 1·28 per cent. If only a limited amount of the serum is at the disposal of the surgeon, the amount injected may be safely reduced from 10 c.c. to 2 c.c.—F. **Gonnessiat**: Solar eclipses: formula for the correction of the elements.—Henri **Villat**: The paradox of d'Alembert and the theory of discontinuous movements.—H. **Bertin-Sans** and Ch. **Leenhardt**: The localisation of projectiles in the body by radiography.—O. **Lignier**: The staminal glands of the Fumaraceæ and their signification.—G. **Arnaud**: The suckers of Meliola and Asterina.—P. **Mazé**: Nutritive exchanges in plants. The rôle of the protoplasm.—Jules **Amar**: Relations between the feeding and strength of Arabs. Arabs were fed on two classes of diet of equal heat value, one following native custom the other French. The former proved more advantageous from the point of view of utilisation of the food in the form of muscular work.—J. **Blier**: Bovine hæmoglobinuria of Chili.—A. **Trillat** and M. **Fouassier**: The influence of the radio-activity of the air on the microbial water particles in suspension in the atmosphere.

New South Wales.

Linnean Society, October 28.—Mr. W. S. Dun, president, in the chair.—T. G. **Sloane**: Revision of Australian Carabidæ. Part v. Part v. deals with the Australian section of the tribe Helluonini, comprising seven extra-Australian, and twelve Australian genera, with twenty-seven species. Four genera and seven species are described as new.—E. **Petersen**: Australian Neuroptera. Part i. Two genera and five species are proposed as new, and supplementary information, with illustrations, of seven species previously described, is given—the entire series being referable to six families.—Dr. A. J. **Turner**: The Lepidoptera of Ebor Scrub, N.S.W. Ebor is a small township, fifty miles N.N.E. of Armidale, on the eastern edge of the New England Plateau, at an elevation of 4000 ft., with an abundant rainfall. Representatives of thirty-one species of Lepidoptera (fam. Arctiadæ, Geometridæ, Pyralidæ, Tortricidæ, Tineidæ) were collected in the scrub. Six genera and twenty-four species are described as new.—L. **Harrison**: Some Pauropoda from New South Wales. Four species of Pauropus, and one of Eurypauropus, are described as new, with observations on the development of one species of these delicate little Myriapods, now added to the Australian fauna.—T. G. **Sloane**: Description of a new tiger-beetle from North-Western Australia.

LEAD POISONING.

Lead Poisoning: from the Industrial, Medical, and Social points of view. Lectures delivered at the Royal Institute of Public Health by Sir T. Oliver. Pp. x+294. (London: H. K. Lewis, 1914.) Price 5s. net.

LEAD and its compounds are among the most serviceable of metallic products, but unfortunately their use is attended by a great amount of human suffering, and lead-poisoning, or, as it is variously called, plumbism, saturnism, *Colica pictorium,* or *Colica pictorum,* is one of the commonest forms of industrial intoxication. Nearly every class of worker handling lead or its compounds is liable to be injuriously affected, from the miner engaged in getting cerusite, the smelter, desilveriser, or flue cleaner who are employed in the extraction of the metal; the worker who oxidises it to litharge and red-lead; the type-founder, stereotyper, and diamond-cutter, who use its alloys; the file-cutter, who employs it as a "bed" or "stock" to, of course, the plumber, who, as his very designation implies, is essentially concerned with the applications of the metal in its finished state. And the compounds of lead are as a class even more directly and immediately toxic than the metal. Many of them enter largely into the composition of pigments, and accordingly colour-mixers, house and coach painters, lithographers, as well as those who make the pigments, are prone to suffer from lead poisoning. Lead compounds are used in metal-polishing, in electro accumulator making, in dyeing, glass-making, pottery manufacture, and in the glazing of hollow ware, and cases of plumbism are particularly rife in those industries. Communities are occasionally subject to an epidemic of lead-poisoning, owing to the action of some kinds of drinking-water upon the leaden pipes and cisterns used to convey and store the water.

It is, therefore, scarcely to be wondered at that the subject of lead-poisoning should have received the earnest attention of pathologists and sanitarians, and of the public departments in various countries concerned with the supervision of the hygienic condition of factories and workshops. In the work before us, Sir Thomas Oliver, who has made the subject a special study, and is an acknowledged authority upon it, gives us an admirable digest from the industrial, medical, and social points of view of what is known concerning it.

He deals with the various industries concerned with the use of lead and lead compounds, and the relative frequency among them of lead-poisoning; explains how it is actually caused, the channels of entrance of the poison, and its symptomatology; its action on the blood and nervous system; its influence on female life and motherhood; and lastly, its treatment, preventive and curative. Incidentally he shows the good that has been effected by legislation, and points out the beneficial results that have followed from Home Office inspection and regulations.

The book is primarily intended for the medical profession, but we commend it to the attention of all who are interested in the manufacture and use of lead and its compounds. Lead, of course, is too valuable a metal to be wholly dispensed with, and its good properties are such that it must continue to be used. But there is no question that certain of its more harmful compounds could be dispensed with, as innocuous substitutes are known; *e.g.*, white lead may in many cases be replaced by zinc white, leadless glaze might more often displace lead glaze. But even where used, less harmful compounds than those actually employed are available, as, for example, fritted glazes in substitution for "raw lead glazes" in the manufacture of pottery. Although a certain amount of progress has been made, lead-poisoning in the Potteries is still far too prevalent; the actual number of cases reported may be fewer than was the fact when the Thorpe-Oliver Report to the Home Office was published, but recent statistics indicate that the number of severe cases, ending in death, has shown no sensible diminution. If, then, lead compounds must continue to be used in this industry, it is only by the intelligent appreciation and study of the facts set forth in Sir Thomas Oliver's little book that progress in remedial measures can be secured. T.

VEGETABLE TANNINS.

Die Gerbstoffe: Botanisch-chemische Monographie der Tannide. By Dr. J. Dekker. Pp. xiii+636. (Berlin: Gebrüder Borntraeger, 1913.) Price 20 marks.

THIS book is the German translation of the earlier Dutch edition (1905–8), and is supplemented and revised up to date. The author is specially fitted to write on the subject of vegetable tannins, as he is both botanist and chemist, and has for many years been engaged in research on these bodies.

In the botanical section of the book a classification of the tannins is given, which is far more complete and useful than any previous work of this kind. The excellence of this part of the book is very largely due to the original work of the author and his collaborators. The value of such

a survey is obvious not only to the man of science, but to the technical leather trades chemist who is always seeking some new tanning material in view of the probable early exhaustion of some of the materials now in common use. A chapter on the physiological *rôle* played by the tannins in the plant concludes the botanical part of the book, and gives a very interesting account of the work done on this difficult subject.

The researches of Emil Fischer and his pupils on the chemistry of the tannins have robbed the earlier work on the subject of much of its interest, and the author might have gone further in cutting down his account of this older work, which will only rarely bear criticism and is scarcely ever suggestive of further work. This applies even to the formula which the author himself suggested for gallotannic acid,

$$C_6H_2(OH_3).C(OH).O.CO.C_6H(OH)_3,$$

a constitution which is merely the tautomeric form of that suggested by Böttinger for oakwood tannic acid,

$$C_6H_2(OH)_3.CO.C_6H(OH)_3.COOH.$$

This fact is not alluded to by Dr. Dekker, or by other authors who have discussed Dekker's formula.

An excellent bibliography of tannin literature, comprising all books published since 1571, and all papers since 1754, forms one of the most valuable features of the book. All who intend working on the chemistry or chemical technology of tannins will find here a valuable guide to original work on the subject. Dr. Dekker also gives accounts of no fewer than eighty-six methods of tannin analysis. This part of his book is of great interest to leather trades chemists. The same cannot be said of the chapter on practical tanning, which would have been better omitted.

Dr. Dekker's book can be thoroughly recommended to all botanists, chemists, or technologists who are specially interested in vegetable tannins, as it is certainly the best and most complete account existing of our knowledge of these bodies.

E. S.

WIRELESS TELEGRAPHY.

(1) *Text-book on Wireless Telegraphy.* By Prof. R. Stanley. Pp. xi + 344. (London: Longmans, Green and Co., 1914.) Price 7*s.* 6*d.* net.

(2) *Wireless Telegraphy: a Handbook on the Fundamental Principles and Modern Practice of Radio-telegraphy.* By A. B. Rolfe-Martin. Pp. vi + 256. (London: A. and C. Black, 1914.) Price 5*s.* net.

THE literature of wireless telegraphy has already become very extensive although the art and practice of the subject is scarcely more than fifteen years old. Leaving out of account the large number of original memoirs on the scientific side, we can say that broadly speaking the books written on the subject fall into three groups. There are first a few which deal in an advanced manner with the scientific exposition of it, making free use of whatever mathematical analysis may be required, and assuming on the part of the reader a sufficient preliminary acquaintance with physics. Then at the other end of the bookshelf we find a large number of smaller books which aim chiefly at imparting to the amateur or practical operator a knowledge of the use of the appliances and instructions for making or operating wireless telegraph apparatus. An intermediate group of books comprises the student's text-books, which, whilst giving descriptions of apparatus, endeavour to impart a certain degree of explanation of its operation suited to those whose acquaintance with mathematics or physics is limited. The two books before us belong to the latter class.

(1) Prof. Rupert Stanley's book is marked by a certain novelty of treatment and originality in illustrations. He has not been content merely to appropriate diagrams which have done duty already in other books, but has prepared with considerable care diagrams of circuits and schemes of connections of apparatus in which the nature of the magnetic and electric fields is clearly denoted. This feature is of distinct assistance to the student coming to the subject for the first time. Also he has judiciously abandoned the usual practice of describing wireless apparatus arranged under various "systems" ascribed to particular inventors, and has grouped the information in chapters comprising descriptions of particular elements in the apparatus.

The first seven chapters of the book are devoted to an exposition of the elements of electrical and electrical engineering knowledge, to which, however, utility is imparted by basing it on the electronic theory. There is no doubt that this method is a useful one. The student is in this manner enabled to visualise some of the operations better, but the teacher should at the same time be careful to point out that there can be no finality in any of our explanations of Nature's processes. Because we can conceive a mechanism by which the effects we see are brought about it does not in the least degree follow that they are actually done in that manner. A commendable feature of the book is a series of questions at the end of each chapter which will aid the teacher in testing the results of his teaching.

Some of the explanations in the book might with advantage have been amplified. For instance, in the description of Goldschmidt's high-frequency alternator no explanation is given of the

reason the non-used lower harmonic frequencies do not dissipate energy to such an extent as greatly to lower the over-all efficiency of the machine. Otherwise the book will prove to be a useful text-book for class teaching for students who come to the subject without much previous knowledge. The book is well printed, and the illustrations are well selected and drawn. The diagram No. 54, representing the lines of electric force round a Hertzian oscillator, is, however, not very true to fact. The loops of force thrown off should be concave on the inner side, and not convex.

(2) The book by Mr. Rolfe-Martin covers much the same ground, but is marked by less originality of illustration and more dependence on diagrams borrowed from commercial publications or magazines than is the case with Prof. Stanley's book. It is also more occupied with descriptive matter of the various appliances used by the Marconi Company, the Telefunken Company, and others. Nevertheless, it is well up-to-date, and for the student who can afford to possess more than one book on wireless telegraphy it is useful to have illustrations of actual apparatus in various forms.

Books which aim chiefly at an exposition of first principles rather than at descriptions of apparatus are likely to have more permanent value because the principles remain, whereas types of apparatus are being perpetually changed. In both of the above-mentioned books the authors have done wisely to discard all reference to early and now antiquated forms of wireless telegraphy. Neither of them, however, devotes much space to the consideration of the problem of radio-telephony.

There is here a wide field yet open for invention. The invention of a simple, easily managed generator of undamped waves and mode of modulating their amplitude in accordance with the wave form of the speaking voice offers a large scope for invention, and one which, if successfully cultivated, may end in replacing radio-telegraphy by radio-telephony to much the same extent as the telephone has replaced the telegraph in the case of wire transmission.

It need scarcely be said that in books intended for students there is no reference made in these publications to the outstanding problems and difficult questions of radio-telegraphy. The mode of propagation of the waves over the earth's surface is, however, dealt with by Prof. Stanley in his tenth chapter in a manner sufficient to impart some ideas of the nature of it as well as of the causes of the variations observed. It is becoming more and more clear that our terrestrial atmosphere plays an important part in long-distance radio-telegraphy, and that if the earth were a good conductor, say, as good as copper, and possessed no atmosphere, anything like long-distance wireless telegraphy on it would probably be impossible.

The progress of real knowledge on this subject will therefore be to a large extent conditioned by the progress of atmospheric meteorology and a knowledge of the state and constitution of the upper air.

J. A. F.

TRANSLATIONS OF POINCARÉ ON METHOD.

(1) *Science and Method.* By Henri Poincaré. Translated by Francis Maitland. With a Preface by the Hon. Bertrand Russell. Pp. 288. (London: Thomas Nelson and Sons, n.d.) Price 6*s.* net.

(2) *The Foundations of Science: Science and Hypothesis; The Value of Science; Science and Method.* By H. Poincaré. Authorised translation by G. B. Halsted. With a special Preface by Poincaré, and an Introduction by Josiah Royce, Harvard University. Pp. xi + 553. (New York: The Science Press, 1913.)

(3) *Wissenschaft und Methode.* Von Henri Poincaré. Autorisierte deutsche Ausgabe mit erläuternden Anmerkungen von F. und L. Lindemann. Pp. vi + 283. (Leipzig und Berlin: B. G. Teubner, 1914.) Price 5 marks.

(4) *Letzte Gedanken.* Von Henri Poincaré. Mit einem Geleitwort von Wilhelm Ostwald. Uebersetzt von Dr. Karl Lichtenecker. Pp. v + 261. (Leipzig: Akademische Verlagsgesellschaft, M.B.H., 1913.) Price 4.50 marks.

DURING his lifetime Henri Poincaré published many articles on the philosophy of science, and these were republished in three books: "La Science et l'Hypothèse," "La Valeur de la Science," and "Science et Méthode." After his death, his "Dernières Pensées" were collected and published in 1913. Of the books under review, (1) gives an English translation of the third of Poincaré's works just mentioned; (2) the first volume of a series on science and education, gives an English translation of the first three; (3) gives a German translation of the third; and (4) gives a German translation of the posthumous work.

Poincaré's lively style is very well reproduced in (1), but in (2) the translation seems to aim at the French spirit, and succeeds in giving an almost comically literal rendering which is not English and not even American. We will reproduce parallel passages of both books to show

this. On p. 159 of Mr. Maitland's translation we have:—

"Well, one day I received a visit from M. Hadamard, and the conversation turned upon this antinomy [of Burali-Forti].

"'Does not Burali-Forti's reasoning,' I said, 'seem to you irreproachable?'

"'No,' he answered; 'and, on the contrary, I have no fault to find with Cantor's. Besides, Burali-Forti had no right to speak of the whole of *all* the ordinal numbers.'

"'Excuse me, he had that right, since he could always make the supposition that

$$\Omega = T' \text{ (No. } \bar{\epsilon} >).$$

I should like to know who could prevent him. And can we say that an object does not exist when we have called it Ω?'

"It was quite useless; I could not convince him (besides, it would have been unfortunate if I had, since he was right). Was it only because I did not speak Peanian with sufficient eloquence? Possibly, but, between ourselves, I do not think so."

Dr. Halsted's translation on p. 459 is as follows:—

"Now, one day M. Hadamard came to see me, and the talk fell upon this antinomy.

"'Burali-Forti's reasoning,' I said, 'does it not seem to you irreproachable?' 'No, and on the contrary, I find nothing to object to in that of Cantor. Besides, Burali-Forti had no right to speak of the aggregate of *all* the ordinal numbers.'

"'Pardon, he had the right, since he could always put

$$\Omega = T' \text{ (No. } \bar{\epsilon} >).$$

I should like to know who was to prevent him, and can it be said a thing does not exist, when we have called it Ω?'

"It was in vain, I could not convince him (which besides would have been sad, since he was right). Was it merely because I do not speak the Peanian with enough eloquence? Perhaps; but between ourselves I do not think so."

Of course, Poincaré spoke of "*le péanien*," but this is scarcely a sufficient excuse for Dr. Halsted's translation.

On the other hand, it is rather evident that technical terms presented a difficulty to Mr. Maitland. He translates "*invariant*" by "invariable" on p. 35, "*la théorie des congruences*" by "theory of congruents" on p. 41, and "*implique*" by "involves" on p. 161. Dr. Halsted gives, as we should expect, the correct translations at the corresponding places of his book (pp. 375, 379, 460). It is rather unusual to speak of analytic functions as "analytical functions," as Mr. Maitland does on p. 77; Dr. Halsted uses "analytic" on p. 403. It seems to be confusing to speak of a paper, published by Mr. Russell in the Proceedings of the London Mathematical Society, as a "treatise," as Mr. Maitland does on p. 184. Dr. Halsted has "memoir" on p. 477, but has no reference on his p. 479 to the paper in question, whereas Mr. Maitland has (p. 187). Mr. Maitland carefully speaks of a Frenchman as "M." so-and-so, of an Englishman as "Mr.," and of an Italian as "Signor"; but for Germans he has no regular prefix: we often come across "Mr. Hilbert," and, quaintly enough, on p. 192, "Signor Zermelo." Of greater importance than this is that a formula of Burali-Forti, expressed in Peano's symbols, is wrongly reproduced on p. 157 of (1), owing to the fact that Burali-Forti's symbol "Un" is translated "one," thus giving some colour to Poincaré's mistaken contention that the idea of *one* is used in the very definition of "1." In (2) the formula is correctly reproduced (p. 488).

It does not seem necessary to characterise here Poincaré's philosophical writings: Mr. Russell, in his preface to (1), has done this admirably. All the four books under review will be useful in spreading a knowledge of the lighter works of a truly great man. As is so often the case, a lively and amusing style is here, too, sometimes accompanied by superficiality, and original thoughts by obstinacy. Poincaré's preface to (2) is very welcome at the present time: it lays stress on the fact that there is no reason for wishing the world exclusively impressed with the characteristics of one particular race.

As we might expect, (3), which is the seventeenth volume of the series "Wissenschaft und Hypothese," which contains translations of the first two of Poincaré's works quoted above, is admirably translated and provided with learned and excellent notes by Prof. F. Lindemann.

Finally, (4) is provided with a portrait of Poincaré, and the translation seems well done. The remark that the word "Anzahl" means the same thing as "Mächtigkeit" (p. 108) is wrong, and a title is wrongly spelt on p. 111. A somewhat serious mistake, which appears in the editor's note on p. 124, is the failure, like Schröder's, to distinguish between the notions "is contained in" and "is a member of."

ϕ.

NEW CHEMICAL BOOKS.

(1) *A First Book of Chemistry.* By W. A. Whitton. Pp. vi+150. (London: Macmillan and Co., Ltd.; New York: The Macmillan Co., 1914.) Price 1*s*. 6*d*.

(2) *An Introduction to the Study of Organic Chemistry.* By Dr. H. T. Clarke. Pp. viii+484. (London: Longmans, Green and Co., 1914.) Price 6*s*. 6*d*.

(3) *Methods of Quantitative Organic Analysis.* By P. C. R. Kingscott and R. S. G. Knight. Pp. xvi+283. (London: Longmans, Green and Co., 1914.) Price 6*s.* 6*d.* net.

(4) *Elementary Household Chemistry, an Introductory Text-book for Students of Home Economics.* By Prof. J. F. Snell. Pp. viii+307. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 5*s.* 6*d.* net.

(1) WE fancy that reviewers of a new book would generally appeal first to the preface to learn the object of its author in committing his ideas to print, then try to discover, especially in an elementary text-book, any originality in the method of treatment or arrangement, and finally read the descriptive part. Taking these points in reference to this little "first book of chemistry," it is interesting and satisfactory to learn that it follows no particular syllabus and so gives the author entire freedom in his method of treatment. Books on elementary chemistry are so numerous that there seems to be little room for novelty either in arrangement, description, or experimental illustration, and we have failed to discover anything intrinsically new; but such experiments as have been selected are simple and suggestive in character, and the illustrations which accompany them are unusually good. The treatment is essentially qualitative and non-theoretical. There is no attempt to impose on a student any immature notion of what chemical changes denote. He studies them in great variety and observes their results. He is troubled with no atomic theory, no symbols, and no equations. He learns a lot of hard experimental facts in the first fifteen chapters, and in the sixteenth and last he obtains a little glimpse into the quantitative relations of the reactions he has examined.

We can conceive of no better introduction to chemistry than this book provides.

(2) The volume has been written to cover the new syllabus of the Board of Education and possibly to meet the needs of candidates for medical examinations in organic chemistry.

In his preface the author points out that there are two distinct and incompatible systems of imparting a knowledge of organic chemistry by means of a text-book, one being based upon the theoretical, and the other on the practical, point of view. Why they are incompatible is not apparent; for every theoretical statement must be built upon an experimental foundation and, to be logical, a clear statement of the experimental part should either precede or at least accompany the theory. For the author, it should be added, assumes that the reader is entirely unfamiliar with the nature of organic substances. To illustrate the author's method, we may refer to the paragraph on page 2, that is, at the very commencement of the book, before any description of an organic substance is given. "Now it has been found that when methane is *treated* with chlorine in diffused daylight, a mixture is obtained of products which contain carbon, hydrogen, and chlorine, together with one which contains only carbon and chlorine. On separating these substances by *fractional distillation* and *analysing* [the italics are the reviewer's] them we find the composition of the various pure constituents may be expressed by the formulæ: CH_3Cl, CH_2Cl_2, $CHCl_3$, CCl_4."

Without inquiring too closely into how these four substances, one of which is a gas, can be separated by fractional distillation, or how the formulæ can be ascertained by an ordinary analysis, we would point out that the student is left quite in the dark as to the nature of any one of the three operations referred to.

Of the two incompatible systems, it seems preferable to the writer to attempt to memorise the description of a series of experiments, which he can understand and visualise, even if he has not the opportunty of performing them, than to learn by heart the mere names of operations which have not been explained and, in the present case, are incapable of giving the results suggested.

Supposing, however, that a practical course of instruction accompanied or preceded the perusal of this book, so that the student was able to realise the significance of the expressions "treat with" or "react with," which frequently recur, and the practical meaning of the series of equations which fill (without any description of the substances involved) the first eighty pages, the book, though overloaded with formulæ, should be of considerable help in acquiring a knowledge of the structure of a large number of groups of compounds and of equations representing fundamental reactions.

(3) This volume, which has been compiled with evident care by its authors, is of a sound, practical, and useful character, and should commend itself to chemists in general and to organic chemists in particular.

The information here collected is not always easy to obtain, unless the reader has had recourse to the German of Hans Meyer. So far as the writer can judge the methods described are well established and of considerable value.

If one criticism may be offered, it is that the

authors give few results of their own individual experience. Such intimate knowledge of detail, as the frequent repetition of an analytical method affords, is invaluable to those who have occasion to employ a new analytical process without previous experience, and adds enormously to the value of the description. For example, a knowledge of this kind would decide which of the three modifications of Zeisel's method here given is the most convenient and trustworthy, and so save the necessity of an elaborate account of all three.

Apart from this and as a compilation and accurate transcript of important methods and of references to original memoirs, the book is eminently useful, and is sure to find a secure place on the library shelves of most organic chemists.

(4) The author's object is to introduce the applications of chemistry to household affairs as early and as often as possible. This has been systematically carried through, yet one feels that the introduction of these household topics are in the nature of a concession to the title rather than an integral part of a scheme for teaching chemistry. The book begins, after the usual fashion, and with the usual doubtful success, by attempting to distinguish between a physical and chemical change. It then passes on to the elements, chemical notation, and the atomic theory, after which, by a curious reversal of the ordinary sequence, the law of definite proportion is discussed. Combustion is followed by an account of fuels, gas burners, and illuminants, and so forth, and about half-way through we come upon organic compounds, soaps, food stuffs, etc., whilst textile fibres, dyeing, and bleaching complete the final chapters.

The book, no doubt, represents an honest attempt to build on a theoretical foundation a superstructure of technical facts and problems more or less connected with our daily life; but this attempt within the limits of a small volume renders the superstructure top-heavy, and the result is that much of the information is superficial, the explanations frequently inadequate and confusing, by reason of their brevity, and the style essentially didactic. We would refer especially to the chapters on the atomic hypothesis, on ionisation, and on the organic radicals, which are mere statements of theory.

These defects are to some extent compensated by many well-chosen experiments and by the excellence of the "get up" of the book, which is embellished by numerous portraits. It should be added that the statements in small print under the portrait of John Mayow are incorrect.

J. B. C.

OUR BOOKSHELF.

Transactions of the Paisley Naturalists' Society. Vol. ii. Lists of Renfrewshire Plants, Macro-Lepidoptera, Fresh-water Fishes, Amphibians, Reptiles, Birds, Mammals, and other papers, with introductory notes by the editor, the Rev. C. A. Hall. Pp. xvi+120. (Paisley: A. Gardner, 1915.) Price 3*s*. 6*d*. net.

A WELCOME sign of the continued vigour of natural history interests throughout the country is the increasing number of regional surveys The last we saw—a few months ago—was from Bournemouth, and now we have one from Paisley. Some of these scientific guides have had their origin in visits of the British Association, others have been due to the enthusiasm of a single individual, and others, like the one before us, express the activity of a local society. The editor leads off with a useful introduction on Renfrewshire as a whole. It might well have been longer, but he tells the reader where to go for further information. In the list of plants by Mr. Daniel Ferguson, the stations have been deliberately omitted as it is one of the main objects of the society to guard the treasures of the county against extermination. Mr. Alexander M. Stewart deals with the Macro-Lepidoptera, Mr. Thomas Malloch with the birds, Mr. Malloch and the editor with mammals, and Mr. Duncan Smith with the fossils in the Paisley Museum. There are also lists of reptiles, amphibians, and fresh-water fishes. While we cannot regard the volume as more than the beginning of the kind of regional survey every county should aim at, we appreciate the industry and carefulness represented in the lists. For future editions we suggest that introduced forms such as the edible frog, the natterjack toad, and the grass snake should not be included in the ordinary list, however clearly it may be noted that they should not be there. With a multitude of names it is difficult to avoid misprints, and it is with sympathy that we call attention to Pel*ius* and Tropidon*atus* on one page. The classification of reptiles is new to us and strange. But these are trifles; the volume is a step in the right direction and a credit to those concerned. We wish for the Paisley Naturalists' Society, which this year attains its majority, a long and prosperous life.

Biology. By Prof. G. N. Calkins. Pp. viii+241. (New York: H. Holt and Co., n.d.) Price 1.75 dollars.

THIS introduction to general biology has a pleasing freshness, a quality difficult to attain in these days of many books. It has necessarily much in common with other good introductions, such as Parker's "Elementary Biology," but it is distinctive. It considers general biology as having to do with fundamental facts and principles—with protoplasm and vitality, metabolism, food and transformations of energy, organic architecture, inter-relations, the curve of life from development to senescence, and, finally, species and the factors

in evolution. These are the seven divisions of the book, which aims at providing a foundation suitable for the further study of one or more of the many branches.

Prof. Calkins has selected his material judiciously, and by exercising unusual restraint he has kept his introduction within appropriately small dimensions. His treatment is beautifully clear throughout and he drives his nails home. Only in a few cases, *e.g.* in the last chapter, is the treatment too short to be of great use to the ordinary student, who must always have a certain amount of solid concrete stuff to chew at. We have two or three other suggestions to make—though it is a little like trying to adorn the rose. We have a strong impression that general biology deals with the fundamental principles not of living matter, as the author insists, but of organisms. We do not admire the striking first figure in which Prof. Calkins makes general biology the centre of twelve sub-sciences, duplicated for plants and animals, for the arrangement of these does not appeal to us and we have grave doubts regarding the neurology of plants. There are a few typographical errors, which should be seen to: the function of the "sdnalgs" is immaterial, but Dalton instead of Galton (both in the text and the index) is awkward. These are pin-point blemishes on a work of great excellence, which is sure to be found very useful. Many of the new figures deserve great praise, *e.g.* the stereogram of the earthworm for its utility and the picture of Hydra for its beauty. J. A. T.

Farm Accounts. By C. S. Orwin. Pp. 209. (Cambridge University Press, 1914.) Price 3*s.* net.

As might be expected, Mr. Orwin has made this a very valuable book. Many works on book-keeping are arid and unconvincing because the transactions described are obviously artificial, but here we come into contact with the actual thing, and feel that the author is writing from large practical experience of farm accounts. The introduction demonstrates that the farmer is a manufacturer, not a merchant, so that his book-keeping should be conducted on the principle of tracing the cost of production right through to the time of sale. Farm valuations are then lucidly explained, and illustrated—as are all the other topics—"from actual accounts kept by tenant-farmers in various parts of Britain." The following chapter on farm records deals with manual and horse labour, foods and manures. Next comes a clear and detailed description of the way books ought to be kept, accounts closed, and the figures used for construction of a profit and loss account and balance sheet. The final chapter sets forth some of the conclusions and deductions that may be arrived at by study of the year's accounts. An index is appended.

The work is primarily intended for use in farm institutes, and should be well within the comprehension of full-time county council students in agriculture, though probably too difficult for short coursers, whose school education has often largely evaporated. The value of the book would be enhanced by the addition of exercises for class work. J. R. A.-D.

Who's Who, 1915. An Annual Biographical Dictionary, with which is incorporated "Men and Women of the Time." Pp. xxx+2376. (London: A. and C. Black, Ltd.) Price 15*s.* net.

We have again to note an increase in the size of this invaluable work of reference. The many excellent characteristics of this annual are familiar to all who take part in the world's activities; and it will be enough to remind readers of Nature that it contains biographies of distinguished men of science, including, for instance, the fellows of the Royal Society, and those occupying important professorial and professional positions in this and other countries.

Magnetism and Electricity, including the Principles of Electrical Measurements. By S. S. Richardson. Pp. ix+598. New and revised edition. (London: Blackie and Son, Ltd., 1914.) Price 4*s.* 6*d.*

The first edition of Mr. Richardson's book was reviewed in the issue of Nature for December 31, 1908 (vol. lxxix., p. 246), and a description of its chief characteristics was then given. The whole of the text of the new edition has been revised, several portions have been re-written, and a chapter on the principles underlying the action of dynamos and motors has been added.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. No notice is taken of anonymous communications.]

The Appley Bridge Meteorite.

In Nature of November 5, 1914, Mr. W. F. Denning gave an account of the meteorite of October 13, 1914, in which he mentions that the object had been found, and was then at the Godlee Observatory, Manchester.

The object which fell at Appley Bridge belongs to the aerolites or stony meteorites, and not to the siderites or irons. In appearance there is the striking meteoric features of deep thumb marks—piezoglyphs—and the general coating a dark brown to black. This was in distinct contrast to the interior, which was of a light grey colour. In general the figure gave one the impression of its being a segment of a spherical shell, the dimensions being:—

Length	... ...	9·65 in.
Depth	... ...	9·13 ,,
Width or thickness	...	6·62 ,,

The longest diagonal measurement gave 10·76 in.

When the aerolite reached the Godlee Observatory, it was in two pieces, weighing 28 lb. 13 oz., and showed evident signs that some considerable portions had been broken away since its discovery.

The very friable nature of the mass was such that portions could be readily broken off by the thumb and fingers, and it is to this softness of texture that its losses are due, as the weight at the time of discovery was given as more than 30 lb.

It is certainly a remarkable object, as on a comparison with the list of meteorites recorded in Great Britain, published in the British Museum Guide to Meteorites, there is only one given of greater weight, that fell at Wold Cottage in Yorkshire in 1795.

The outer coating, which varies from a very thin film to nearly 2 mm. in thickness, presents a very finely-pitted surface, with evidence of a tendency to show lines of movement, as though the heated skin was being pushed backwards from the direction of motion. The portions which had become fused showed a dark glazed or shiny surface, this evidently being the forward end, and the portion to which the heat from the compressed air in front of it was most effective. The appearance of the pittings suggest that the heating of the surface was the means of liberating some portions of the structure of the mass, and that these would provide what is seen as the trail of the meteor after it has passed in its flight through the air, being the continued glow of the heated emissions by combination with the oxygen in the air.

There is evidence that some portions of the surface had only come into contact with the air during the later portion of its traverse. These regions have all the appearance of flakes of the outer skin having been broken away, a slight tarnishing of the pyrites, if at a distance from the edge of the fracture or slight fusing when close to the general outer coating, indicating a removal of portions of outer layers of the mass.

Appley Bridge Aerolite, October 13, 1914.

This is quite in keeping with the assumption that the fragments were split off at the time of the apparent burst in the air, at about twenty miles' altitude, as from that position the speed of the meteor would be so much reduced by the compressional friction, that it would be losing more heat than gaining.

The fractured surface on an inspection appeared to be made up of a glittering mass of white and yellow points in a grey setting. These proved to be chiefly pyrites, and their presence accounted for the apparent great weight according to the size. The specific gravity of the mass determined from a fragment was 3·33, and is in accord with what would be expected from the mineralogical contents. A magnetic examination of the mass as a whole gave no appreciable effect, although a search amongst the dust which accumulated from the rubbing of the two pieces, indicated portions of magnetic nature though small in amount which proved to be metallic iron.

The pyritic material contains nickel as well as iron, portions being crystalline, the olivine being of a pale yellowish-green colour, whilst the enstatite is whitish or grey.

The proportions of the minerals worked out on the basis of the composition and solubility are approximately:—

Pyritic and metallic matter	5·07
Enstatite	31·5
Olivine	63·43

The analysis which has been made by Mr. E. L. Rhead indicate the presence of the following in order of amount:—

Silica	SiO_2	Phosphorus	P
Magnesia ...	MgO	Soda potash	
Iron...	Fe	Chlorine	
Alumina	Al_2O_3	Lime, etc.	
Sulphur	S	With oxygen in combination	
Nickel	Ni		

The accompanying illustration shows the front view of the aerolite with the thumb marks.

WILLIAM C. JENKINS.

A Suggested Definition of Magnetic "Permanence."

FROM time to time accounts appear of experiments on new kinds of steel which have been undertaken with the object of determining the most suitable material from which to construct a permanent magnet. Experiments of my own on this subject, made a good many years ago, led me to think that it would be an advantage if precision could be given to the term "permanence" in magnetism, and inasmuch as a high coercive force is the principal factor in the preservation of the magnetism in a magnet the measure of *permanence,* I think, might be taken as the *coercive force per unit of residual magnetic intensity*. Thus the inclination of the intensity-field curve as it falls from residual to zero intensity indicates what the permanence of the magnet may be expected to be.

According to this definition the permanence of soft iron is about 0·0024. Recent experiments by Miss Margaret Moir (*Phil. Mag.,* November, 1914) on chrome steel give the high permanence of 0·165, or, if the calculation is made from final residual magnetism after shocks and changes of temperature, of 0·201. These examples show a range of permanence from 0·0024 to 0·201, in the ratio of 1 to 84, but it is not unlikely that these limits may be exceeded.

J. R. ASHWORTH.

55 King Street South, Rochdale.

EUROPEAN AERODYNAMICAL LABORATORIES.[1]

IN the summer of 1913 Prof. Zahm and Lieutenant Hunsaker, of the United States, visited the European aerodynamical laboratories in order to study apparatus and methods in use, before finally deciding on the details of the material to be

[1] Report on European Aeronautical Laboratories. By Dr. A. F. Zahm. Smithsonian Miscellaneous Collections, vol. lxii., No. 3. (Washington: Smithsonian Institution, 1914.)

provided by laboratories in America. Prof. Zahm is the Recorder of the Langley Laboratory of the Smithsonian Institution, whilst Lieut. Hunsaker is connected with the School of Technology, Boston. Report No. 2273 is a critical study by Prof. Zahm of European apparatus and methods, but the detailed application of the criticism is still unknown

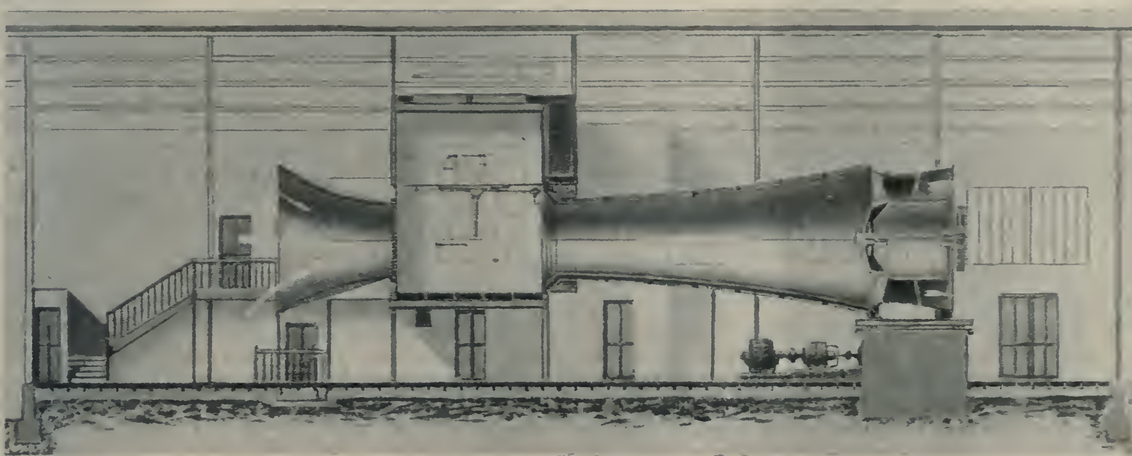

FIG. 1.—Longitudinal section of the large wind tunnel, Eiffel Aerodynamical Laboratory.

as the re-opening of the Langley Laboratory cannot yet be said to be effective.

The present position appears to be that a scheme of work has been submitted to an advisory board which advocates the provision of a wind tunnel and of facilities for large-scale experiments, and it appears to be intended that the work of the Lang-

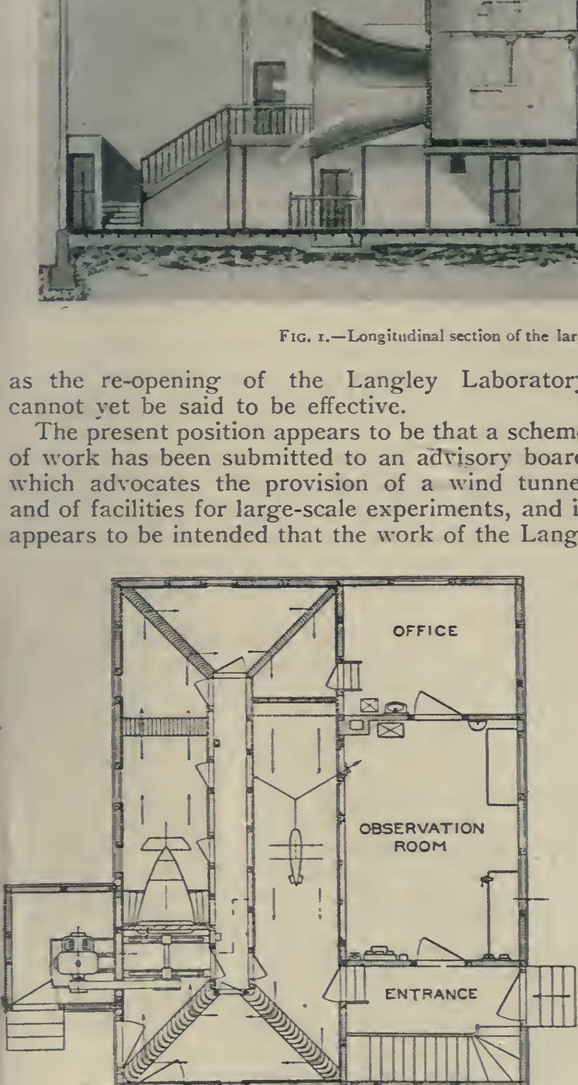

FIG. 2.—Göttingen Aerodynamical Laboratory.

ley Laboratory should be practically unlimited in its scope.

Lieut. Hunsaker is not directly represented in this report, but it is known that immediately on his return to America he proceeded to erect a four-foot wind tunnel similar to that at the National Physical Laboratory, the aerodynamic balance being made for him by the Cambridge Scientific Instrument Co. It is probable that the installation is now in working order in the Massachusetts Institute of Technology.

In his report Prof. Zahm gives brief descriptions of the wind tunnels in Paris, Göttingen, and London, and some of the illustrations in the report are reproduced in Figs. 1, 2, and 3. In M. Eiffel's apparatus the air current traverses the centre of a large room, and one of its advantages is the facility with which models can be moved into and out of the air current. It is further claimed by M. Eiffel that the absence of walls is an advantage in removing some constraint usual in wind tunnels.

In the Göttingen installation, Figs. 2 and 3, air

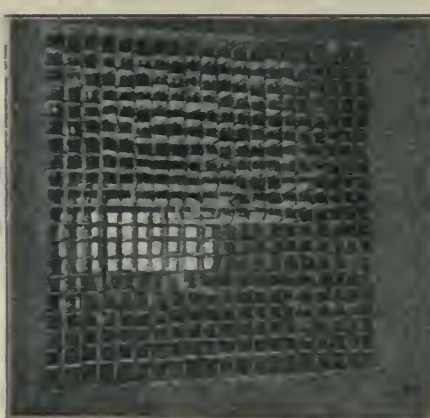

FIG. 3.—Prandtl's honeycomb in wind-tunnel.

is circulated horizontally through a tunnel containing four right-angle bends, and numerous guide-blades are necessary in order to produce a good distribution of velocity in the working section. Fig. 3 gives some indication of the amount of labour involved in the production of a satisfactory result, and for this reason the writer was informed by Prof. Prandtl that the design would not be followed in a new wind tunnel under consideration.

The wind channels at the National Physical Laboratory were recently described in NATURE, and little need be reproduced of Prof. Zahm's report. He describes the aerodynamic current as the steadiest in the world with limits of ½ per cent. in both time and space. The steadiness of the air-flow in the Eiffel apparatus is stated to be 2 per cent. in time and space.

Prof. Zahm claims priority for the use of bell-crank balances for aerodynamical work, and says that he is of opinion that several new types can be devised which shall be equally precise with those at the National Physical Laboratory, and probably more expeditious. Such new types have been in contemplation since first devising the bell-crank aerodynamic balance in 1902. It is therefore probable that the balance for the wind tunnel of the Langley Laboratory will be of the bell-crank type, but will differ in detail from those in use in Europe at the present time.

In reference to full-scale experiments, Prof. Zahm considers that the Royal Aircraft Factory most nearly approaches the organisation projected for large-scale work at the Langley Laboratory, though he excludes the possibility of manufacturing aircraft in considerable numbers. He considers the outcome of the large-scale experiments at the Royal Aircraft Factory to be the production of a stable, efficient, and safe biplane. Reports from the seat of war add strong support to this view.

A considerable amount of space in the report is devoted to a description of the apparatus for large-scale experiments at St. Cyr, near Paris, and the remark is made that the relative importance of such large-scale tests as can be carried out on moving carriages, as compared with model tests or full-scale flights with instruments mounted on the aeroplane, has yet to be determined. The difficulties of experiment are indicated by the statement that the lift measurements on simple lifting surfaces are 5 per cent. in error, whilst the resistance measurements are much less accurate.

It is interesting to note that at the time of the visit, no aerodynamical experiments had been made in Germany other than those at Göttingen, but that arrangements were almost completed for large-scale work at Adlershof, near Berlin. For further particulars reference should be made to the original report.

CHEMISTRY OF WHEAT AND FLOUR.

FEWER than ten years ago most millers and bakers would have scoffed at the idea of there being any connection between chemistry and wheat or flour, and even the man of science would have admitted that the application of chemistry to such problems as the cereals presented was in its earliest infancy. Progress, however, has come rapidly and not only is the actual knowledge in the field now very considerable, but it has been already of the utmost value when applied in practice, so that scientific milling as well as scientific baking have made great strides.

It is safe to forecast that chemistry is destined to play as important a part in the manufacture of flour in the future as mechanical science has done in the past, and it is satisfactory to note that there is every indication that Britain is more than prepared to hold her own in this development.

Flour is primarily a starchy material, but those characteristic properties which enable it to be made into bread are due almost entirely to the presence of some 10 per cent. of nitrogenous material—the gluten. Consequently, from the point of view of the miller and the baker, gluten is the all-important constituent of flour. Somewhat irrationally gluten has come to be regarded as such also by the would-be food expert, who overlooks the fact that bread is eaten primarily, not as a source of protein, but as an easily digestible, attractive form of starch. The man in the street properly regards bread as equivalent to rice, potatoes, or the like, rather than as a substitute for meat; it is, therefore, not surprising that the would-be agitators have failed.

Gluten, which is readily obtained from a piece of dough by washing and kneading it in a stream of water until the starch has been removed, is a light brown material which has considerable elasticity.

From the chemical aspect, gluten is a mixture of several proteins, of which two only are of importance so far as its bread-making properties are concerned. These are named gliadin and glutenin, and they are apparently chemical entities so far as this description can be applied to any protein. Gluten is characterised by the properties of ductility and tenacity so that in dough it can entangle air in its cavities, which swell during fermentation and still more when heat is applied.

Wheat grown in different parts of the world is far from being always the same nor does the flour derived from it give the same type of bread. It has long been known that certain types of flour give a large, well-aerated loaf, generally white in colour, and very palatable, whereas other types give a small loaf which is close in texture, dull in colour, and of a stodgy character. Such flours are distinguished as strong and weak and are valued with a difference of several shillings a sack in their price. It has been attempted to express this difference between strong and weak wheats by analysis, and from time to time strength has been correlated with high nitrogen content or, what amounts to the same, a high percentage of gluten, or again to a certain ratio of glutenin to gliadin. Though there is a rough parallelism between strength and these factors, it is in no case absolute, so that no one of them could be said to be the cause of strength. Indeed, the solution of the question has been found in quite another direction.

Gluten prepared from the strongest flour, when carefully cleaned by repeated washing in distilled water, loses its properties; it has neither ductility nor tenacity and partly dissolves in the water.

It acquires these properties again directly small quantities of electrolytes are present, and it is argued, therefore, that the physical properties of gluten are largely controlled by the presence of salts. The analytical study of strong and weak flours, made by Prof. Wood, in following this clue, indicated that the former contained a larger proportion of phosphates: this gave the stimulus to Mr. A. E. Humphries—a practical miller—to try the addition of an extract of phosphates from bran to a weak flour, and when this addition proved advantageous in increasing the strength, the effect of adding small quantities of pure phosphoric acid was tried in its turn. A great deal of painstaking research has been necessary for the elaboration of the new technique of improving flour, and it is now commercially possible to impart the qualities of strength to a weak flour, so that it works better in the dough, has an increased water absorption, and gives a larger loaf of lighter texture, which is more easily digested than when untreated. One result of the treatment, which is of the highest national importance, is that it enables a larger proportion of English wheat to be used in the bread mixture. Notwithstanding all that is said by food reformers and agitators in the daily Press, the public do demand a certain degree of lightness and texture in their daily bread, for which the presence of a considerable proportion of strong foreign wheat in the mixture is essential. This is especially the case in the large manufacturing towns in the North: any sceptic as to the difference can easily make the experiment of comparing the bread from two kinds of flour at his own table.

English wheats as a class yield weak flours, characterised by their excellent flavour. Since they can only be used by the baker to a limited extent they fetch a correspondingly lower price on the market, and to-day are very largely used for household purposes where strength does not matter. The possibility of using a considerably increased percentage of home-grown wheat in the bread mixture is bound to have a favourable effect on the price, the more so as the small country miller can make use of the local supplies near at hand and will be much less dependent on the supplies of foreign wheat, on which he has to pay freight from the ports of entry where the large milling concerns, with which he is in competition, are usually situated. Chemical science has thus rendered a service which promises to be of the utmost importance to the farmer and the country miller.

It is, of course, necessary that a close control should be exercised over the materials allowed to be used as improvers, and nothing but the spraying with soluble electrolytes in minute quantities should be allowed, anything in the nature of loading the flour being strictly prohibited. There is still much prejudice to be overcome against any scientific treatment of wheat, although the baker is allowed free latitude to make the best possible looking loaf from the flour available —an obviously irrational position.

Returning to the scientific aspect of the difference between strong and weak flours, it would appear to be yet another instance of those elusive problems in the chemistry of organic colloids such as are concerned in most physiological problems and most of all in that of life itself. The state of aggregation of the colloid and its susceptibility to this and that alteration, owing to the presence of electrolytes of acidic or basic character, as manifested by changes in the physical properties is a general problem which is engaging the attention of many workers. In the case of flour, sufficient has been done to enable great advances to be made on the purely utilitarian side, though their theoretical explanation may be still veiled in obscurity.

Although strength in flour has been traced as due to the state of the colloid protein brought about by the presence of a certain proportion of electrolytes, our knowledge is still too indefinite to enable the farmer to produce a strong wheat by appropriate manurial treatment. The Cambridge School of Plant Breeders has offered good evidence that strength is a factor in the Mendelian sense, and it is considered possible by appropriate selection to obtain a wheat suitable for English soils which will combine strength with the equally important factors of yield and good straw. The efforts of the Home-grown Wheat Committee to encourage the growth of strong wheats in this country have met with only partial success, because, as a rule, strong wheats give poor yields and inferior straw. Much further research is necessary, which can only be done effectively at agricultural stations, such as Rothamsted, or by the agricultural departments of the universities. The composition of the flour is due to the state of maturation of the wheat berry at the time of harvesting, and it will be valuable to know the strength of the wheats produced on the individual plots at Rothamsted with different manurial treatment.

However, as shown above, the short cut which the miller is able to take renders him much more independent of the nature of his wheat supply, and it is probable in consequence that the considerable difference in price between strong and weak wheats will disappear to a large extent in the near future, so that the incentive to the farmer to grow strong wheats in this country will disappear. That they can be grown has been proved.

E. F. ARMSTRONG.

THE FOOD OF BRITISH WILD BIRDS.

SCIENTIFIC investigations concerning the economic importance of our British wild birds are of comparatively recent date, so that at present the sum total of our knowledge is only limited. To arrive at the precise economic value of each of our commoner species is a task of no mean magnitude, and yet it is slowly but surely being forced upon the minds of all thinking people who are concerned with the produce of the land

and of our fisheries, that such work is more and more becoming a necessity and one also fraught with great possibilities. So clearly has this been recognised by other countries that special State officers devote the whole of their time to the elucidation of the various problems in connection with economic ornithology. If a particular species confers greater benefits than injuries, and we are not affording it all the protection possible, we are pursuing a downgrade and very dangerous course, which cannot fail but produce direct injury to the State.

The subject is a complex one, approachable from many sides, and any investigations, to be of real value, must entail a large amount of careful and detailed work extending over some considerable period of time. The mere cataloguing of the crop or stomach contents of a limited number of specimens of any species, obtained at a particular period from one locality is really of very little value. As the writer has elsewhere stated,[1] "In order to arrive at a proper understanding of the food of any particular species, it is necessary to examine the food contents found in the intestinal tract during the different seasons of the year and from various districts. Further, careful observations must be made in the field, and of the nature of the food brought to the nest by the parents during the breeding season, and also of the fæcal contents extruded from the nest."

We now know that many of the earlier records are either only partially correct or will scarcely bear the interpretation put upon them by their respective authors, for two most important factors have been overlooked, viz., the rate of digestion, and the intestinal food contents found beyond the region of the gizzard. The rate of digestion, according to experiments at present in hand, would seem to vary in different groups of birds; as yet but little work has been done in this interesting field, a more accurate knowledge of which must largely alter our ideas of the various statistical tables which have been given for different species.

Under certain conditions, *e.g.*, during dry summers,[2] a much larger percentage of weed seeds pass through the intestinal canal uninjured, due to the fact that under such climatic conditions a much smaller percentage of grit and soil is taken into the intestinal canal. Thus, observations made upon the grit and soil content in the gizzard of thirty-six rooks during the dry summer of 1911 (June to September) showed that the average content was 108 grains, of which not more than one-sixth was grit, whereas in the same number of birds examined during the wet summer of 1912, the average amount was 214 grains, of which nearly one-third was grit. Similar investigations carried out on the starling and house-sparrow gave an average, in 1911, of 42 and 27½ grains respectively, as against 68 and 53 grains in 1912.

In the past it has been all too readily assumed that those species that feed upon insects and upon weed seeds must be beneficial. We now know that no hard and fast line can be drawn: much careful and extended work is necessary on each individual species before it can be definitely stated that a species is injurious or beneficial.

To the farmer and fruit grower such information is of the greatest import, for at the present moment they suffer enormous annual losses due to certain species of birds.

Of the majority of species of British wild birds, it is generally agreed that they are beneficial, of the remainder the present writer has elsewhere stated that: "Many species which are injurious at one season of the year are distinctly beneficial for the remainder. Again, many birds that are beneficial, may, if allowed unduly to increase, become equally injurious. In other cases the partial failure of their natural food supply, or other causes, may lead to a change in their food habits, in a like manner, the alteration or removal of their natural environment may lead to equally disastrous results."

Although in some districts farmers and others are loud in their complaints of the injuries inflicted, any policy of wholesale destruction would, we believe, be equally disastrous. In nearly all cases, "the misdeeds of birds are much more manifest than the benefits they confer upon us."

With the exception of doves and pigeons, practically all birds feed their young upon an animal diet, whatever the nature of the food of the adult may be, and the bulk of the food consists of insects. These are destroyed just when they are capable of inflicting the greatest possible harm upon our crops and orchards. Further, during the nestling season, the young birds require an enormous amount of food; feeding commences before sunrise and continues after sunset. The starling is known to pay nearly 200 visits to the nest a day, and in the case of the house-sparrow, between 220 and 260 visits daily have been counted. In any attempt, therefore, to estimate the value or economic status of a species, the nature of the food of the nestlings must be taken into consideration.

A careful investigation extending over a period of ten years, entailing an examination of the stomach contents of upwards of 4000 adult birds and 600 nestlings, and numerous observations in the field and laboratory shows that we can classify the commoner species under five headings, viz.:—

1. *Distinctly injurious.*—House-sparrow, bullfinch, sparrow-hawk, wood-pigeon, and stock-dove.

2. *Too plentiful, and consequently injurious.*—Missel thrush, blackbird, greenfinch, chaffinch, starling, and rook.

3. *Injurious, but not plentiful.*—Blackcap.

4. *Neutral.*—Jay.

5. *Beneficial.*—Song thrush, fieldfare, white-throat, great tit, blue tit, wren, goldfinch, linnet, yellow bunting, magpie, jackdaw, skylark, barn owl, brown owl, kestrel, and plover.

The so-called "avian rat," the ubiquitous house

1 "The Food of Some British Wild Birds," 1913, p. 7.
2 *Journ. Econ. Biology*, 1914, vol. ix., p. 69.

sparrow, has probably received more attention from naturalists than any other wild bird, but in spite of all the deprecatory language that has been applied to it, this bird has its redeeming features. It has been allowed to increase to such an extent that it has become one of the worst bird pests we have.

In the writer's investigations upon this species, commenced in the early part of 1910 and completed in May, 1914, 404 adult birds were examined and 329 nestlings. Of the former, 207 were shot in or near orchards, 138 in agricultural districts, and 59 in suburban districts. The stomach contents of the birds from the fruit-growing districts showed that the bulk of the food consisted of the caterpillars of injurious insects and weed seeds; in only twenty-three cases were the remains of blossom buds discovered, and in twenty-seven cases wheat grains. There is only one conclusion that we can come to as regards this record, viz., that this much maligned bird is distinctly beneficial in such districts. Unfortunately when we examine the record of 138 specimens from agricultural districts, we find a very different result. Remains of insects occurred on only twelve occasions, whereas wheat grains were found on 115, and the remains of other grains 43 times. The 59 specimens from suburban districts showed a very mixed diet. The stomach contents of the 329 nestlings consisted almost entirely of insect remains.[3]

From the above somewhat exhaustive record it would seem clear that in all agricultural districts sparrows should be given no quarter, whilst in fruit-growing districts and towns they are far too plentiful.

Undoubtedly the worst bird pest the farmer has to contend with is the wood pigeon. Gilmour[4] examined the stomach contents of 265 birds, and stated of the results: "There is no uncertainty, no dubiety about the meaning here: the figures, as given by himself, condemn, and we cannot but convict." The writer examined 388 birds and concluded that there were no extenuating circumstances that would lead him to alter an opinion formed many years back, that no quarter should be shown to it, and that every means should be taken to destroy it.

It frequently happens that when a particular species of bird becomes too plentiful, it changes its food habits, and this, to a large extent, is what has happened in the case of the birds scheduled under this heading. The missel thrush and blackbird have increased enormously in recent years and both have become serious pests to fruit-growers. The damage occasioned by the greenfinch and chaffinch is chiefly to newly sown seed and sprouting corn; both species are too numerous. Each year we hear more and more of the damage done by the starling and the rook. During the past ten or twelve years the former species has greatly increased; such increase being largely due to migration and to the protection afforded wild birds generally. At present it commits a large amount of damage, but if it were considerably reduced in numbers, it would prove, as in the past, a most useful bird.

Numerous investigations on the food of the rook have been carried out, and all have shown that the species is too numerous and consequently injurious. Gilmour[5] examined the stomach contents of 355 birds, Florence[6] 162, Thring[7] 141, and the writer[8] 689.

One regrets to have to condemn such a pretty little summer visitant as the blackcap, but careful observations, extending over eight or nine years, proves that it commits grave havoc in the orchard, and further, it has considerably increased in numbers during this period. Owing to the persecution of the gamekeeper, the jay is, in many districts, annually becoming rarer. Where it is at all plentiful, it undoubtedly steals the pheasant food and the eggs of game birds; it also bites pieces out of rosy-cheeked apples and strips the pods of peas, but it destroys blackbirds and mice, and consumes large quantities of injurious insects and slugs.

In connection with all the species mentioned as beneficial, we should like to see more stringent laws for their protection. It is ridiculous fining the schoolboy for taking a few eggs and allowing the dealer and bird catcher to defy the law.

There is no longer any doubt as to the great value of the barn owl and the brown or tawny owl to the agriculturist, and yet they are destroyed wholesale by gamekeepers and others. Or take the case of the plover. It would be difficult to exaggerate the value of this bird to the farmer. The good it does cannot be over-estimated, and yet the farmers of this country are annually watching its gradual reduction with indifference.

Many species of birds, that otherwise are beneficial, are active agents in the dispersal of weed seeds. In some species the seeds are ground up in their muscular gizzards, but in others this action is so slight that many of the seeds pass through the body uninjured. Thus, such birds as the blackbird, thrush, house sparrow, bullfinch, and greenfinch are now known to be great distributors of weed seeds, and such must be taken into consideration in any attempt rightly to fix their economic status.

Space forbids any reference to such matters as the status of game and sea birds, or the subject of legislation and other means of protecting wild birds, but enough has been said to show how wide is the range of investigation in this important subject. Unfortunately, none of our universities have chairs or departments of economic ornithology, nor is there any adequate aid being offered to the investigator by the State. In common with most scientific investigations, those concerning economic ornithology entail considerable time and expense, frequently beyond the means of the private individual, to whom the

[8] *Ibid.*

work has, thus far, been very largely left. With some State recognition very important results would accrue which would prove of value to agriculture and the fisheries.

WALTER E. COLLINGE.

ATTEMPTS TO MANUFACTURE SCIENTIFIC DISCOVERY.

IN an excellent article forming one of his admirable series of essays entitled "Science from an Easy-chair," published in the *Daily Telegraph* of December 15, 1914, Sir Ray Lankester deals particularly with the case of the recent proposal that the Lister Institute should be handed over to the Medical Research Committee of the National Insurance Commission. The proposal was rejected on November 18 by the votes of the members; and Sir Ray Lankester preaches a useful sermon upon this text. He maintains that men of science "have no confidence in vague invocations of 'centralisation' and 'co-ordination'—abstractions with which Lord Moulton endeavoured to allure them. They do not wish to see the Institute placed at the disposal of centralisers and co-ordinators. The men they desire to maintain in undisturbed control of the Lister Institute are of a totally different class, namely, the rare individuals known as 'scientific discoverers'—a variety of humanity impossible to drive or to co-ordinate, inevitably paralysed by official programmes and stultified by ignorant though well-meaning superintendance." He continues:—

There is a widespread but erroneous belief in official circles, and among wealthy philanthropists, to the effect that you can hire a scientific discoverer and then say to him, "Discover me this" or "Discover me that" (naming to him a possible and greatly desired piece of new knowledge), and that he will thereupon proceed right away to make the discovery which you want. . . . But valuable and important scientific discovery cannot be produced directly in response to orders given and money expended. You cannot manufacture scientific discovery like soap. The great difficulty, in the first place, is to catch that rare and evasive creature—a scientific discoverer—and when you have found him you have to humour him and let him do as he fancies. Then he will discover things, but probably not the things which either you or he wanted or expected.

All this is very true, and I for one entirely agree. But I think that we should distinguish between *major discovery* and *minor research*. To be frank, the former has been made almost entirely by amateurs, or at least by men who were amateurs when they started; and such discoveries are somewhat rare and depend upon the production by nature of a peculiar and equally rare type of mind. Thus history shows that there are vast nations, consisting of hundreds of millions of people, who never make a scientific discovery from century to century; while, on the other hand, small peoples who appear to be in some favourable biological condition, turn out major discoveries by the score. To me it has always seemed that major discovery is a kind of efflorescence of the human race, occurring only for a brief period in the life of a people. But minor discovery, or rather research, is of another order. It is not of the epoch-making type of major discovery, but is still useful and must not be depreciated. In the present day, when science has advanced so much, this second class of research becomes absolutely necessary for the purpose of filling in the innumerable petty details which go to complete a great scientific theorem; and the difference of opinion which certainly exists regarding the best method of encouraging discovery depends chiefly upon a failure to make this distinction. Thus, when some of us talk of research, they refer only to major discovery, while others refer only to the minor work.

My own opinion is that both should be clearly recognised. The best way to encourage major discoveries is to remove difficulties as much as possible from the path of the unique individuals who make them; and that is why I have always advocated a proper State recognition of such work. On the other hand, minor researches do require a certain amount of organisation—though, even here, great care must be taken not to interfere by too much direction from above; and the question is what kind of organisation is the best. At any rate, most men of science will agree with Sir Ray Lankester when he records a note of objection to "the existence of a Board of Trustees with a Managing Committee, or of any committee playing the part of employers and proprietors towards the men of science who are heads of laboratories in an institution designed for scientific discovery."

Personally, I think that our British notion of constructing such committees chiefly out of "superannuated politicians, retired civil servants, lawyers, medical men, peers, and clerical dignitaries, as well as men who have made fortunes and retired from business," is quite foolish, and indeed improper. But we seem to pursue this habit in nearly everything—the argument being apparently that the men who know nothing about a subject are the best to direct efforts in connection with that subject; so that we appoint lawyers to be heads not only of scientific and learned institutions, but even of the War Office and the Exchequer. In my own humble opinion, lawyers would be much better employed in revising or reforming the mass of confusion (as they themselves admit it is) called law. I do not object to lawyers more than to other amateurs being placed in such positions; but the point is whether research institutions should not be put exclusively under the management of men who have proved their capacity for research by success in it—and only under such. The existing British custom has an unpleasant savour of secret wire-pulling and other methods of acquiring "influence." It would be quite useful, were it possible, to analyse the committees of our few research institutions; but the time has come when men of science should begin to look into all these matters a little more closely than they have done in the past.

RONALD ROSS.

NOTES.

THE Royal Society is represented in the New Year's Honours List by Dr. J. J. Dobbie, principal of the Government Laboratories, and Dr. F. W. Dyson, Astronomer Royal, each of whom has received the honour of Knighthood. Sir William MacGregor, G.C.M.G., who retired recently from the Governorship of Queensland, and whose scientific work is well known to geographers and anthropologists, has been made a Privy Councillor. Prof. J. Marnoch, regius professor of surgery, Aberdeen University, has been appointed a commander of the Royal Victorian Order (C.V.O.). Dr. J. H. Marshall, director-general of archæology in India, is among the new knights in the Indian list; while Major S. R. Christophers, officer in charge of the Malarial Bureau of the Central Research Institute, Kasauli, and Mr. Montague Hill, Chief Conservator of Forests, Central Provinces, have been appointed Companions of the Order of the Indian Empire (C.I.E.). Dr. C. A. Bentley, special officer under the Sanitary Commissioner, Bengal, has been awarded the Kaisar-i-Hind medal for public service in India.

IT is highly gratifying to be able to record that the board of trustees of the University of Illinois has given the sum of five hundred dollars to the fund inaugurated for the purpose of erecting a laboratory at Rothamsted in commemoration of the centenary of the birth of Lawes in 1814 and of Gilbert in 1817. There has always been a great community of interest between the agricultural experiment stations in the United States and those in this country, and in few branches of science is there better organisation for ensuring that results obtained at any one institution shall be known at the others. Having regard to the fact that the University of Illinois includes such distinguished agricultural investigators as Dean Davenport, Prof. Cyril Hopkins, and others of wide repute, the British workers have reason to be pleased with this practical recognition of the value of the Rothamsted investigations. Although the war has automatically put an end to all attempts to collect money, the fund is now so far complete that only 100*l*. is wanted to make up the 12,000*l*. necessary to build and equip the new laboratory.

MR. FRANCIS H. CARR, who for sixteen years was chief of the chemical manufacturing operations of Messrs. Burroughs Wellcome and Co., at Dartford, has been appointed to Boots Pure Drug Co., Ltd., Nottingham, with a seat on the board of directors.

WE regret to see the announcement of the death, at seventy-one years of age, of Lieut.-Col. D. D. Cunningham, F.R.S., honorary physician to the King, and formerly professor of physiology in the Medical College, Calcutta.

NEWS has been received of the following French geologists and palæontologists:—Jean Boussac, wounded in the foot; Jean Cottreau, in a territorial regiment at Creuzot, well; Robert Douvillé and G. Groth, either killed or wounded; Marius Filliozat, paymaster attached to the Fourth Army Corps, well.

WE learn from the *Scientific American* that the American Society of Mechanical Engineers, New York, has awarded the John Frick medal to Prof. J. E. Sweet, honorary member and past president of the society, "for his achievements in machine design and for his pioneer work in applying sound engineering principles to the construction of the high-speed steam engine."

THE death is reported, in his sixty-sixth year, of Dr. Albert Charles Peale, who was a geologist in the U.S. Geological Survey from 1883 to 1898. He had since been employed in the section of palæobotany in the U.S. National Museum. In addition to contributions to scientific reports, Dr. Peale's published work consisted mainly of volumes on the mineral springs of the United States.

WITH the death of Mr. Thomas Bryant, on December 30, there has disappeared the last of the leading British surgeons of the Victorian period. Although in his eighty-seventh year, he still retained the erect carriage and mental vigour of his younger days. When he commenced the study of medicine at Guy's Hospital in 1846, Lister was already in his second year at University College, and the "cell-doctrine" was still in its infancy. Bryant was eminently a practical surgeon, applying himself to the various problems which confronted the surgical leaders of his time. He opened up no new field of surgical endeavour, but he brought an inquiring mind and an industrious pen to help in the general progress of his art. He retired from the surgical staff of Guy's Hospital in 1888, delivered the Hunterian oration in 1893 (having H.M. King Edward VII. in his audience), and served as president of the Royal College of Surgeons of England from 1896 to 1899.

THE death is announced of Mr. Henry William Manly, actuary of the Equitable Life Assurance Society, and a distinguished member of the actuarial profession. He completed his third year's examination as an associate of the Institute of Actuaries as long ago as 1867, when he was on the actuarial staff of the London and Provincial Law Assurance Society. He became in due course a fellow, served for several years as one of the honorary secretaries, was elected vice-president, and ultimately became president of the institute in its jubilee year. In all these capacities he took a leading part in its work, contributing many papers to its journal. He was also a prominent member of the International Actuarial Congresses, being the treasurer and secretary for home correspondence of that held in London in 1898. He made the intricate subject of superannuation allowances one of his special studies, and was for that reason consulted by the Royal Commission on Civil Service Superannuation, of which Lord Courtney of Penwith was chairman. It was under Mr. Manly's advice that the new and liberal system of combining life insurance and the provision of a capital sum with the allowance for old age was finally adopted.

WE regret to see that one of the pioneers of the Indian Forest Service has just passed away in his seventy-sixth year—Col. J. C. Doveton, of the Madras

Staff Corps, one of the band of military officers selected in the early years of the Department to start work in various provinces. Readers of Capt. Forsyth's charming book, now somewhat forgotten, the "Highlands of Central India," will remember that it was in 1861 that the Central Provinces became a Chief Commissionership under Sir Richard Temple, who took great interest in forestry, so that almost at once he procured the services of Capt. (now Col.) G. F. Pearson as conservator, with Capt. Forsyth and others as assistants. In 1864 they were joined by Doveton, who, on Pearson's transfer, became the conservator, and remained such until his retirement from the service in 1896. During these thirty-two years he devoted himself to the selection and demarcation of forests for permanent reservation and careful management, he studied the welfare not only of the agricultural people, but also of the half-civilised jungle tribes who lived in and near the forests, and he endeavoured to introduce systems of working suitable for supplying the huge amount of small timber and fuel required by the people, and the timbers of better quality wanted for building and railway works. His paper on the growth and cultivation of bamboo in vol. ix. of the *Indian Forester* is still one of the best on the subject. He was a good sportsman, and had a great knowledge of the wild life in the forests, the "atmosphere" of which is now so well known from the wonderful pictures of it in the "Jungle Book."

AT the instance of Mr. H. S. Wellcome, the founder of the Wellcome Bureau of Scientific Research, an Ambulance Construction Commission has been inaugurated to consider the improvement of motor ambulances and the standardisation of patterns. The list of members of the commission includes, among other well-known names, those of Sir Frederick Treves, Bart., Sir John Cowans, K.C.B., Sir Arthur May, K.C.B., Sir Alfred Keogh, K.C.B., Sir Claude Macdonald, K.C.B., and Prof. W. E. Dalby. The commission will in the first place act as a judging committee for the award of prizes of the value of 2000*l*. provided by the Wellcome Bureau of Scientific Research. These prizes are offered for the best designs of an ambulance-body which shall fit a standard pattern motor chassis for field motor-ambulances. The last day for the receipt of competing designs is June 30, 1915. It is anticipated that the competition will bring in a number of ingenious designs, from which the ideal field ambulance-body will be evolved. It is hoped that the information obtained by the competition will be published in a permanent form, available for future reference. The first prize is of one thousand pounds, the second of five hundred, and the third of three hundred pounds. All details of conditions may be obtained from the secretary, the Ambulance Construction Commission, 10 Henrietta Street, Cavendish Square, London, W. The competition is open to citizens of all nations.

RECORD rains for December were registered in London and at other places in the south and south-east of England. At Norwood the aggregate for the month was 6·74 in., the measurement being in strict agreement with the ordinary rules. The Meteorological Office record at South Kensington is said to be 6·60 in., at the Royal Botanic Society's Gardens, Regent's Park, 6·45 in., at Camden Square, 6·34 in., in the City, at Holborn Viaduct, 5·95 in., and at Wandsworth Common, 5·4 in. At Brighton and Torquay the rainfall is reported to have measured more than 9 in., and at Bournemouth 9·8 in. The wettest December previously, according to the Greenwich returns for the past 100 years, is 5·76 in. in 1876, and there are only five instances of 6 in. or more in any month at any period of the year. These abnormal falls are 1828, July, 6·43 in.; 1852, November, 6·00 in.; 1880, October, 7·65 in.; 1888, July, 6·75 in.; and 1903, June, 6·07 in. It will be seen that the rainfall, 6·75 in. in July, 1888, is similar to the amount measured last month in Norwood, and the only monthly fall actually to surpass it is 7·65 in. in October, 1880. The opening days of January have been equally wet, and generally over the metropolitan area the rainfall for the first three days of the month amounts to fully an inch, which is one-half of the usual normal fall for January. It is almost needless to say that these excessive rains are occasioning serious floods in the Thames Valley and over a large part of the country.

IN *Bulletins et Mémoires de la Société d'Anthropologie*, Paris, No. 1 for 1914, M. J. Castagné describes a series of stone monuments in Ferghana. They seem usually to take the form of cairns, and the writer is inclined to believe that they were ossuaries in which the ancient inhabitants of the mountains of Ferghana used to deposit the bones of their dead, already picked clean by dogs or other animals, as was the custom in Sogdiana up to the beginning of the seventh century.

THE seventh annual report for 1913–14 of the governors of the National Museum of Wales is a record of steady progress. The south block of the new building is under construction at a cost of about 66,000*l*., and a welcome donation has enabled the governors to proceed with the erection of two additional galleries. Arrangements have been made for the decoration of the building with a series of appropriate sculptures. Though the present is not a good time for an appeal for public support, the governors are naturally desirous of securing funds for the completion of the building. Meanwhile numerous donations of valuable specimens have been made, and it may be hoped that the public spirit of Welshmen, aided by grants from the Treasury, will enable the governors to complete this important building, and to arrange for the display of the valuable collections already in their possession.

MR. ZAE NORTHRUP describes a bacterial disease of the "white grub," or larva of the May or June beetle (*Lachnosterna*, spp.). The organism is a micrococcus which can be isolated and cultivated, and the suggestion is made that it might be employed for the destruction of this larva, which causes considerable depredations among the crops (Technical Bull., No. 18, 1914, Michigan Agricultural College Experiment Station).

TO *Naturen* for December, 1914, Dr. A. W. Brögger contributes an illustrated article on certain swords,

lance-heads, etc., recently discovered at Haldalsnosi, Hallingdal, and other Norwegian localities, and now exhibited in the Bergen Museum. Six of these weapons are shown in the illustrations to the article.

In the report of the Clifton College Scientific Society for 1913–14 the want of interest taken on the part of members in the geological class, which had absolutely no supporters, is deplored, as is also the lack of any entries of essays or collections for the Joshua Saunders prize during 1914. The museum is undergoing rearrangement.

In the *Times* of December 30 appeared an announcement that the London Museum possesses a tooth of a mastodon recently found in the neighbourhood of Southwark. If trustworthy, such a statement would be of great interest, seeing that, with the exception of certain specimens alleged to have come from a Derbyshire cave, mastodon remains are known in this country only from the East Anglian crags. As stated in a letter in the *Times* of January 5, if really found near Southwark, the London Museum specimen must almost certainly be a mammoth's tooth.

In concluding his experiences of the notes of tropical birds in *Bird-Lore* for November and December, 1914, Mr. L. A. Fuertes takes occasion to record his impressions of the voice of howling-monkeys. After stating that it is not really "howling," according to his conception of that term, he observes that the cry is a hundredfold more "thunderous" and terrible than an animal not much bigger than a large cat could be imagined capable of emitting. Although the party under observation comprised only a male and a female and two half-grown young, "the terrible noise, that issued principally from the throat of the old male, seemed to make the atmosphere quake. . . . The noise was a deep, throaty, bass roar . . . fully as loud as the full-throated roaring of lions."

In an article in *La Nacion* (Buenos Aires) of Sunday, November 22, 1914, claim is made to the discovery of definite proof of the existence of man in South America during the Miocene epoch. The claim is based on the discovery by Señor Carlos Ameghino, in a deposit in the Chapalmalal stream, on the Atlantic coast of the province of Buenos Aires, of a femur of an ancestral member of that group of ungulate mammals typified by the genus Toxodon of the Pampean, in the shaft of which is embedded part of what is regarded as a flint arrow-head. According to a figure given in the article, this presumed arrow-head is broken short off at the level of the surface of the bone; but no explanation is offered how such a feeble weapon could have penetrated the solid shaft of a bone of the type of a toxodont femur. Other traces of the presence of man are stated to have been obtained from the Chapalmalal beds, which are regarded as immeasurably older than the Pampean formation, in which occurs the so-called "*Homo pampaeus*," and if we accept the views of Señor Ameghino with regard to the embedded arrow-head, it must apparently be admitted that a human being acquainted with fire, and capable of making bows and arrows, lived with the extinct Chapalmalal fauna. Even so, however, this is very far from affording proof that man, in common with the rest of the fauna, was of Miocene age, and in existence prior to the union of South with North America.

A useful contribution to ecological botany is made in the Transactions of the Botanical Society of Edinburgh (vol. xxvi., part iii.), where Miss Lamont gives an account of the ecology of the family estate of Knockdow, Argyllshire. The area of some 6000 acres is largely uncultivated land, and lies mainly on the metamorphic rocks; its overlying soil is peat, and with a flora typical of the western Highlands. On the portion of the area lying on the Old Red Sandstone a slight change in the flora is noticeable, *Galium verum*, *Ononis spinosa*, and *Linaria vulgaris*, for instance, only being found on the Old Red.

The longevity of seeds is a subject on which specific information is always desirable, and the paper by G. H. Shull, on the longevity of submerged seeds in the *Plant World* (vol. xviii., November, 1914), gives some valuable information on the subject. By the bursting of a dam a lake some seventy years old was drained, and the covering of vegetation, both dense and diverse, which appeared on the dried mud in the following spring, suggested clearly that it arose chiefly from seeds which had been buried for seventy years. The paper describes a series of careful experiments to test the longevity of submerged seeds, which, though only carried on for four and a quarter years in some cases, and nearly seven years in others, show that the vitality of many seeds was fully retained at the end of these periods of time.

The periodical flowering of the bamboo, resulting in the death of all the plants in a given area, is a well-known phenomenon. The flowering of *Bambusa polymorpha* in Burma is the subject of a communication in the *Indian Forester* for November, 1914, and it is stated that the last time this species flowered in its peculiar extensive manner was in 1859–60. Last year a few clumps flowered, and this year every clump is in full flower. It is of interest to notice that in the year before flowering no new shoots are sent up. The bamboo is regenerated from the seed ripened at these long intervals, hence all the bamboos in a large area are of the same age, and the life-cycle is repeated with regularity. When the bamboo flowers sporadically, as is the case with some species, seeds are not matured, apparently because the bamboo is self-sterile.

A useful and interesting note on fruit-growing in the East Africa Protectorate is contributed to the *Kew Bulletin*, No. 8, 1914, by Mr. H. Powell, who has had about ten years of experience in this subject in various parts of the country. Following the pioneer work, extending over twenty years, by the late Rev. S. Watts, of the N'Gomeni Mission Station, who devoted much attention to establishing European fruit trees, and obtaining, by means of acclimatisation and selection, varieties best suited to the climatic conditions of East Africa, the importance of fruit culture was recognised, and ever since the founding of the Department of Agriculture in 1903 the introduction,

cultivation, and distribution of improved varieties of tropical fruit plants have been actively carried on at two experimental stations, while similar attention is being given to temperate and subtropical fruits at a third station. Detailed notes are given regarding a considerable number of fruits and vegetables which have been found to thrive well in different parts of the Protectorate.

THE remarkable character of the South African flora is emphasised by Dr. R. Marloth in his recently delivered presidential address before the South African Association for the Advancement of Science, at the meeting held at Kimberley. It is also of interest to note that Dr. Marloth was this year the recipient of the South Africa medal and grant for research, founded by members of the British Association in commemoration of their visit to South Africa in 1905. The adaptation of the vegetative organs of plants to their environment occupies part of the address, and some of the most striking examples are furnished by several species of Mesembryanthemum, Anacampseros, and Crassula. *M. bolusii* and *M. simulans* exactly resemble the singular stones among which they grow, both in shape, colour, and texture. The examples grown at Kew show how stone-like these and other species may be even when grown under glass. The papery-white *Anacampseros papyracea,* which grows among white quartz, is one of the most difficult of plants to detect in its native habitats. *Mesembryanthemum calcareum,* which grows in a lime-tufa region, has the surface of the leaves roughened, exactly resembling the limestone among which it occurs. The colours of some species of Mesembryanthemum and Crassula are also found to vary in accordance with the type and colour of the soil on which they are growing. Examples of this curious mimicry or adaptation in the South African flora might be multiplied, but the explanation of the phenomena is not easy to suggest, and experiment is needed to prove whether, as Dr. Marloth suggests, the light reflected from the soil may be capable of producing a reaction in the plant.

ILLUSTRATIONS of the importance of magnetometric surveys in tracing iron ores are given by Mr. E. Lindeman in papers on the magnetite of Calbogie, Ontario, and on the famous Moose Mountain district, near Sellwood, in the same province (Canada Department of Mines, Mines Branch, 1914). Several detailed maps accompany the latter paper. The geological relations of the iron-bearing rocks at Moose Mountain have been described by Prof. Coleman for the Ontario Bureau of Mines ("Excursion to the Sudbury Area," Guide Book No. 7, 1913); but much remains to be done in distinguishing between the material of igneous origin and the rocks into which both granite and diorite have intruded. The possibility of a sedimentary origin for the Moose Mountain series is by no means excluded, in view of the similar bedded siliceous iron ores of South Africa; and the same may be said of the magnetite of Kiruna, which is commonly cited for comparison. The smoothly glaciated surfaces at Sellwood offer excellent opportunities for study.

To the State librarian of Hartford, Connecticut, we are indebted for a copy of the fourth volume of the Bulletins of the State Geological and Natural History Survey. It is an exceedingly bulky volume, containing half a dozen separately paged bulletins (Nos. 16 to 21), originally published at various dates from 1910 to 1913, four relating to local faunas, and two to the work of the survey. The faunistic papers include (1) the first and second parts of a guide to the insects of Connecticut, by Messrs. W. E. Britton and B. H. Walden, originally published in 1911; (2) an account of the Triassic fishes of Connecticut, prepared, with a section on the study of fossil fishes in general, by Prof. C. R. Eastman, also originally issued in 1911; (3) a survey of the echinoderms of the Connecticut coast, by Dr. W. R. Coe, originally published in 1912; and (4) a systematic list of Connecticut birds, with notes on their habits and distribution, by Messrs. J. H. Sale, L. B. Bishop, and W. P. Bliss, first issued last year. The first three of these publications are fully illustrated.

As the time is now approaching when icebergs and other forms of drifting ice will make their appearance in the North Atlantic, it may be of interest to extract a few of the main facts with reference to the behaviour of the ice in 1914 from the Monthly Meteorological Chart of that ocean for January, 1915, issued by authority of the Meteorological Committee. Icebergs were seen at Belle Isle early in January, and several in 46° N., between 46° and 49° W., with some field ice between January 17 and February 5. On June 17 a berg was passed near $51\frac{1}{2}°$ N. and 41° W., and on July 11 another was seen about $46\frac{1}{2}°$ N., $40\frac{1}{2}°$ W.; these were the easternmost bergs seen up to date of chart (about the middle of December). The loftiest berg of the season was passed near 42° N., $48\frac{1}{2}°$ W., on May 19 (estimated at 500 ft. high). On July 27, near 41° N., $67\frac{1}{2}°$ W., a small berg was passed; the furthest west in that year. In a very useful article on the subject by Commander Hepworth, C.B. (marine superintendent) in the "Seaman's Handbook of Meteorology," issued by the committee, he shows that icebergs and field ice reach the trade routes earlier in some years than in others; the maximum quantity may be met with as early as April and as late as August. Drifting ice may, it is stated, be observed in almost any part of the North Atlantic north of 30° N. latitude, about as far east of the 10th meridian of west longitude on the eastern side of the ocean, and about as far west as the 75th meridian on the western side, north of 35° N.

IN two papers which appeared in the Bulletin of the Bureau of Standards in 1908 and 1912 Mr. W. W. Coblentz described and compared the sensitiveness of the various forms of radiomicrometers. As a result of a series of measurements he concluded that a thermopile with silver and bismuth as its elements gave promise, when used *in vacuo,* of a degree of sensitiveness about half that of a bolometer under the same conditions, while its readings were much steadier. In a further paper reprinted from the bulletin for 1914, he gives details of the methods of construction he has found most suitable for thermopiles

to be used in various circumstances. He shows that the attainment of a high degree of sensitiveness is in the first instance a question of neatness of design, and that high thermo-electric power is of secondary importance. For absolute measurements, in order to make the surface receiving the radiation definite in area, he attaches to each junction a small strip of tinfoil, and has already determined the radiation constant σ for black-body radiation by means of the instrument. The result, $\sigma = 5{\cdot}61 \times 10^{-12}$ watt cm.$^{-2}$ degree^{-4}, is about 2 per cent. lower than the value generally given.

The mid-December issue of the Journal of the Institution of Electrical Engineers contained a report on the standardisation of symbols, which has been issued by the International Electrotechnical Commission. Differentiation between italics and ordinary Roman letters is not encouraged, as both appear the same in ordinary handwriting, and "Gothic" type is abandoned. Of course, for the greater part, the old and generally accepted symbols are adhered to, but there are some notable exceptions. For "work" A is recommended, W for energy, and P for power. While t is adopted for temperature, the Continental hieroglyphic which does duty for θ, but has a likeness to the fourth letter of the Greek alphabet as written here, as well as to the partial differential and the printers' reader's deletion mark, is given as a second substitute. The small Greek ω, used here for ohms, is adopted for $2\pi/T$, and in consequence the German practice of designating ohms either by O (a regular trap owing to its similarity to zero) or Ω (which is here employed for megohms) is "provisionally recommended." Other symbols adopted are I for current instead of C, which is allotted to capacity, ϵ for dielectric constant, X for reactance, Z for impedance, and S for reluctance, also a subscript m for maximum values. Arc sin x is to replace $\sin^{-1}x$, the comma or full-stop is to be used for the decimal point, and the comma is to be replaced by a white space for dividing off thousands. Finally, the commission will recommend next year that the name Siemens is to replace the old mho on the rare occasions that a unit of conductance is required.

In the current issue of *Electrical Engineering* there is an interesting article on the transmission of electric power from Sweden to Denmark across the Sound through a submarine cable which will carry current at 25,000 volts pressure. The width of the Sound at this point, namely, between Helsingborg and Elsinore, is only about 3½ miles. Power will be supplied from the network of the South Swedish Power Company, which has several water-power stations, and provision is made for a total power of 5000 kw. to be transmitted to Denmark. This will be utilised for the existing network of the North Zealand Electricity Company, and will include supply to Copenhagen. The case is a typical one for which international transmission should be useful, for, while Sweden has both water-power and cheap coal, Denmark has neither. One cable has already been laid, but it is proposed that it should only be used experimentally at first, and possibly two years may elapse before the Danish network is permanently connected up to the Swedish one. Although this will be the first instance of a submarine supply of electric light and power for industrial purposes between two countries, there have nevertheless been a few other cases of electric power transmission from one country to another. Nancy, Toul, and Verdun get part of their electric power supply from German Lorraine, or at any rate did so before the war, and there is also electric power transmission from Silesia in Germany to Austria, and from the south of Switzerland to Italy. Moreover, the Rheinfelden Works supply current both to the Swiss and German sides of the Rhine.

As mentioned in a recent article (Nature, December 3) the House of Commons' Select Committee on Patent Medicines formulated a number of recommendations as to the enactment of new legislation, and the administration of existing laws, controlling the advertisement and sale of secret remedies. We learn that a committee of the General Medical Council has had these recommendations under consideration, and completely endorses them. One of the proposals is that the administration of the law should be co-ordinated and made part of the functions of a Ministry of Public Health when such a department is created, and that in the meanwhile it should be undertaken by the Local Government Board. With reference to this proposal, the committee in its report urges the necessity for the immediate creation of a Ministry of Public Health. The report has been approved by the General Medical Council.

The publication of the new British Pharmacopœia will be followed closely by several books based upon the information contained in the official work. Three of such to be issued by Messrs. J. and A. Churchill early this year are:—"Materia Medica," fourteenth edition, by Dr. W. Hale White; "The Book of Prescriptions," tenth edition, by Mr. E. W. Lucas; and "The Book of Pharmacopœias," by Mr. E. W. Lucas and Mr. H. B. Stevens, this being a new book containing about 5000 formulas, British and foreign, arranged on a comparative system.

Mr. H. K. Lewis, 136 Gower Street, W.C., announces that the new edition—the sixteenth—of "The Extra Pharmacopœia," by W. H. Martindale and W. W. Westcott, will be published in the course of a week or two. The work will be issued in two volumes, as on the last occasion, and will embody much new matter as well as the necessary revision to bring it into conformity with the new British Pharmacopœia.

OUR ASTRONOMICAL COLUMN.

Bright Meteors of December 29 and 31.—Mr. W. F. Denning reports that fine meteors were observed by Mrs. Wilson at Bexley Heath on December 29, 6h. 59m., and December 31, 11h. 14m. The former was twice as brilliant as Jupiter, and its path was from $94^\circ + 43^\circ$ to $91\frac{1}{2}^\circ + 24\frac{1}{2}^\circ$. It was also observed at Bristol and at Essex. The radiant was at $261^\circ + 61^\circ$, and height of the meteor sixty-seven to forty-six miles, path forty-four miles, and velocity eighteen miles per sec. The meteor of December 31 was a fireball

much brighter than Venus, and its flight was from $324^\circ+67^\circ$ to $350\frac{1}{2}^\circ+55^\circ$, which it traversed in 2 sec. This magnificent object was evidently one of the Quadrantids from a radiant at $228^\circ+54^\circ$. It would be interesting to hear of another observation of it, and also of remarkable meteors reported by Mrs. Wilson as under:—

Date 1914	G.M.T. h. m.	Mag.	Path From ° °	Path To ° °	Duration sec.
Dec. 3	8 7	♀	103+28	109+30	—
5	6 47	♃	20−4	17−6	0·5
	7 14	1	350−20	340−31	2·0
7	8 25	♃	45+17	$8+7\frac{3}{4}$	2·0
15	7 4	>1	64+10	52 0	3·5
16	9 57	>1	$64+14\frac{1}{2}$	$48+2\frac{1}{2}$	2·0
19	10 3	>1	106+70	133+39	8·0

The last in the table had an extraordinarily slow flight, the duration being carefully estimated as 8 sec.

WATER VAPOUR IN MARS'S ATMOSPHERE.—Lowell Observatory Bulletin, No. 65, contains a paper by Dr. F. W. Very on the intensification of oxygen and water vapour bands in the Martian spectrum. The spectrograms of Mars and the moon were taken by Dr. V. M. Slipher, at the Lowell Observatory, on February 6, 1914, and on the plates taken C, B, and *a* have been measured at the Westwood Astrophysical Observatory, with a spectral band comparator. Each plate contained two sets of spectrograms, and each set consisted of a central Martian spectrum flanked by two of the moon, taken at nearly the same altitude and within a few minutes of each other. By the use of a new stain the photographic sensitiveness of the plate at *a* makes the intensities of *a* more accurate. The observations confirm the supposition that the melting snows of the Martian Arctic regions are the sole source of aqueous vapour in the Martian air, and that the equatorial regions are excessively dry. They indicate also that the actual amount of oxygen in the Martian atmosphere is about half as great as upon the earth.

A SECOND HARVARD MAP OF THE SKY.—Harvard College Observatory Circular, No. 71, contained a description of a photographic map of the entire sky, the map consisting of double contact prints on glass of fifty-five photographs taken with anastigmatic lenses, each having an aperture of 1 in. and a focal length of about 13 in.; the cameras were mounted at Cambridge and Arequipa. Each plate was 8 by 10 in. in size, and included a region of 30° square. The total number of stars shown was 1,683,000, and the limiting magnitude about 11·5. Circular No. 185 now contains an announcement by Prof. E. C. Pickering that a second set of plates has been selected, and another map of the sky has been prepared by Prof. King. In these photographs the centres of the plates coincide with the corners of the first set; this was done as it was found that owing to the large area of the sky covered in the first set the stars near the corners were distorted, and faint stars were not recorded there. The circular contains a catalogue of the plates employed. It is proposed to issue this new set of photographs at the same price as the first, namely, 15.00 dollars—a price, as is stated, somewhat less than cost.

THE SHORT-PERIOD VARIABLE, SZ TAURI.—An investigation of the light curve of the short-period variable, SZ Tauri, is contained in the Harvard College Observatory Circular, No. 186, and was made by Miss Leavitt. Prof. Schwarzschild, in 1911, published the elements of this variable, basing them on observations by Prof. Hertzsprung, and the times of minima were found to be represented by the formula, J.D. 2,418,724·16 M.E.Z.+3*d* 1484 E. It was with the object of securing a more precise period that the present investigation was undertaken, and 210 plates taken at the observatory between October, 1891, and February, 1914, have been utilised for this purpose. A table is given showing all the observations of the variable used, and a curve is added indicating the nature of the light variation. By reducing the observations by the above formula it was found that those previous to 1903 were not satisfied. They were, however, all well represented by the formula for times of maximum, J.D. 2,410,000·60 G.M.T.+3*d* 1487 E, and this has been used in computing the epochs and phases given in the above-mentioned table.

ONE HUNDRED NEW DOUBLE STARS.—Dr. R. G. Aitken, in the Lick Observatory Bulletin, No. 264, gives the twenty-third list of double star measures, the present one containing one hundred new double stars. The mean results of his measures are arranged in the same form as his earlier lists. The angular separation of the pairs ranges from 0·17″ to 4·78″.

PRIZE AWARDS OF THE PARIS ACADEMY OF SCIENCES FOR 1914.

Geometry.—The Francœur prize to A. Claude, for the whole of his astronomical work, and the Poncelet prize to M. Lebesgue. The Grand prize of the mathematical sciences was not awarded.

Mechanics.—The Montyon prize to Ed. W. Bogaert, for his memoir on the gyrostatic effect and its applications; the Henri de Parville prize between Jean Rey (1000 francs), for his work in mechanics and electromechanics, and Marcel Biver (500 francs), for his pamphlet on a system of transmission and transformation of movement. The question proposed for the Fourneyron prize, the theoretical and experimental study of the question of combustion or explosion turbines, is postponed until 1917, as no memoir was received.

Astronomy.—The Lalande prize to J. N. Guillaume, for the whole of his astronomical work; the Valz prize equally between Pierre Salet and Stanislas Chevalier; the Janssen prize to René Jarry-Desloges, for his studies on the planets, especially Mars; the Damoiseau prize to M. Gaillot, for improvements in Le Verrier's tables of Jupiter. No award was made of the Pierre Guzman prize.

Geography.—The Tchihatchef prize between Commandant Audemard (2000 francs) and Paul Labbé (1000 francs), the former for his hydrographical work in China, the latter for his work in Asiatic Russia in the fields of natural history, anthropology, and ethnography; the Gay prize to R. de la Brosse, for his hydraulic studies in the Alps; the Binoux prize between Ernest Esclangon (1500 francs), for his observations on the acceleration of gravity in the south-west of France, Alfred Vialay (500 francs), for his contribution to the study of the relations existing between the atmospheric circulation, atmospheric electricity, and terrestrial magnetism, and Paul Schwartz and Fernand Villatte (500 francs jointly), for the whole of their work; the Delalande-Guérineau prize to Jacques Liouville, for his work in the Antarctic regions.

Navigation.—The extraordinary prize of the Navy is divided between M. Roussilhe (2000 francs), for his works on the French Congo, M. Poincet (2000 francs), for his studies on the association of screw propellers and turbines, M. Crémieux (1500 francs), for his work on the powders of the Navy, and M. Lafon (500 francs), for his memoir on naval and military aeronautics (France and abroad); the Plumey prize between M. Dumanois (2000 francs), for his memoir on the application of the internal-combustion motor to

warships, M. Moritz (1500 francs), for his work on thermal motors in their relations with thermodynamics, and M. Schwartz (500 francs), for his work as a whole.

Physics.—The Hébert prize to M. Mauduit, for his treatise on electric machinery; the Hughes prize to Louis Benoist, for his researches on the X-rays; the L. La Caze prize to Jean Perrin, for his work on the kathode rays, X-rays, and Brownian motion; the Victor Raulin prize to Mme. Marchand.

Chemistry.—The Jecker prize to Marcel Delépine, for his work in organic, inorganic, and general chemistry; the Cahours prize to MM. André Meyer and Vavon (in equal parts); the Montyon prize (unhealthy trades) is not awarded; the La Caze prize to M. Debierne, for his researches on the radio-active elements.

Mineralogy and Geology.—The Fontannes prize to Jean Boussac, for his memoir on the evolution of the Cerithideæ in the mesonummulitic of the Paris basin.

Botany.—The Desmazières prize to MM. de Istvanffi and Palinkas, for their study of the mildew of the vine, a mention being accorded to M. Bruchmann; the Montagne prize divided between M. Sauvageau (1000 francs) for his monograph on the Cystoseira, and M. Coppey (500 francs), for his bryological researches; the de Coincy prize to M. Gard, for his studies on hybrids of Cistus.

Anatomy and Zoology.—The Savigny prize to J. M. R. Surcouf; the Cuvier prize to M. Bordas, for his anatomical researches; the Thore prize to J. Feytaud, for his researches on ants.

Medicine and Surgery.—Montyon prizes (500 francs each) to H. Bierry, for his works on the glycogenic function, Ch. Nicolle, L. Blaizot, and E. Conseil (jointly), for their works on the etiology and prophylaxy of recurring fever, and E. Pinoy for his researches on the pathogenic fungi. Mentions, 1500 francs each, to Ed. Delorme, for his memoir on the direct surgical treatment of cardo-pericardiac symphysis, E. Maurel, for his work on alimentation and nutrition in normal and pathological states, and P. Chaussé, for his work on tuberculosis. Citations were accorded to André Broca, for his book on infant surgery; Robert Picqué, for his practical treatise on surgical anatomy and operative medicine; M. Roussy, for his book on five original methods for measuring the surface of the skin of the human body; M. Aynaud, for various memoirs on the question of the third element of the blood; M. Brunon, for his works relating to tuberculosis; MM. Gautrelet and Laubie; and M. Couveiaire, for his introduction to uterine obstetrical surgery; the Barbier prize in equal parts between H. Carré, for his memoirs on contagious agalaxy of the kid and goat, and Albert Ranc, for his studies on the physiological action of light; the Bréant prize between H. Vincent (3000 francs), for his works on the typhoid bacillus and on typhoid fever, and O. Arnaud (2000 francs), for his work on cholera in the Greek army during the Balkan war; the Godard prize to Antoine Lacassagne, for his studies on the action of the X-rays on the ovary; the Baron Larrey prize divided equally between Dr. Reverchon, for his medico-military studies on the second Balkan war, and H. Billet, for his work on the treatment of skull wounds caused by small projectiles; the Bellion prize between M. Gorini (1000 francs), for his work on vaccines, the bacteriology of milk, and pathogenic micro-organisms, and M. Marotel (400 francs), for his researches on parasitic diseases, Raoul Dupuy receiving an honourable mention for his memoir on backward children and their treatment; the Mège prize to M. Bruntz, for his researches on the excretory organs of vertebrates and invertebrates.

Physiology.—The Montyon prize (experimental physiology) to A. Mayer and G. Schæffer (jointly), for their work on the lipocytic coefficient; the Philipeaux prize to Pierre Girard, for his researches on electrical osmosis; the Lallemand prize between Henri Piéron and René Legendre (900 francs jointly), for their memoir on the physiological problem of sleep, and J. Mawas (900 francs), for the whole of his work on the anatomy and physiology of the nervous membrane of the eye in vertebrates and in man, André Barbé being accorded a mention; the Pourat prize is not awarded; the La Caze prize (physiology) to E. Gley, for the whole of his work; the Martin-Damourette prize between M. Fauré-Fremiet (1000 francs), for his memoir on the germinative cycle in *Ascaris megalocephala*, and A. Lanzenberg (400 francs), for his work on ammonia and urea: origin, methods of estimation.

Statistics.—The Montyon prize to René Worms, for his studies on sexuality in French births and on agricultural associations.

History of the Sciences.—The Binoux prize is not awarded.

General Prizes.—A Berthelot medal to M. Debierne; the Gegner prize (2000 francs) to J. H. Fabre; the Lannelongue prize between Mme. Cusco and Mme. Rück; the Trémont prize to Charles Frémont; the Wilde prize between Perrier de la Bathie (3000 francs), for his geological explorations in Madagascar, and M. Schulhof (2000 francs); the Lonchampt prize to M. Javillier, for his work on the biological properties of zinc salts; the Saintour prize between R. Bigeard and H. Guillemin (1500 francs jointly), for their work on fungi, and J. Révil (1500 francs), for his geological work; the Henri de Parville prize between M. Berget (1000 francs), M. Houllevigue (1000 francs), M. Joubin (1000 francs), M. Altermann (500 francs), and M. Coupin (500 francs); the Houllevigue prize to M. Vershaffel; the Caméré prize to Augustin Mesnager; the Jérome Ponti prize between Henri Bröllemann (2500 francs), for his work on the Myriapods, and M. Pelourde (1000 francs), for his researches on plant palæontology; the Serres prize to A. Prenant, for his work in histology, cytology, and embryology; the Jean Jacques Berger prize (15,000 francs) to the Marquis de Vogüé, for the military hospital organised by the institute; the prize founded by the Marquise de Laplace to M. Sasportès; the prize founded by Félix Rivot between MM. Sasportès, Lévy, Jeannin, and Pélissonnier; the Bordin and Henri Becquerel prizes are not awarded, and the Gustave Roux prize is postponed to 1915.

ECONOMIC GEOLOGY IN THE UNITED STATES.

WE have received from the United States Geological Survey a number of bulletins dealing with economic geology, namely:—"Reconnaissance of Oil and Gas Fields in Wayne and McCreary Counties, Kentucky," "Oil and Gas in the Western Part of the Olympic Peninsula, Washington," "The Ore Deposits of North-Eastern Washington," "Mining Districts of the Dillon Quadrangle, Montana," "Electric Activity in Ore Deposits." The first two of these possess merely a local interest; the same is true to a large extent of the two next on the list, though their perusal will well repay the students of mineral deposition, more especially in the case of the bulletin on the Dillon Quadrangle, which is from the pen of Mr. Alexander N. Winchell. The last pamphlet contains an interesting study of the possible modes of development of electromotive force in ore deposits and of some of its effects, amongst which latter the deposition of the precious metals in the metallic state by electrolytic

action is perhaps the most interesting. It is worth while to direct attention to a sentence in the preface by Mr. George Otis Smith:—"It should be emphasised that the results thus far obtained afford no adequate basis for any method of electric prospecting nor any promise of the development of such a method by connecting the presence of ore deposits with readily or definitely measurable electric activity." Although no very definite results are recorded in this bulletin, it contains much suggestive material, and will probably lead to a fuller investigation of the subject.

We have also received a series of pamphlets dealing with the mineral production of the United States for 1913. In order to enable this information to be issued with the least possible delay, each chapter is issued separately as soon as the necessary statistics shall have been prepared, instead of waiting as heretofore until the whole of the statistical information needed for the entire volume was available. This system not only enables the various chapters to be issued more promptly but enables a producer to whom the statistics of one or of a limited number of substances alone are of importance to concentrate his attention on these and to find what he needs in a handy little pamphlet instead of having to deal with a bulky volume. The chapters hitherto published are—

Part i., "Metals":—(1) Bauxite and aluminium; (2) chromic iron ore; (3) gold, silver, copper, and lead in South Dakota and Wyoming; (4) manganese and manganiferous ores; (5) recovery of secondary metals. Part ii., "Non-Metals":—(1) Mica; (2) fuel briquetting; (3) sand-lime brick; (4) sulphur, pyrite, and sulphuric acid; (5) mineral paints; (6) slate; (7) potash salts; (8) fuller's earth; (9) cement industry; (10) feldspar; (11) talc and soapstone; (12) barytes; (13) silica; (15) abrasive materials; (16) phosphate rock; (19) sand and gravel.

It need scarcely be said that the high standard of accuracy, and abundance of detail, that we are accustomed to find in the statistical publications of the United States Geological Survey have been fully maintained.

IRON IN ANCIENT INDIA.

BULLETIN No. 12 of the Indian Association for the Cultivation of Science contains an interesting article on iron in ancient India, by Mr. Panchanan Neogi, professor of chemistry in the Rajshahi College, Bengal. The author discusses the question whether iron was known in the Vedic age, and advances evidence, chiefly based on the Rigveda, in favour of the view that iron was known and used between 2000 and 1000 B.C. Whether absolute reliance can be placed on this evidence, especially as to the dates, may be open to question, but the find of ancient iron weapons on a burial site in Tinnevelly proves that iron was undoubtedly known in India in very early times; while the piece of iron slag unearthed at Bodh-Gaya shows that iron smelting had been carried on in the third century B.C., and the iron clamps found in a temple on that site, to which the date 400 to 600 A.D. has been assigned, bear evidence to a considerable advance that had then been made in the working of the metal. As regards the metallurgy of the metal, wrought iron was produced, as in all countries in early times, by the direct process from ores by smelting them in small blast furnaces without the intermediate production of cast-iron. The well-known iron pillar near the Kutub Minar, Delhi, and the rectangular iron beams of the temple at Puri, to which the dates 640 A.D.–1174 A.D. have been ascribed, are cited as examples of the scale on which iron forgings were made and of the remarkable skill attained by the workers in the metal. These gigantic forgings were constructed by welding together small blooms of iron, a method which continued to be practised in China and Japan until the middle of last century. The Delhi pillar has not rusted to a marked degree, and this resistance to corrosion is ascribed by the author to the composition of the iron, which is free from manganese and sulphur, and contains a tolerably high percentage of phosphorus. The paper also includes an interesting account of the method of making wootz or Indian steel as practised in India long prior to the manufacture of crucible steel in Europe.

AN ALL-METAL DIVING DRESS.

THE *Engineer* for December 11 contains an account of an all-metal diving dress invented in the United States of America by Mr. Chester E. Macduffee. This dress is the result of about five years' experiment, and is now claimed to have reached a practical stage.

Macduffee Diving Dress. Diver coming up after submergence.
From the *Engineer*.

Divers have used this armour at a maximum depth of 212 ft., and could have gone deeper had more water been available. The dress is made of an aluminium alloy of great strength, and weighs empty about 480 lb.; its very considerable displacement gives it a good deal of buoyancy when in the water, and necessi-

tates the addition of lead ballast. The suit consists of a series of articulated sections having sliding or rotating joints, sealed sufficiently by means of leather and rubber packing; there are fifty-six of these flexible joints. Roller bearings working upon steel rings prevent jamming of the joints under high water pressure. The various parts of the suit are strengthened by internal and external ribbing. The diver in the Macduffee armour breathes air at ordinary atmospheric pressure, no matter how deep he goes, and this differentiates the new suit from the ordinary flexible diving dress. Every part of the diver is enclosed, and this necessitates the addition to the dress of ingenious mechanical hands operated from the interior of the dress. Dangerous accumulations of water due to leakage are dealt with by means of a small pump attached to the dress and worked by compressed air; suction pipes lead from the pump to each foot.

GEOPHYSICAL MEMOIRS.[1]

THE reproach has frequently been levelled at meteorologists as a class that they are almost entirely devoted to the accumulation of masses of undigested and possibly indigestible data, but the aptness of the reproach has been steadily modified of late years, and one of the chief agencies in this country in producing this modification has been the activity of the reconstituted Meteorological Office, under the directorship of Dr. Shaw. When he was awarded the Symons gold medal by the Royal Meteorological Society, one of the grounds specifically mentioned as influencing the council in making the award was Dr. Shaw's capacity for suggesting fruitful lines of research for other people, and the memoirs contained in the volume now being completed bear testimony to this contention.

About ten years ago Dr. Shaw instituted fortnightly meetings during the winter session at the Meteorological Office, to which he invited people interested in meteorology and kindred subjects, and at which definite work on such subjects was discussed and freely criticised in an informal manner, and among the regular attendants at these meetings for some time past has been Mr. J. Fairgrieve, who, having sufficient spare time, amid scholastic duties, undertook the investigation which forms No. 9 of the Geophysical Memoirs. It is to be hoped that his example will be freely followed. No. 10 is a more strictly "office" production, being the continuation of No. 1, in which the superintendent of the Department of Marine Meteorology discusses the effect of the Labrador current year by year upon the surface temperature of the Atlantic and upon the meteorology of the British Isles.

It must be admitted that a considerable proportion of meteorological data is scarcely available for discussion, so that the first duty of the investigator is to sift his material and try to introduce homogeneity. For this reason pioneer work such as Mr. Fairgrieve's "On the Relation between the Velocity of the Gradient Wind and that of the Observed Wind," in which the data are numbers estimated on the Beaufort scale, is the more valuable, in that future investigators are given precious hints as to what to avoid, and observers may take notice of directions in which the form of their data can be improved. The conclusions are encouraging, and the plates of illustration interesting, although the most obvious deduction from them is simply that sea-winds predominate at coast stations, which is scarcely novel. It is evident that more work of the kind is needed, and equally evident that on this subject, as on many others, the proportion of chaff among the available data is inconveniently high. There is a valuable introductory note by Dr. Shaw, who takes the opportunity to print some tables of great wind pressures and velocities at the British stations in the twelve years 1899–1910.

W. W. B.

[1] Meteorological Office. Geophysical Memoirs. Vol. i., Nos. 9 and 10, completing the first volume. No. 9. On the Relation between the Velocity of the Gradient Wind and that of the Observed Wind. By J. Fairgrieve. Pp. 189–207.
No. 10. The Effect of the Labrador Current upon the Surface Temperature of the North Atlantic, and of the latter upon Air Temperature and Pressure over the British Isles. Part ii. By Commander M. W. C. Hepworth. Pp. 211–220. (London: Meteorological Office, 1914.) Price 1s. and 8d. respectively.

THE ARTIFICIAL PRODUCTION OF VIGOROUS TREES.

IN an article on the artificial production of vigorous trees, contributed to the Journal of the Department of Agriculture and Technical Instruction in Ireland (No. 1, October, 1914) Prof. Augustine Henry discusses the nature of species, varieties, races, sports, and hybrids, as they appear to be from his researches. Natural species, in the case of trees, are readily recognised by the occurrence of each in a definite region or habitat. We have thus one species of silver fir in Central Europe, another in Algeria, a third in southern Spain, etc. Of our common trees—oak, birch, and elm—there are pairs of species in the same region, each, however, occupying a different habitat, one species adapted to a dry situation, the other suited to a moister soil. The pedunculate oak is a native of valleys and alluvial flats. It is not protected against evaporation of water, the supply of which in the ground it prefers being always ample. The sessile oak is a native of hilly and rocky districts, where water is not abundant in the soil. Its leaves are covered beneath with hairs, which guard against excessive loss of water by transpiration in windy weather. Similarly two alders exist on the Continent, but only one species, *Alnus glutinosa,* reached our islands, after the retreat of the ice sheet, and before the land connection with France was severed by the formation of the Straits of Dover. The other species, *A. incana,* grey alder, is absent from our native flora, but when introduced is very hardy, and is useful for planting in low-lying situations liable to spring frosts. The ash requires such special conditions of soil, that only one species exists in Northern and Central Europe, there being no suitable soil for a second species to inhabit.

A natural species is often a set of individuals uniform over a large area; but it may consist of two or more "geographical varieties," which correspond with distinct territories, each marked by slight differences of foliage, etc., that render the variety better fitted for its own habitat. Thus the Corsican and Austrian pines are closely related, but the latter keeps its leaves two years longer on the branches, so that the dense shade of its abundant foliage preserves moisture in the crevices of the hot limestone rocks, on which it grows in its Austrian and Servian home. The Corsican pine, with half the foliage of the other tree, thrives on granite soil in the moist insular climate of the mountains of Corsica. These two pines—only notably distinct in one character, the amount of their foliage—are usually regarded as two geographical varieties of the same species, *Pinus Laricio,* but by some botanists are considered to be two distinct species.

In a species apparently uniform over a large area there may exist varieties, characterised by minute and scarcely describable differences. This is exemplified

by the Scots pine. Plots of its seedlings, raised from seed of trees in the forests of Scotland, Russia, Switzerland, etc., differ in vigour and in other respects (immunity to certain fungi, etc.), when all are grown together under identical conditions. Such varieties, with slight differences of structure, may be called races, and are of great practical importance in forestry. Only seeds of the best race, that is, from vigorous trees of the most suitable locality, should be used.

A sport is usually a solitary phenomenon, arising either as a sporadic peculiar seedling from a seed, or developing out of a bud on a tree as a single branch with some peculiarity of twig or leaf. A sport may be looked upon as a freak, not forming the starting point of a new species, but speedily becoming extinct if left to nature. Sports, when of interest on account of the curiosity or the beauty of their appearance, are propagated usually by grafts, cuttings, or layers; being only in rare cases perpetuated by seed. Some sports are due to arrested development. The tree, in the course of its life, often passes through stages, like those of an insect. The seedling of many species differs from the adult tree as a larva from a butterfly. The infant ash has simple leaves. The sport known as the simple-leaf ash is simply a seedling ash, which has never progressed to maturity and may be called a persistent larval form (Fig. 1).

Fig. 1.—Adult foliage of common ash on left, of simple-leaf ash on right; two ash seedlings in the middle, showing primary leaves above the pair of cotyledons.

Abnormal colouring of leaves, so-called variegation, is a sport, usually starting as a solitary branch on an otherwise normal tree, which, when noticed, is propagated by grafting. Deeply-lobed, crumpled, pitcher-like, and other abnormal leaves occur in many species, and are propagated as curiosities. In sports, reversion is often seen; thus on a fern-leaf beech one or two branches with normal leaves are not uncommon. This reversion may be due to the influence of the stock, as these sports are usually grafted; or it may be explained as the triumph locally of normal over abnormal factors. Such reversions are never seen in hybrid trees. The occurrence of a sport seems to predispose to further sporting; a tree with leaves abnormal in shape will sometimes take on, in one branch, abnormal colour as well. These double sports are common in the holly.

Hybrids are combinations of two species or of two varieties, which arise either in the wild state or in cultivation. They are met with in nature as rare individuals on the boundary line between the areas occupied by two species. This is well seen in Yorkshire, where a hybrid oak is found in the localities in which the sessile oak of the hills comes in contact with the pedunculate oak of the valleys. Hybrids arise frequently in nurseries, gardens, and parks, where several species are cultivated together.

Hybrid trees are more common than has been supposed. Many valuable trees, the real history of which has not been suspected by botanists, are of hybrid origin. As an example, may be mentioned the fine elm, which is universally planted in Holland and Belgium, where it is known as *orme gras* or *Ulmus latifolia*, Poederlé. This is not, as sometimes imagined, a natural species peculiar to those countries. It is unquestionably a hybrid, which is invariably propagated by layers, all the individual trees on this account being uniform in appearance. It seems to have originated three or four centuries ago, probably as a single seedling, which has given rise by vegetative reproduction since to millions of descendants.

The distinction between sports and hybrids is well known in the numerous so-called "varieties" of the holly (Fig. 2). Some are sports of *Ilex Aquifolium*, our native holly; others are hybrids, one parent being the common holly, whilst the other is either *Ilex Perado*, which was introduced from Madeira in 1760, or *Ilex Balearica*, the holly of the Balearic Isles, which was cultivated at Versailles in 1789. Miller, in his account of the hollies in 1750, was acquainted only with the sports, which had arisen from the common holly, as the other species had not been introduced at that time and hybridisation was impossible. The hybrids originated soon after 1800, the earliest apparently being *Ilex Hodginsi* and *Ilex Hendersoni*, which were found by Hodgins as seedlings in his nursery at Dunganstown, Wicklow. Here *Ilex Perado* was cultivated; and old specimens producing flowers and fruit freely are still common in Wicklow gardens. The holly hybrids are vigorous trees, bearing large leaves intermediate between the parent species. The sports of the common holly are always grafted, and are feeble in growth, with a tendency for single branches to revert occasionally to the normal form.

Fig. 2.—Holly. Species:—1. *Ilex Perado*; 2. *I. Balearica*; 3, 4. *I. Aquifolium* (native). Hybrids:—5. *I. Wilsoni*; 6. *I. Hodginsi*; 7. *I. Hendersoni*. Sports:—The leaves not numbered are those of different sports of the native holly.

With regard to hybrids, Prof. Henry, by historical research and experiment, has established the fact that many fast-growing trees in cultivation as the Lucombe Oak, Common Lime, Cricket Bat Willow, Black Italian Poplar, etc., are hybrids. By artificial pollination (Fig. 3) he has succeeded in raising new hybrids,

FIG. 3.—Cross-fertilising a walnut tree. The bags are on the branches above and to the left of the operator.

which display the extraordinary vigour characteristic of the first generation cross; and in his paper gives an account of these. The most notable so far are a new hybrid Poplar (*Populus generosa*) and crosses between the Common Ash and American species of Fraxinus.

OPTICAL GLASS AND SCIENTIFIC INSTRUMENTS: UNITED KINGDOM IMPORTS AND GERMAN EXPORTS.

IN reply to a request for information upon the subject of imports of optical glass and scientific instruments from Germany and elsewhere, the Commercial Intelligence Branch of the Board of Trade has favoured us with a statement showing the imports of scientific instruments and apparatus and parts into the United Kingdom in 1913, distinguishing principal countries whence consigned. We have received, in addition, a statement of the German exports of optical glass and glass instruments in 1912, distinguishing, *inter alia*, the exports to the United Kingdom, as well as particulars of the exports from Germany to the United Kingdom in 1912 of other scientific instruments. As these particulars are of interest and importance at the present time, in connection with efforts being made to provide for increased supplies of optical and chemical glass and scientific instruments from manufacturers in the United Kingdom, they are here reprinted by permission of the Board of Trade.

IMPORTS OF SCIENTIFIC INSTRUMENTS AND APPARATUS AND PARTS INTO THE UNITED KINGDOM IN 1913. EXTRACTED FROM THE "ANNUAL STATEMENT OF TRADE OF THE UNITED KINGDOM."

Scientific Instruments and Apparatus (other than Electrical) Complete.

	£
Total imports	710,341
Of which from Germany ...	362,891
Belgium ...	28,939
France ...	108,040
Switzerland ...	19,872
U.S.A.	182,293

Parts thereof (including Kinematograph Films, Photographic Plates, and Films and Sensitised Photographic Paper).

	£
Total imports	2,373,426
Of which from Germany ...	310,229
Belgium ...	126,725
France ...	522,682
Switzerland ...	28,762
Italy	121,842
U.S.A.	1,256,311

EXPORTS OF SCIENTIFIC INSTRUMENTS (OTHER THAN GLASS) FROM GERMANY TO THE UNITED KINGDOM IN 1912. EXTRACTED FROM THE OFFICIAL GERMAN TRADE RETURNS.

	100 kilogs	Marks
Optical measuring instruments (polariscopes, etc.) nautical compasses, astronomic telescopes, and other astronomic, geodetic, nautical, etc., instruments ...	87	317,000
Pedometers, pocket instruments for recording, etc., automatic measuring and registering apparatus, speed indicators, automatic balances, etc.	1,991	1,222,000
Cases of geometrical instruments, ruling pens, mathematical instruments, etc.	75	167,000
Calculating machines	94	173,000
Surgical instruments	472	766,000
Precision balances, instruments for metrology and gauging barometric, calorimetric, thermometric, and chemical instruments	453	402,000
Physical teaching apparatus ...	75	67,000

100 kilogs. = 220·46 lb. Mark = 11·8*d.*

EXPORTS OF OPTICAL GLASS AND GLASS INSTRUMENTS IN 1912, DISTINGUISHING PRINCIPAL DESTINATIONS. EXTRACTED FROM THE OFFICIAL GERMAN TRADE RETURNS.

Terrestrial Telescopes, Opera Glasses of all Kinds.

	100 kilogs	1000 marks
Total exports	1618	7104
Of which to France	78	372
United Kingdom...	132	695
Italy	140	534
Austria	191	1034
Russia	390	1686
Switzerland ...	67	494
Turkey	55	212
United States ...	102	273

Other Optical Glass, Ground and Mounted (Telescope Objectives); Stereoscopes, Microscopes, Unmounted Lenses for Optical Work.

	100 kilogs	1000 marks
Total Exports	1764	4659
Of which to France	92	265

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—Arrangements are to be made for special intermediate examinations for refugee students, internal and external.

A new syllabus has been approved for hygiene at the M.B., B.S. examination.

The Paul Philip Reitlinger prize has been awarded to Alfred Hope Gosse, London Hospital Medical College, for an essay on the heart in acute rheumatism.

The Sir John William Lubbock Memorial prize for mathematics has been awarded to Ruth Wilks, Bedford College, on the result of the B.A. and B.Sc. honours examination.

Two courses of free lectures in scientific subjects for advanced students of the University and other persons interested are announced in the issue of the *London University Gazette* for December 30, 1914. A course of nine lectures with practical work in dynamical meteorology will be held at the Meteorological Office, South Kensington, by Dr. W. N. Shaw, on Fridays from 3 p.m. to 5 p.m., beginning on January 22. A course of fourteen lectures on development and life-cycles in the Protozoa will be given at the Lister Institute of Preventive Medicine by Prof. E. A. Minchin, at 5 p.m. on Tuesdays and Fridays during the second term, beginning on January 26. Each lecture will, when possible, be followed by exhibits of microscopic preparations illustrative of the subject of the lecture.

AT the Sir John Cass Technical Institute, Aldgate, E.C., on Wednesday, January 13, Sir Robert G. C. Mowbray, Bart., prime warden of the Worshipful Company of Goldsmiths, will distribute the prizes and certificates and open the new metallurgy laboratory for the mechanical testing of metals and alloys, presented to the institute by the company.

IT appears from the new issue of "The Classified Directory to the Metropolitan Charities" that the approximate income for 1913–14 of the various groups of benevolent institutions with headquarters in or near London was 8,705,980*l.*, an increase of 617,202*l.* on the previous year, notwithstanding that upwards of four millions and a quarter had been given to the National Relief Fund, and great sums were raised for other purposes to ameliorate the conditions arising out of the war. The institutions receiving this help include hospitals, religious organisations, charities for the afflicted, and so on, and among them we notice educational institutions which together received 625,289*l.* The educational institutions which have received such aid include training colleges for teachers, public schools for boys and girls, and colleges where scholarships and exhibitions endowed by City companies and other corporations are held.

THE report to the Clothworkers' Company of the advisory committee on the work during 1913–14 of the departments of textile industries, tinctorial chemistry, and dyeing and art in the University of Leeds has been circulated. The department of textile industries is now under the direction of Prof. A. F. Barker, who had under his supervision during the session 154 students, 53 of whom were day students. The report points out that the South African Government is undertaking most exhaustive experiments on the effects of various sheep dips on the wool during the subsequent processes of combing, spinning, weaving, and finishing. Half the specially treated wool is being manufactured in the department, duplicate lots being treated at the Bradford Technical College. Most useful results from this interesting work are anticipated. The department of tinctorial chemistry has continued to take a prominent part in the movement directed by the Textile Institute to bring about legislation dealing with falsification of "indigo dyed" woollen materials, and Prof. Green, the head of the department, was a member of a deputation from this body which was invited by the Board of Trade to lay the case before them. The work conducted has already had a marked influence on the quality of the dye used for "indigo" cloths.

THE first number of the fiftieth volume of the Bulletin of the Massachusetts Institute of Technology, Boston, that for December, 1914, takes the form of a catalogue of the officers and students of the institution, with a statement of the requirements for admission and a description of the courses of instruction. Regular four year courses of study leading to a degree are offered in fifteen branches of science and engineering. In most of these courses distinct options are offered in the later years which enable the student to concentrate more of his attention upon some one side of his profession. In no case, however, is the

specialisation carried so far as to preclude a thorough training in all the fundamental branches of the subject. The courses in applied chemistry, metallurgy, electro-chemistry, and sanitary and industrial biology serve to prepare students as scientific experts and for professional positions in manufacturing establishments and Government laboratories. Thorough courses in pure science, namely, in chemistry, physics, biology, geology, and general science, are also arranged.

SOCIETIES AND ACADEMIES.

LONDON.

Linnean Society, December 17, 1914.—Prof. E. B. Poulton, president, in the chair.—M. **Christy**: A remarkable gall believed to be new in this country. The gall is in the nature of a "witches'-broom," but appears on *Salix fragilis*; whereas no "broom" of the kind has hitherto been recorded on any species of willow in this country. It appears in great abundance on all trees of the species named growing in proximity. According to Prof. Nalepa, it is due to a gall-mite *Eriophyes triradiatus*, but not improbably a parasitic fungus may assist. So far, the gall is confined, apparently, to a limited area within a radius of, say, twelve or fifteen miles around London. The gall is remarkable in that it appears on the female flower, which develops during summer, until it resembles a bunch of moss, of an olivaceous green colour, from 2 to 8 in. in length, hanging from a small twig. The bunch consists of hundreds, perhaps thousands, of abnormal flowerets.—W. M. **Webb**: The Brent Valley Bird Sanctuary. Twelve years ago the Brent Valley Branch of the Selborne Society took steps to protect a wood of nineteen acres in its district, not far from Ealing, which had long been known as an abiding place for birds. The immediate object was to preserve the nightingales; and a small committee was formed to approach the tenant of the farm on which the wood was situated with a view to the appointment of a watcher. Ultimately, the committee appointed its own keeper, took over the wood from the farmer, and now rents it direct from the owners. No very rare birds occur in the wood, but it is important in the neighbourhood of large towns to give an opportunity to the commoner kinds of nesting undisturbed. Forty-one species have been recorded as breeding in the wood, thirty-nine of them during recent years. Among these may be mentioned the nightingale, lesser whitethroat, the blackcap, garden-warbler, chiffchaff, willow-warbler, long-tailed tit, marsh-tit, tree-creeper, hawfinch, goldfinch, redpoll, nuthatch, wryneck, cuckoo, red-backed shrike, turtle-dove, and wild duck. Including the winter migrants and occasional visitors, eighty-eight species have been observed in or close to the wood. Of these, the golden-crested wren, all the three British woodpeckers, the nightjar, the brown owl, the barn owl, the snipe, and the kingfisher are seen commonly or from time to time. Owing to the introduction of nesting-boxes, several species have increased in numbers or have been induced to nest.

DUBLIN.

Royal Dublin Society, December 15, 1914.—Prof. W. Brown in the chair.—J. **Doyle**: The change of the petiole into a stem by means of grafting. A sprout was grafted on a petiole of *Pelargonium zonale*, v. *meteor*, all the other buds and leaves being removed. After a short time the petioles carried large plants, completely functioning as stems, while the qualities of a stem, viz., indefinitely active cambium, the appearance of interfascicular cambium, considerable secondary thickening, periderm formation, were all taken on by the petiole. The possible causes of this secondary thickening are to be sought (1) in the removal of correlational influences; (2) in increased mechanical strain; (3) in some influence exerted as a result of foliar development. This influence is probably bound up with the water economy of the plant—particularly transpiration—but its precise nature has still to be determined.—Prof. J. B. **Butler** and J. M. **Sheridan**: A preliminary account of a new œdanometer for measuring the expansive force of single seeds or similar bodies when wetted. The apparatus described consists of two strong iron castings bolted together, and holding between them a diaphragm of sheet rubber. The seed to be tested is dropped through a cylindrical passage in the lower casting on to the rubber diaphragm. It is then packed round with fine sand, and covered by a disc of wire gauze. A strong plunger is screwed firmly home on the seed and sand, packing it tightly. Water can be admitted through holes drilled in the plunger. A hemispherical space directly over the rubber diaphragm in the upper casting contains mercury, which is in communication with a fine bore thermometer tube containing air. The upper end of this tube is closed. When water is admitted to the seed it swells; the swelling force is transmitted through the rubber diaphragm to the mercury, and thence to the air in the thermometer tube, compressing it. In this way the pressure, developed by one or more large seeds, can be measured. From single broad-bean seeds pressures of from 28 to 30 atmospheres were obtained. Six peas placed in the apparatus registered from 45 to 50 atmospheres.—Prof. J. **Wilson**: An example of the multiple coupling of Mendelian factors. The English varieties of the campine breed of fowl are described from the Belgian varieties, but are now slightly different in type as regards plumage. The matings by which the Rev. E. Lewis Jones and others produced the English type show that four factors are coupled. If M=the male factor, F=female; E=English type, b=Belgian; Bl.=black colour, g=gold; and Bd.=barred plumage, and p=plain, the factorial representation of a Belgian type "silver" campine hen is

$$\begin{array}{c|c|} \mathrm{M} & \mathrm{F} \\ \mathrm{b} & \mathrm{E} \\ \mathrm{Bl} & \mathrm{g} \\ \mathrm{Bd} & \mathrm{p} \end{array}$$

The four factors placed in the closed bracket are coupled.—Prof. H. H. **Dixon** and Miss E. S. **Marshall**: A quantitative examination of the elements of the wood of trees in relation to the supposed function of the cells in the ascent of sap. Measurements of the cross-sections of the various elements of the wood of various trees were made by weighing the parts of cut-out photomicrographs of the wood. In this way the percentage of the total cross-section occupied by vessels, tracheids, cells, and walls was determined. The assumption that the transpiration current is raised by the protoplasmic streaming in the cells is shown to be untenable owing to the velocity of streaming it would require.—Prof. H. H. **Dixon** and W. R. G. **Atkins**: Osmotic pressures in plants. Part iv.—The constituents and concentration of sap in the conducting tracts, and on the circulation of carbohydrates in plants. Throughout the year appreciable quantities of carbohydrates are present in the transpiration stream of trees. Their concentration is always greater than that of the electrolytes. In deciduous trees the concentration of the carbohydrates attains a maximum in spring, and is at its minimum in summer. In evergreens there are two cusps in the concentration curve. The distribution of carbohydrates is a function of transpiration no less important than the conveyance of nutritive salts. The coating of

wood parenchyma round the vessels is to be regarded as a glandular sheath for the secretion of carbohydrates into the transpiration stream. The medullary rays store these materials and convey them to the sheaths.

PARIS.

Academy of Sciences, December 28, 1914.—M. P. Appell in the chair.—Paul **Appell**: The principle of the minimum of the energy of accelerations and the substitution of force linkages.—Ph. A. **Guye** and F. E. E. **Germann**: The influence of the gaseous impurities of silver on the values of the atomic weights determined by the classical methods; the atomic weights of chlorine and of phosphorus. Referring to their recent determinations of the amounts of carbon monoxide and water in highly purified silver found after fusion in hydrogen, it is shown that the use of such silver in atomic weight determinations would lead to a value about 0·005 too high, a negligible quantity. The effect of such an error on other atomic weights based on silver is discussed. The resulting corrections are of the order of 1 to 2 units in the second decimal place, exceptionally 3 to 4 units. Phosphorus, for example, would be lowered from 31·028 to 31·007.—F. **Gonnessiat**: The eclipse of the sun: results.—A. **Buhl**: The intervention of the formulæ of Riemann, Stokes, and Green in the extensions of Abel's theorem.—Lucien **Godeaux**: Triple surfaces endowed with a finite number of points of diramation.—R. **Marcille**: Determination of the Hübl iodine number in alcoholic liquids. The iodine numbers of essential oils. The determinations must be made in liquids containing a definite alcohol concentration, and the reaction must be carried out in the dark.—Henry **Hubert**: The diabase veins of western French Africa.—D. **Eginitis**: The recent earthquakes at Thebes. The village of Thebes was ruined by an earthquake on November 17, 1914, this being the fourth time this has happened within the last sixty-two years. The seismographs at Athens due to this earthquake are discussed. The three violent shocks of the first day have been followed by a series of smaller ones. Up to the middle of December more than 500 shocks coming from the same epicentre have been recorded at the Athens Observatory. This long duration is one of the characteristics of earthquakes in this part of Greece.—E. M. **Martel**: The Mammoth Cave, Kentucky. Diagrams of four transversal sections are shown, showing the arrangement of the three principal stages.—L. G. **Seurat**: The morphology of the female genital apparatus of the Spiruridæ.

THE WAR.

THE war drags on; and we are learning to understand the mentality of the German race more completely. It is being revealed in various forms. The policy always adopted by the bully, of attempting to terrorise by attack on defenceless persons, is shown by the shelling of the watering-places of Yorkshire, resulting in the murder (for that is the only word which fits the case) of 103 harmless people. "Murder" should certainly have been the verdict, although it was disallowed by the coroner; for although the commanders of the German vessels may not yet be known by name, a verdict of murder would have rendered them subject, when captured, to trial by a British jury. The cowardly and murderous onslaught has led, we are told, to rejoicings in Berlin. It is as we feared; the German nation has lost its moral perspective. They may rest assured, however, that there will be no similar reprisals on the side of the Allies. We do not revenge ourselves on innocent women and children.

It was scarcely worth while, perhaps, for the French universities and British men of letters and science to have replied to the self-named "intellectuals" of Germany. Neutral countries have already made up their minds from the perusal of official documents, not the least important being those from German sources, that the war is one of pure aggression on the part of the Germans. We hear from Switzerland, from America, and from Scandinavia that the public in these countries now pay no attention to German polemic literature. If they had conceivably had any case, they have given it away by their inhuman acts, which have raised a sentiment of disgust in every civilised mind.

We look with contemptuous amusement at the childish renunciation of foreign honours by our Teutonic colleagues in science. That is even the attitude of some of their own countrymen; Prof. Verworn, of Bonn, writing in the *Berliner Tageblatt,* describes it as unworthy of German men of science, and Profs. Waldeyer, Martin, and Orth have protested against the foolish conduct of their countrymen. We can only shrug our shoulders and say that the loss is theirs, not ours.

We have also been disillusioned by the words of the well-known Celtic scholar, Prof. Kuno Meyer, late of Liverpool University, now of Berlin, who has acted, and is acting, as an agent of the Prussian Government in attempting to excite the feelings of Nationalist Ireland and of American Irish in favour of Germany. Here is a man, eminent in his own subject, speaking English without an accent, who has spent thirty years of his life in an English university, a man who has (or had) many intimate friends in this country and has been received in many English households as a friend, turning out to be a dastardly enemy. Savages have a code that, after breaking bread in a man's house, it is treacherous to war against him; not so Prof. Kuno Meyer. This is evidently another instance of "Kultur." It behoves us to treat with suspicion all naturalised aliens of Teutonic extraction; and yet we know, alas! that in doing this, we are acting unjustly in some cases. But the individual, in these days, must suffer for the crimes of his countrymen. It is such instances as these which make the Allies determined that such a race must be deprived of power to do further mischief, whatever be the cost in life and money.

Some correspondence has appeared in the Press as to the relative merits of German contributions to science, as compared with the achievements of members of other races. The discussion is perhaps a useful one; for there is little doubt that the German estimate of the scientific ability of their own people is a much exaggerated one. The statement made in a previous issue of NATURE (October 8) that German science has not been remarkable for originality appears to meet with general assent. We in England have been always more intent on welcoming a discovery than in inquiring into the nationality of the discoverer; indeed, it is a common saying that science is international. But we are beginning to revise our verdict. Prof. Karl Pearson, Prof. Sayce, and Sir E. Ray Lankester have shown that Germany has played only a small part in inception of scientific truths, although by organisation she has greatly extended their application. Huxley and Bywater held this view, each as regards his own subject; and it appears to be shared by geologists, physicists, and chemists. "Ausarbeiten" is the goal of the Germans; the inventive faculty has not been their strong point. Perhaps a mixed race gains in original ability; both flint and steel are necessary to produce a spark. But one thing the German man of science knows how to do well—to exalt the achievements of his nation, often by ignoring that of others. This has probably been done in many cases without intention; it appears to be one way in which German patriotism manifests itself.

Dr. Hugo Schweizer, an Americanised German,

writing in the *Popular Science Monthly* (December issue), maintains the thesis that the development of science owes much, if not all, to the stimulus of the demands of Prussian military requirements. Naturally, his examples refer entirely to technical applications of science. And here, again, if they are analysed, it can be shown that the development of which he boasts is due to concentrated and organised effort; of the starting-points of the manufactures which he cites, few are of German origin. They have been appropriated and worked out, no doubt, in order to place the materials of war at the disposal of the German Army; but it is not proved that the necessities of peace are not more effective as a stimulus to progress than those of war. To take only one instance, it is probable that sooner or later all our railways will be electrified; but that would not suit military exigencies; each train must have an independent motive power; and so long as German militarism persists, we may reckon that German railways, at least, will not be run by the electric current.

The aims of science are the antitheses of those of war. It is the object of pure science to attempt to know and correlate natural phenomena, and its devotees are inspired by an insatiable curiosity; it is the object of applied science to make use of that knowledge for the benefit of mankind. To degrade its applications to the destruction of life and property is the most unscientific act of which a people can be guilty.

LORD AVEBURY: BANKER AND NATURALIST.

Life of Sir John Lubbock, Lord Avebury. By H. G. Hutchinson. Two vols. Vol. i., pp. xiv + 338. Vol. ii., pp. x + 334. (London: Macmillan and Co., Ltd., 1914.) Price 30*s.* net, 2 vols.

SIR John Lubbock was a notable figure in the period of our scientific history which saw the birth and development of evolutionary theory. If the part he played was not as weighty as that of Lyell, of Huxley, and of Hooker, it was even more effective. For he spoke as a man of affairs and with convinced sincerity; and if he was "a great banker amongst scientists" so much the better. Like Spottiswoode, he could show that a scientific mind was capable of business success; both, in fact, were members of the X Club, that mysterious body, impossible of successor, which was said "to govern scientific affairs," and "not to do it badly"; Lubbock was, indeed, its last surviving member.

Biography is an art in which any great measure of success is rare. For it demands that the subject should reveal itself while we remain almost unconscious of the hand of the artist. Mr. Hutchinson is more artless, and rivals Boswell in the feat of giving us himself as well. He could not draw on letters, the biographer's best resource; to Lubbock, he explains, "exposure of the holy sanctities of his being would have been impossible." Apology seems unnecessary, then, for Lubbock's "attending the services at the village church" and reading his Bible, though Huxley did the latter and to some purpose. The explanation is found in the belief "that there was some room, after all, among the atoms for the spirits." After this it is pleasant to know that 40,000 people attended the last race meeting in his father's park at High Elms; amongst them were the Archbishop of Canterbury and the Lord Chancellor, evidently spirits. Picking holes is rather futile. But two statements, at any rate, catch the eye as perplexing. Sir Gabriel Stokes (i., 85) is made to say that the chance of laying the first Atlantic cable was "only $(\frac{19}{20})20 = \cdot 3585$, or about 2 to 1 against it"; obviously this should be $(\frac{19}{20})^{20}$, and one wonders who and what was the "Consul D'État" (ii., 23) whom Lubbock went to see in Paris.

Mr. Hutchinson says reasonably enough that to anyone who did not know Lubbock's "serene, unruffled calm" one might easily conceive him as "an animated hurricane." Even to read the life is like travelling in an express train with but a blurred impression of successive landmarks. Only one of his many personalities needs treatment here, and that requires a little more justice than it has always received.

Lubbock's father was a mathematician of some repute, and treasurer of the Royal Society when the Duke of Sussex was little more than nominal president. His mother notes that at the age of four "His great delight is in insects." He was some four years at Eton, where he was thought "exceedingly inaccurate," but that must be taken in an Etonian sense. "Against the advice of his tutor he read some natural history and geology." At the age of fourteen his father was obliged to make use of him in the bank. "He and I with a worthy old clerk carried on the business." Lubbock thought that "beginning so early gave him an instinct for business," and well it might. At the age of nineteen he made a minute time-table for his day from half-past six to midnight. Science and literature fill the compartments; 9.30 to 10 was devoted to "sermons (if I read them any later they invariably send me to sleep)." Such a discipline would have sterilised most men. But his neighbour Darwin gave him a wider training.

He did much sound and valuable work in entomology, and at the age of twenty-four was elected into the Royal Society. He had already made the acquaintance of many well-known scientific men.

And then in 1860 came the "Origin." Lubbock warmly grasped the principle of evolution. The same year he saw Boucher de Perthes at Abbeville; he satisfied himself as to the human manufacture of its stone implements, and that they were contemporary with the mammoth. In 1865 he published "Prehistoric Times." Darwin wrote, "Though you have necessarily only compiled the materials, your general result is most original." He was then contesting Maidstone and was advised to keep the book back, but thought it "would be scarcely honourable"; it is believed to have increased the majority against him. It is rather remarkable that Mr. Hutchinson thinks his writing wanting in "style." Darwin in this respect, and he was no mean judge, thought the book "perfection." A little later he showed that our bronze implements were not, as supposed, of Roman date, and he established against Ferguson the prehistoric age of Stonehenge and Avebury. He secured what was left of the latter from destruction by the builder.

The "Origin of Civilisation" followed in 1870. Frazer admits that it contributed to his own opinions as to the evolution of religion and society, and that Lubbock had anticipated him as to the relation between magic and religion, and the priority of the former.

In his later life he occupied himself with geology and botany, but always from an evolutionary point of view. The former won him the Prestwich medal. He was a keen observer; when exploring with Huxley and Tyndall the lake-dwellings in the Lake of Geneva, he dived more than once after a supposed stone axe, and he produced consternation amongst Swiss geologists by finding nummulites in a rock mapped as Triassic. His botanical work has been thought to deal too much with the trite and obvious, and perhaps it was so to the instructed. But our scientific knowledge is too much a thing apart from ordinary life, and Lubbock wanted to extend its field; no one could be more competent for the task. His "British Wild Flowers considered in Relation to Insects" would be a revelation to most people. The later "Notes on the Life History of British Flowering Plants" show that mere "collecting" leaves the problem of every species untouched. In his great work on "Seedlings" he availed himself of the help of others; it breaks new ground which still awaits a generalisation.

In literature he has been subject to the same criticism. The answer is the wide-world popularity of his writings; the "Pleasures of Life" "was the first book ever published in the Soudan." "Best Books" are on every bookstall.

Lubbock was an optimist. He enjoyed life and laboured that his fellow-creatures might enjoy it more. To that end, as Lord Buxton tells us, he could suppress "interest and desire" if they conflicted with his purpose. His life has been described by one who knew him well as "one of the most useful that was ever lived." It is a worthy epitaph.

ARBORICULTURE AND FORESTRY.

Trees and Shrubs Hardy in the British Isles. By W. J. Bean. 2 volumes. Vol. i. Pp. xvi+688. Vol. ii. Pp. vi+736. (London: John Murray, 1914.) Price 42*s.* net, two vols.

THE appearance of this book, the work of the Assistant Curator of the Royal Botanic Gardens, Kew, will be welcomed by all who are interested in hardy trees and shrubs, for it is the best and most comprehensive work upon the subject that has appeared since the advent of "Loudon's Encyclopædia of Trees and Shrubs," more than seventy years ago. The need for such a work has long been evident, for Loudon's book is hopelessly out of date, not only by reason of the large number of plants which have been introduced in the intervening years, but also on account of the many changes which modern research have necessitated in nomenclature. Since Loudon wrote his famous book the rich regions of western North America, Chile, China, Japan, and other countries have been ransacked for horticultural treasures, and the scope of the present work places good descriptions of these and other woody plants in an easily available form.

The book is divided into two parts, the first being devoted to chapters on cultural requirements and various special subjects, whilst the latter is given up to descriptive matter. The opening chapter gives an interesting epitome of the history of the introduction of hardy exotic trees and shrubs to the British Isles between the middle of the sixteenth century and the present date, due credit being given to the many nurserymen, collectors, and private individuals who encouraged and made such work possible. Following this are chapters upon propagation, hybridising and selection, nursery work, transplanting, arrangement of shrubberies, staking and other means of support, pruning, care of old trees, evergreen trees and shrubs, climbing shrubs, pendulous trees, fastigiate or erect-branched

trees, dwarf trees and shrubs, trees and shrubs with handsome fruits, handsome-barked trees and shrubs, variegated and coloured trees and shrubs, fine-foliaged trees and shrubs, autumnal colour in trees and shrubs, early- and late-flowering trees and shrubs, street planting, hedges, trees and shrubs for wet places, shrubs for dry positions and poor soils, shrubs for shady places, and trees and shrubs for the seaside.

All the necessary general information upon each subject is given in a clear and concise manner, but special details of culture required by individual plants are given later in the descriptive part of the work. The early part of the book will appeal specially to the purely practical man, but the more important part, which commences at page 113 of vol. i., and is continued to the end of the second volume, will be found to be of value to everyone who is interested in hardy ligneous plants, whether from the point of view of the botanist, student, landowner, gardener, or forester. Descriptions are given of all the species of trees and shrubs, so far identified, which are of any importance in the British Isles, with many of the most distinct botanical varieties, and in almost every case the descriptions have been prepared from living plants in the Kew collections. The arrangement of genera and species is, as far as possible, alphabetical, this arrangement only being altered where two species are very closely allied, and the distinguishing features can be more clearly defined when the descriptions run concurrently. An ample index of some forty pages, however, atones for this little digression.

One system of description obtains throughout the work. The name of each genus appears in large capitals with the order to which it belongs in small capitals. Then follows a general description of the genus with distribution and special cultural directions. The principal species are then described, each description being headed by the scientific and common names, and, when necessary, the chief synonyms, together with an indication as to where a good botanical drawing of the plant can be found. The following description gives an idea of the general style of the work:—

L. TRAGOPHYLLA, *Hemsley*. CHINESE WOODBINE.
(Bot. Mag., t. 8064.)

A deciduous climbing shrub, with smooth young shoots. Leaves oval, tapering about equally to both ends; 2 to 4½ ins. long, ¾ to 2 ins. wide; slightly glaucous above, glaucous and slightly downy beneath. The uppermost pair of leaves are wholly united by their bases, forming a diamond shape; the next pair lower down are less united, but still clasp the stem; still lower down come short-stalked leaves. Flowers bright yellow, produced in a terminal head of ten to twenty. Corolla-tube 2½ to 3½ ins. long, slenderly cylindrical, smooth outside, downy within; across the two lips the corolla measures 1 in. or more in width. Berries red.

Native of the province of Hupeh, China; discovered by Henry and introduced for Messrs. Veitch by Wilson in 1900. It flowered for the first time at Coombe Wood, in July, 1904. L. Caprifolium is closely related, but differs in its whorled flowers and in the smooth interior of the corolla-tube. L. tragophylla is the largest flowered and most showy of the true honeysuckle (Periclymenum) group. It likes a deep moist loam, and Mr. Wilson recommends for it a semi-shaded position.

It will thus be seen that the descriptions are clear, concise, and ample for all practical purposes. Botanical terms have been avoided whenever possible, but in such a work they could not be excluded, and for the benefit of readers who are unfamiliar with such terms an excellent glossary precedes the commencement of part ii.

Mr. Bean's intimate connection with the Kew collections for upwards of a quarter of a century, coupled with his keen powers of observation and critical knowledge of everything connected with hardy ligneous plants, offer a sufficient guarantee for the thorough trustworthiness of the book, and it should find a place in the library of every lover of trees and shrubs, whilst nurserymen and others would do good work, and indirectly pay a graceful compliment to the author, by adopting it as the national standard of nomenclature.

The publisher has done his share in a manner worthy of the firm, and Mr. E. J. Wallis and Miss E. Goldring are to be complimented upon the photographs and drawings. Both author and publisher are to be congratulated upon the production of a book which is likely to be the standard work upon trees and shrubs for at least half a century.

W. DALLIMORE.

FIRST PRINCIPLES OF MATHEMATICS.

Neue Grundlagen der Logik, Arithmetik und Mengenlehre. By Julius König. Pp. viii+259. (Leipzig: Veit and Co., 1914.) Price 8 marks.

THIS is an interesting and very readable book which, with a comparatively small amount of new notation, discusses the elements of the theory of sets. The most original section is that on "logical forms"; this is a theory of induction more or less corresponding to Whitehead and Russell's theory of types, and axioms of reducibility. The most controversial chapter is that on Zermelo's axiom, and the principle of selection; here the author is very ingenious, but, we fear, not very convincing. Given a class (a, b, c, . . .) he treats the term "a or b or c or . . .", that is (nearly)

in ordinary language, "any arbitrary element of the class" as a definite object. He quite rightly observes that this is not an element of the class; but he goes on to say, "In spite of this 'or,' '*a* or *b* or . . .' is a clear experience of our thinking." Of course it is for certain small finite sets, but if we try to extend it, as the author does, to infinite sets, there seems to be a risk of begging the question at issue in the theory of selections. What we want is to justify, and generalise, so far as we can, such expressions as "*take* an arbitrary point on the given circle," "*take* an arbitrary prime number," and so on.

These two examples are of the same type, but they will serve to show part of the difficulty of the question. When a circle is drawn, few would object to the postulate "It is possible to choose an arbitrary point on the circle," it seems so obvious intuitively. But now consider the set of primes, and suppose them arranged in order of magnitude; the millionth of them is a definite existent prime, but what do I mean by "taking" it? I cannot take it in the same sense as I can take two or three or 101, because it has not, so far as I know, been calculated; so I must consider "taking" it as specifying it by a description, belonging to it and to nothing else. But what is there in the general definition of a class to enable us to take an element of it, in the sense required for the theory of selections? How can I "take," for instance, an arbitrary sound or colour? What sort of set (mathematically) is that of pure musical tones? Can we arrange all periodic sounds ordinally? and so on.

It is rash for an outsider to intrude upon such a thorny topic, but we cannot help surmising that Zermelo's axiom (or an equivalent to it) may be like the axiom of parallels in geometry; not necessarily true, but leading, if assumed, to a large body of valuable conclusions. In geometry we have practically only two alternatives to the parallel axiom; it took a long time to discover them, and the only way to disprove the truth of Zermelo's axiom is to find a case that contradicts it. Meanwhile, a safe course is to imitate Whitehead and Russell, and introduce the axiom as a working hypothesis.

It may be noticed that the author pays a warm tribute to Russell's important contributions to the theory of logic. There can be no doubt that they have done much to advance clear thinking, and avoidance of fallacies.

The work is, unfortunately, not quite complete, as the author died before finishing the last chapter. His portrait is given as a frontispiece.

G. B. M.

EGYPTIAN FOLKLORE.

Amulets, Illustrated by the Egyptian Collection in University College, London. By Prof. W. M. Flinders Petrie. Pp. x + 58 + plates. (London: Constable and Co., Ltd., 1914.) Price 21*s.* net.

PROF. PETRIE is certainly right in suggesting that the subject of Egyptian amulets is one that appeals to the reader of folklore as well as to the Egyptologist. In amulets we are dealing with magic in a concrete form, and it is a problem of no small fascination to recover the meaning which underlay the origin and use of each. It will be obvious that a wide knowledge of Egyptian religious belief is essential, if we are rightly to understand those amulets of peculiarly Egyptian origin. But where the texts fail us we are necessarily thrown back upon comparison with amulets of other races, particularly those of Central African tribes. It is here that folk-lore finds its opportunity, for it not infrequently supplies a clue to the meaning of an otherwise obscure or doubtful symbol.

In the work before us Prof. Petrie has combined both these converging lines of research in a remarkable degree. His material is mainly drawn from amulets in the University College collection, which, as the result of excavation and purchase carried out for many years, he has made as varied as possible; but he has also supplemented these with reference to examples in other collections. He has consequently been able to describe some two hundred and seventy different kinds of amulets, and his classified list, largely the result of pioneer work, places the study upon a scientific basis. Under each heading the Egyptian name is given when known, its meaning and use are suggested, varieties, periods, and material are noted, and references given to the collections where specimens occur.

In his discussion of general principles, the author is certainly right in dismissing with scant sympathy the "confidence theory" and the "faith theory," for though these undoubtedly explain the actual efficacy of amulets, they are entirely out of place as explanations of origins. By far the greater number of Egyptian amulets are most satisfactorily interpreted on the principles of sympathetic magic, or in Prof. Petrie's own phrase, by the "doctrine of Similars." The whole body of funereal magic, as practised by the ancient Egyptians, partakes of this general character, and it is but natural that amulets, whether worn by the living or the dead, should fall under the same category. It is only when we come to detailed explanation that lines of underlying

thought or feeling sometimes remain uncertain and obscure. For in sympathetic magic the most obvious connection is not necessarily that which actually led to the employment of a particular object or substance. To take a single example. Prof. Petrie compares the Egyptian series of animal-claw amulets with a leopard's claw from Central Africa (Leicester Museum), and he explains it as an amulet for protection from wild beasts. This explanation at first sight commends itself as not only reasonable but obvious. Yet when we turn to Burton's "Central Africa" we find that in Central Africa the "mganga" or sorcerer might employ a leopard's claw for curing disease. The spirit or ghost with which the sick man was believed to be possessed could by drumming and dancing be driven out of him into a leopard's claw, and when this was hung to a "devil's tree" the disease-spirit was laid. It is true that the leopard's claw was not essential to the process, for in its place a peculiar bead, a nail, or even a rag could be used as the medium for exorcising the disease. But the fact of its employment for this purpose in Central Africa at least suggests the possibility of some other explanation of its use in ancient Egypt than the fear of attack by wild beasts. In several other cases the possibility also suggests itself that the original reason for the use of an object in primitive magic may not have coincided with its later associations when it had survived as an amulet worn on the person.

We have merely referred to these points as indicating the wide interest attaching to the study of the subject. We cannot conclude without a reference to the excellent photographic plates, as well as to the chapters on the use of amulets, in which not only the student and collector, but also the general reader will find much to interest him. L. W. K.

OUR BOOKSHELF.

Science and Religion. By Seven Men of Science. Pp. 138. (London: W. A. Hammond, 1914.) Price 1*s.* net.

IN a week of November last, a series of seven addresses upon the mutual relations of science and religion were delivered by scientific men of distinction at Browning Hall, Walworth Road, London. The lecturers were Sir Oliver Lodge, Prof. J. A. Fleming, Prof. W. B. Bottomley, Prof. E. Hull, Dr. J. A. Harker, Prof. Sims Woodhead, and Prof. Silvanus P. Thompson; and their remarks are now published in convenient and cheap form in the little volume before us.

It would be easy to discuss at great length many of the statements made in these addresses, but no useful purpose would be served by doing so here. In the opening address Sir Oliver Lodge made the definite announcement that he had conversed with departed friends "as I could converse through a telephone with anyone in this audience now"; but apparently it is not everyone who is capable of receiving this evidence of survival of existence. The only evidence upon which a man of science cares to base a conclusion is that derived from his own observations; but in spiritual matters conviction takes the place of phenomenal knowledge. The poet and the metaphysician feel that certain thoughts are true, and the ideas thus conceived are to them as definite facts as any inferences depending upon the use of the senses. Such feelings do not admit of objective demonstration, and cannot, therefore, be measured by the standards of natural or physical science. They belong to another world, which the describer of phenomena may contemplate, but is usually unqualified to enter.

It is not to be expected, therefore, that these addresses will bear the severe criticism to which observations and theories are subjected in scientific circles, and serious students of philosophy are not likely to be impressed by most of the evidence adduced of intelligent design in Nature. The somewhat shallow treatment of this profound subject is, we suppose, explained by the popular audiences to which the addresses were delivered. The book is interesting as a declaration of men of science to the reality of religious conviction; but it may be doubted whether any particular significance should be attached to their views upon questions outside the domain of objective truth in which alone they can give authoritative testimony.

A Study of the Circular-arc Bow Girder. By Prof. A. H. Gibson and E. G. Ritchie. Pp. viii+80. (London: Constable and Co., Ltd., 1914.) Price 10*s.* 6*d.* net.

THIS book treats of the difficult problem of girders forming a circular arc in plan such as are often used to support the balcony of a theatre. The principles on which the general problem may be solved are given in the early portion of the volume, and are amplified from a paper read by Prof. Gibson before the Royal Society of Edinburgh in 1912. Values of the end fixing moments and reactions have been calculated for the more important practical cases, and these values, together with typical bending moment diagrams which are given, will be found useful aids to the designer. The authors have carried out experiments with a view of checking the theoretical investigation, and remarkable agreement is shown. Up to the appearance of this volume there has been no data available for the torsional rigidity of beams of ordinary commercial section, and part of the investigation undertaken by the authors has been the experimental determination of the product CJ (*i.e.*, modulus of rigidity × equivalent polar moment of inertia) for such sections. Mathematical calculations in such cases present insuperable difficulties, and the experimental work given in the book is an interesting and valuable contribution

to our knowledge of materials. A chapter on the general principles of design of the bow-girder is included, and will be of service to the practical designer, to whom a considerable portion of the volume will be sealed on account of necessarily complicated mathematical treatment. The authors may be congratulated on the success with which they have solved a very difficult practical problem.

Spectrum Analysis, applied to Biology and Medicine. By the late Dr. C. A. Macmunn. Pp. xiv + 112. (London: Longmans, Green and Co., 1914.) Price 5*s.* net.

THE late Dr. Macmunn belonged to a class of which British science does well to be proud: the class of men who, notwithstanding the arduousness of their professional labours, find or make time to engage in research. Born in Ireland and educated at Trinity College, Dublin, Macmunn practised medicine for twenty years at Wolverhampton, and during that period published his researches in the application of spectrum analysis to biology and medicine. The present work, as we learn from the preface by Prof. Gamble, was begun and continued between attacks of severe illness and was left in an unrevised state.

Dr. Macmunn was an early worker in the field and deserves the credit of the pioneer. Although no remarkable discovery attended his efforts, he contributed valuable observations on the nature of the various colouring matters both in animals and in plants. He demonstrated that the pigments of not a few animals contain chlorophyll: a demonstration confirmed in certain cases by the discovery of algæ living symbiotically in the tissues of these animals.

Although the professional man of science who specialises in this department of research may not need to consult this work, we welcome it and hope that it may be widely circulated and read, for it is a worthy record of the labours of one who loved research and ensued it with ardour and success.

The Geographic Society of Chicago, Bulletin No. 4. The Weather and Climate of Chicago. By Prof. H. J. Cox and J. H. Armington. Pp. xxv + 375. (Chicago: University of Chicago Press, 1914.) Price 12*s.* net.

MESSRS. COX AND ARMINGTON have made a statistical study of the climate of Chicago of extraordinary detail. The result is valuable as a book of reference, but cannot be described as easy reading, chiefly owing to one hundred and forty-five tables intercalated in the text. Records of temperature extend back to 1830 and of rainfall to 1843, but the series are not homogeneous, there being several changes even in the shorter period 1871 to 1911, which is adopted for normal values. Normals, however, are not regarded as so important as the occurrences of abnormal conditions and rapid variations which render the climate healthful and invigorating—and with a temperature range from $-16°$ to $+103°$ F. there is abundant room for rapid changes. The extremes would be even greater but for the near neighbourhood of Lake Michigan, as is well shown by a study of the lake breezes, and by temperature records at different distances from the shore. The abnormal periods are further considered, not merely locally, but as part of the weather of the whole States, and this aspect is illustrated by reproductions of the daily synoptic charts, unfortunately sometimes so small as to be almost undecipherable. Full use is made of isopleth diagrams for exhibiting hourly variations; a feature with less to recommend it is the replacement of departures from normal temperature by accumulated departures, which are said to be "more vivid"—though it is not self-evident that an "accumulated" departure of $+1262°$ conveys more to the mind than a mean departure of $+3\frac{1}{2}°$.

LETTERS TO THE EDITOR.

Experiments on Hay Infusions.

DR. BASTIAN'S interesting experiments suggest further considerations, particularly as to the osmotic effects of solutions of different strengths and temperatures. A solution of hay made at a higher temperature will probably be a stronger solution containing more soluble matter, and also more silicate from the glass. A solution kept for a fortnight may evaporate and become more concentrated. Does one concentration produce Zooglœa, and a greater concentration produce spores?

Am I right in thinking that the general effects of increasing concentration are crystallisation, precipitation, an increasingly dense protoplasm, a thickening cell-wall, and cell subdivision? Is free-cell formation another process brought about by increasingly concentrated solutions? Is dilution, and especially dilution with warm water, the necessary osmotic condition for bursting the cell-wall and liberating naked or amœboid forms? Can we explain the phases of an organism in terms of its previous history and present conditions?

Where a change takes place in the population of a pond this may, of course, be due to individual transformations of tadpoles into frogs with rise of temperature, or it may be due to differential rates of increase or death, as when in a dry summer sticklebacks die and frogs survive. It is not quite easy to disentangle the transformation and the survival processes when the organisms are minute.

HUGH RICHARDSON.

Stocksfield-on-Tyne, December 31, 1914.

THE ASCENDING SPIRAL.[1]

MANY years ago the author of this interesting and stimulating book became impressed with the widespread distribution of "spirals" in nature. He has persistently followed the clue in the hope of discovering the significance of this form, which is ever-recurrent, especially in the realm of organisms. Many others have been on

[1] "The Curves of Life. Being an Account of Spiral Formations and their Application to Growth in Nature, to Science and to Art; with Special Reference to the Manuscripts of Leonardo da Vinci." By T. A. Cook. Pp. xxx+479. (London: Constable and Co., Ltd., 1914.) Price 12*s.* 6*d.* net.

the same track, and the author refers to Sir John Leslie, Canon Moseley, Prof. Goodsir (on whose tomb in Edinburgh a logarithmic spiral was graven), and Mr. A. H. Church, whose studies of phyllotaxis are well known. It is a track to be followed. A symbol, which adorns the cover of the book before us, is held by the author to indicate that Chinese philosophy had adopted the logarithmic spiral as a symbol of growth so long ago as the twelfth century, and several investigators

are still engaged in the twentieth century in the search for that symbol (which we now call a formula). Nor can we forget that Leonardo da Vinci, whose manuscripts the author has studied, was greatly interested in spiral shells—of both living and extinct types, for he was one of the first to appreciate fossils—and used them in his art. Mr. Cook brings forward evidence that the spirals in natural forms made a deep impression on the early artists; and the development of this idea forms a very interesting part of the book, the parallelism worked out between shells and staircases being especially skilful.

Spirals are sometimes seen in the inorganic domain—in whirling dust, in waterspouts, in starry nebulæ, and in certain crystals. But it is in the organic realm that they abound, and Mr. Cook's record of them is impressive. In Foraminifer and Nautilus, Venus Flower Basket and the horns of an antelope, the typical spermatozoon and the egg-capsule of the Port Jackson shark, the umbilical cord and the cochlea of the ear, the arms of a Lamp-shell and the trachea of an insect, the fir-cone and the Turbine shell, the antherozooid of a Cycad and the stem of the honeysuckle, the spiral vessel of a melon and the twisted fibrils of the muscle-fibres of some molluscs, the fruit-stalk of Cyclamen and the inflorescence of Forget-me-not, the leaves on the stems which find in a Fibonacci series the minimum superposition and the maximum exposure, the seaweed Vidalia like a curled shaving and the still more beautiful staircase of the rare *Riella helicophylla* from Algiers, the twisting tendrils of the vine and the horns of a ram, the double spiral of osseous lamellæ in the shaft of long bones and the staircase within the skate's intestine, a Spirochæte and the muscle-fibres of an arteriole! Sometimes their utility is plain, *e.g.*, in assisting in the distribution of seeds and sperms; or in acting like a spring, as in tendrils and tracheæ; or in allowing many structures to be crowded in a small space, as in buds; or in giving architectural strength as in the lamellæ of bones. Mr. Cook points out shrewdly that there is very often a suggestion of growth under resistance, which might be illustrated by the young leaves in a bud, or the spiral fibre of insect tracheæ, or the Venus Flower Basket building itself up on the floor of the Deep Sea; and we like Mr. Schooling's suggestion that the ϕ proportion is an expression of economy of form.

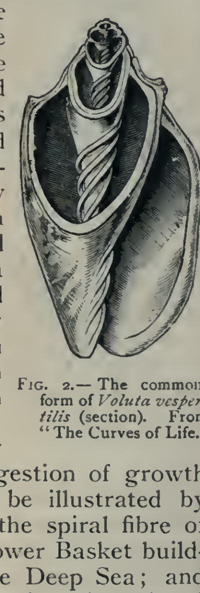

FIG. 2.—The common form of *Voluta vespertilis* (section). From "The Curves of Life."

There is no doubt that Goodsir had a definite expectation that some physiological law of growth or "production" might be discovered by a further study of the recurrent spiral form. We are indebted to Mr. Cook for re-directing attention to this quest.

There are, of course, numberless logarithmic spirals, and Mr. Cook, with assistance from Mr. Mark Barr and Mr. William Schooling, has determined that the form which is most descriptive of those in organic nature is one which he calls the ϕ spiral—one in which the ratio of increase (ϕ) is $(1 \pm \sqrt{5}) \div 2$, or 1·618034, the sum of any two terms being equal to the next term. This kind of spiral is illustrated approximately by many very successful forms of organic growth. We must emphasise the word approximately, for

if the ϕ ratio be that of "perfect growth," it is one towards which vital architecture *tends* rather than one which it reaches. Even the Nautilus shell is only an approximation to it, and this to Mr. Cook is half the charm. For the approximateness reveals the *endeavour*, which arouses our sympathy, while mathematical exactness leaves us dull. Life is like an artist, full of individual variability. "Perfect beauty, like natural growth, implies irregular and subtle variations."

But the ϕ proportion is not only a descriptive formula for natural growth, it shows itself in statues and in the proportions of pictures. It looks as if the secret of one type of successful growth (of course, there are other non-spiral architectural creations) echoed in the artist's expression of the beautiful, and even in our appreciation of it. Perhaps the logarithmic spiral with the Pheidias ratio is an "objective" element in beauty, not merely in the sense that mankind was literally brought up on spirals—in days when spiral phyllotaxis was a problem by no means academic, when the coils of the succulent bulb and the toothsome whelk had an interest much more than æsthetic, when the spiral conch called the tribe to war—and when, for we need not expatiate, the spiral mode of growth became the Swastika symbol of good growth and good luck. We should be inclined to press the point that spiral architecture became prevalent in the evolution of organisms because it was, for certain conditions, particularly fit. It was a successful architectural style, discovered among the unicellulars, and always kept, with the sublime conservatism of vital evolution, *available*, for whatever experiment in internal structure or external form might be demanded or prompted by the exigencies of the situation. The secret was much too good to lose. But Man is conservative as well as Nature, and he began to accumulate pleasant feelings in association with all manner of spirals. But Mr. Cook will not be content with any position of this sort. "If ϕ in some way describes the principle of growth, which is one revelation of the spirit of Nature, would not the artist most in touch with Nature tend to employ that proportion in his work, even though he was not conscious of its exisence?" We confess to wishing to work for a while longer with the hypothesis that the artist uses the ratio of Pheidias because it figures largely in Nature, and thus in Man's upbringing. But Mr. Cook's view is subtler, that Leonardo and the Nautilus exhibited a dominance of the ϕ spiral in their respective masterpieces because they were both artists. We like the spiral shell, and still more the spiral staircase of Blois, not merely because impressionable mankind was brought up on spirals, but because the spiral in question represents one of the inmost experiences of life itself—an endeavour after perfect growth. This seems to be Mr. Cook's view, but we are sceptical.

Mr. Cook has given us a delightful study, eloquent of patience in collecting examples of spirals, of delight in measuring them by the Pheidias rule, and of quiet meditation over "the unspent beauty of surprise" and the worldwide treasures of significant form. The personal note is strong and it is pleasant, but we have sometimes wished, as we read the book, that the author had been more methodical, and less swift to move from one problem to another. For there are many problems. (1) There is the question, which Mr. Cook has in part answered, as to the various architectural types—spiral and otherwise—exhibited by organisms—a question to which Haeckel paid considerable attention long ago in his discussion of "promorphology." (2) There is the question of the varied utility of the spiral, which gives it its survival-value. To answering this Mr. Cook has made some contribution. (3) There is the difficult problem of the forces at work in the genesis of the spiral form, of the physical forces or the properties of matter that determine shape. A preliminary (as it were, aeroplane) survey of this borderland between morphology and physics will be found in Prof. D'Arcy Thompson's brilliant presidential address to Section D of the British Association in 1911; and a paper by the same naturalist on the shapes of eggs (Nature, vol. lxxviii., pp. 111, 158) is also important. (4) There is the question of the recurrence of the logarithmic spiral in human works of art. Nor should we forget the spider's spiral, the making of which is to be ranked beside building nests and shaping honeycomb, not beside the secretion and moulding of shells. (5) Then there is the problem of why these spirals please us, and are joys for ever. In regard to which it should be carefully noted that there are (*a*) physiological, (*b*) intellectual, and (*c*) imaginative or sympathetic factors in our appreciation of beauty. (*a*) There are shapes that sing, and produce pleasant eurhythmic echoes in our bodies. (*b*) There are shapes which arouse happy associations, and others of which the adaptiveness never fails to please. (*c*) There are others, again, which strike a deeper note, in which we recognise a triumph of life over its materials and difficulties. It is in the contemplation of these achievements that the artist in us is thrilled most deeply, sharing a vicarious triumph.

ICEBERG OBSERVATIONS.[1]

After the loss of the *Titanic* in April, 1912, had directed attention to the dangers from ice in the North Atlantic, the Government and the shipowners concerned chartered the *Scotia* as an experimental ice-observation vessel to cruise to the north of the trade routes. The *Scotia*, fitted with wireless and carrying three investigators and two Marconi operators, was commanded by Captain T. Robertson, her former captain in Bruce's Antarctic expedition. Her work was carried on from March to August, 1913, and proved so useful that the year following she was replaced by a specially-built ice-patrol boat of larger size, and so perhaps more suitable for the work, though it would be

[1] "Ice Observation, Meteorology and Oceanography in the North Atlantic Ocean." Report of the work carried out by the s.s. *Scotia*, 1913. Text, pp. 142. Price 4*s*. 6*d*. Map and Charts. Price 2*s*. 6*d*. (H.M.S.O., 1914.)

difficult to construct a stronger, handier, and better ice-boat than the *Scotia*.

The most generally interesting parts of the detailed reports in this volume are those relating to the detection of icebergs by temperature observations. A Callendar self-recording electrical resistance thermometer held at a depth of 2 ft. below the surface failed to indicate any effect of icebergs on the temperature of the sea. In most cases the passage of the *Scotia* by an iceberg did not correspond with any hump or depression in the temperature curve, and when it did it was impossible to distinguish these from the ordinary variations in the temperature of the sea. As this thermometer, which indicated trustworthily variations of $1/10°$, was unaffected by passing icebergs it would be useless in practice to employ such a method of detection. In fact, any variation unrecognisable by an ordinary thermometer would be valueless to the seaman. In his investigation on the *Montcalm* Prof. Barnes came to the conclusion that the real effect of an iceberg on the surrounding water is to warm it slightly. Mr. G. I. Taylor found indications of this, but the effect could not be utilised to detect the presence of bergs on the Newfoundland Banks because the temperature of the sea in that region undergoes small rises in places independent of icebergs. Prof. Barnes found his striking indications of these rises of temperature near inshore, but the *Scotia,* on the other hand, was at work hundreds of miles off the land. It cannot have been that the electrical thermometer of the *Scotia* failed to detect these changes, since check temperatures taken in bucket samples with a thermometer reading to $1/20°$ gave little or no such indication.

Nor did Mr. D. J. Matthews, the oceanographer on board, find any relation between icebergs and sea temperature. He noticed no rise in temperature in the vicinity of ice, but, on the other hand, found sudden changes in many parts of the North Atlantic where there certainly was no ice within 500 miles.

Similar changes in temperature in the sea far removed from icebergs were noted by the patrol of the U.S.SS. *Chester* and *Birmingham* in 1912.

In fact, all that a sudden fall in surface temperature means is that the ship has entered the polar current and may meet ice if there is any in the neighbourhood. A rise in temperature shows that the chances of ice are less, but not that the ship is safe.

Therefore, unless wireless warnings of the extent of the pack and the position of bergs can be satisfactorily circulated, which is doubtful, ships will have to rely on a careful watch from near the water-line, and the development on the part of the look-out or ice-pilot of that extra sense which all polar navigators gain in time that enables them, as they say, to "smell" the presence of ice. The report ends with a lengthy study of the plankton distribution by Mr. L. R. Crawshay, who reached results similar to those of the physical observers on ice-bearing currents.

R. N. R. B.

LIEUT.-COL. D. D. CUNNINGHAM, F.R.S.

WE recorded last week, with much regret, the death on December 31, in his seventy-second year, at his residence, Tormount, Torquay, of Lieut.-Col. D. D. Cunningham, formerly of the Indian Medical Service.

D. D. Cunningham was born at Prestonpans on September 29, 1843, and was the son of the Rev. W. B. Cunningham, one of the most scholarly of the clergymen who left the Church of Scotland at the Disruption of that year. After leaving school young Cunningham entered the University of Edinburgh, where he graduated with honours in the Faculty of Medicine in 1867. Early in 1868 he joined the Indian Medical Service, and at the Army Medical School, Netley, he took a position as distinguished as that which he had attained in his university.

While Cunningham was at Netley the attention of pathologists in this country was directed to the theories regarding the causation of cholera advanced by Hallier and De Bary, and at the instance of the teaching staff of the Army Medical School the Secretaries of State for War and for India resolved to depute the two young officers who should secure the highest places in the Queen's and the Indian Medical services respectively to learn at first hand the nature and bearing of the theories. Cunningham was the young Indian surgeon thus chosen; the officer of the British Medical Service selected was T. R. Lewis, a man of the same academic standing as Cunningham, but a few years his senior in age, who had graduated with honours in medicine, also in 1867, in the sister university of Aberdeen.

As a result of this selection Cunningham spent some time as an inmate of the house of the Rev. M. J. Berkeley, F.R.S., and acquired a knowledge of the technique employed by that distinguished mycologist. In company with Lewis he paid visits to Hallier and to De Bary, proceeding thereafter to Munich to study under the celebrated Pettenkofer, with whom both young men contracted ties of close personal friendship, which subsisted in the case of Lewis until the latter died, and in the case of Cunningham until the close of Pettenkofer's career.

After this period of study in Germany Lewis and Cunningham left for India, where they arrived in 1869. Immediately on landing both officers were attached for special duty to the department of the Sanitary Commissioner with the Government of India, and commenced partly in collaboration, partly independently, the series of pathological studies the excellence of which led to the selection of Lewis for the Fellowship of the Royal Society, at the age of forty-five, in 1886, and to the election of Cunningham to the Society, at about the same age, in 1889. This period of activity continued for eleven years with the happiest results, and the eloquent testimony borne to Lewis's share in their work, in the pages of NATURE for May 27, 1886, on the occasion of the untimely death of that distinguished pathologist, will better enable workers of the present

generation to realise and appreciate what the work of Lewis and Cunningham implied thirty years ago.

The collaboration of Cunningham with Lewis came to an end in 1879–80 owing to Cunningham's appointment as professor of physiology in the Medical College of Bengal, and to a modification in the organisation of the Sanitary Commissioner's department. The Sanitary Commissioner was in 1880 made also Surgeon-General with the Government of India, and he was only able to retain the services of Lewis in the capacity of secretary to the Sanitary Commissioner.

The diversion of Cunningham's attention from pathological studies was, however, but of short duration. In 1883 Lewis was offered, and accepted, the post of assistant professor of Pathology at Netley, and Cunningham, who had in the interval established his reputation as a teacher of physiology, was asked to undertake, in addition, the duties of secretary to the Sanitary Commissioner. During the remainder of his Indian career Cunningham fulfilled these secretarial duties on behalf of the Government of India in conjunction with his duties as a professor of physiology on behalf of the Government of Bengal. The conditions under which he had to work differed somewhat from those experienced by his predecessor, whose headquarters, when not on tour, were with the Government of India in their summer capital of Simla, whereas, owing to the exigencies of his college appointment, Cunningham's headquarters were in Calcutta. The work accomplished by Cunningham during the next fourteen years, for which period he was in charge of both posts, was unremitting. This, combined with the fact that his duties involved continued residence in the plains, at length undermined what had been a vigorous constitution, and in 1897 Cunningham's health became so seriously impaired that he had to be invalided to Europe, and a year later found it necessary to retire from the service of the Government. After retirement he settled in Torquay, where, in somewhat indifferent health, he spent the rest of his life.

During the period from 1879 to 1897, spent by him in Calcutta, Cunningham took his share of those unofficial duties that fall to public men. He was a member of council of the Asiatic Society of Bengal and a trustee of the Indian Museum. But the work for which he will longest be remembered in Calcutta was that connected with the Zoological Garden, to the committee of management of which he rendered the greatest service, for many years as their secretary and eventually as their president. Largely owing to his energy and knowledge the institution attained the position which it still holds, whether as regards the wealth of its collection or the health of its inmates. His services to this garden are commemorated by a bronze medallion portrait presented by friends when Cunningham retired from public service.

As a teacher of physiology Cunningham was marked by the philosophical breadth of his thought and by the corresponding width of his outlook. His attention, whether in the class-room or the laboratory, was by no means confined to animal physiology; some of his most suggestive allusions and fruitful studies were botanical. In the pathological field Cunningham was not so much the investigator of morbid processes and diseased states as the student of deviations from normal physiological processes and naturally conditioned tissues. Here again, perhaps to some extent as a consequence of his early association with Berkeley and De Bary, Cunningham was as interested in working out the life-history of pathogenic organisms affecting plant tissues as in studying diseases affecting animals or men.

With capacity for research there went, in the case of Cunningham, great powers of observation, thanks to which we are indebted for the existence of notebooks kept with the utmost care during his thirty years' residence in the East. It was to his friends a source of the keenest satisfaction that although Cunningham after retirement was unable to resume the research work of former years, his health improved sufficiently to admit of his exercising his rare literary gift in presenting some at least of the contents of these notebooks to the world.

Cunningham's work in India was recognised by his being made a Companion of the Indian Empire and, during his residence in the East, an Honorary Surgeon to the Viceroy. After his retirement he became an Honorary Physician to the King.

Possessing a manner of ineffable charm and courtesy, kindly and wise in counsel, Cunningham was endeared to all those who had the privilege of his friendship, and to those of the circle, now sadly diminished, who enjoyed that privilege, his loss is irreparable.

SIR OWEN ROBERTS.

By the death of Sir Owen Roberts, on January 6, in his eightieth year, the cause of technical education in this country has lost one of its most devoted and influential champions. It is nearly half a century (1866) since Sir Owen was appointed Clerk to the Worshipful Company of Clothworkers. At that time the City Companies had fallen into ill-favour. Their immense revenues, it was alleged, had been diverted from their original purpose of trade protection and advancement, and when the movement for improving technical education was started, shortly after the passing of Mr. Forster's Education Act of 1870, longing eyes were cast upon these revenues. It was then that Sir Owen Roberts, in co-operation with Sir William Sawyer, of the Drapers' Company, and Sir John Watson, of the Mercers' Company, conceived the bold policy which at the same time assisted the cause of technical education and saved the companies from the odium into which they had fallen by providing them with a worthy object for their munificence.

The Clothworkers' Company had already taken a leading part in the foundation of the Yorkshire College of Science (which has since become the

University of Leeds), and it had also made large grants towards the establishment of technical schools at Bradford and Huddersfield; but the first great sign of the City Companies' new activity was the constitution of the City and Guilds of London Institute in 1876. It is impossible to trace here the development of this movement, in which Sir Owen Roberts took a leading part. Suffice it to say that, as a result of it, we now have at South Kensington the magnificent Imperial College of Science and Technology, which owes its existence in no small measure to the munificence of the City Companies.

Sir Owen's position as an educational authority was handsomely recognised when he was appointed one of the seven commissioners under the University of London Act, 1898, entrusted with the duty of reconstituting the University. Sir Owen has since confessed that in his opinion the problem of devising an internal university in London is incapable of a satisfactory solution; but he strove with his fellow-commissioners to do the utmost with the materials at their disposal, and for several years he continued loyally to serve the re-constituted university as a member of its Senate. It is probable that he was more completely satisfied with the work which he did at the Royal Society of Arts. One of the chief aims of that royal and ancient institution has, for the last century and a half, been to encourage industry by the application of science and art—precisely the object which Sir Owen had so much at heart. He was elected a member of the Society's council in 1880, and with the briefest break he continued to serve on it until his death. During nearly all this period he acted as Treasurer, and for one year as Chairman of the Council. He had a great grasp of finance, and to his sound advice is due in large measure the prosperity which the society at present enjoys.

Sir Owen will be missed by a very large circle of public and private friends. His genial personality and warm-hearted friendliness ensured him a welcome wherever he went, and he retained to the end a vigorous vitality that might well have been envied by many a man thirty years his junior.

NOTES.

THE council of the Geological Society has this year made the following awards of medals and funds:—Wollaston medal, Prof. T. W. Edgeworth David, C.M.G., F.R.S.; Murchison medal, Prof. W. W. Watts, F.R.S.; Lyell medal, Prof. E. J. Garwood, F.R.S.; Bigsby medal, Mr. H. H. Hayden; Prestwich medal, Prof. Emile Cartailhac (Toulouse); Wollaston Fund, Mr. C. B. Wedd; Murchison Fund, Mr. D. C. Evans; Lyell Fund, Mr. John Parkinson and Dr. L. Moysey; Barlow-Jameson Fund, Mr. J. G. Hamling.

DR. J. SCOTT KELTIE, secretary of the Royal Geographical Society, has been awarded the Cullum gold medal of the American Geographical Society, in appreciation of his services in the advancement of geographical knowledge. Arrangements are being made by the American Geographical Society, through the United States Department of State, for the presentation to be made to Dr. Keltie by the American Ambassador in London.

THE widow of Prof. Henry Draper, of Harvard, the American pioneer in stellar spectroscopy, died recently in New York. Mrs. Draper was herself one of her husband's most capable assistants in the Harvard College Observatory. On his death in 1882 she presented that institution with his eleven-inch telescope and provided the main funds for the preparation of the great "Draper Catalogue," recording the spectra of more than ten thousand stars, as a memorial to her husband. It is announced in the issue of *Science* for December 25 last that Mrs. Draper has, by her will, left large bequests for public purposes. She bequeaths 30,000*l*. to the Harvard College Observatory for the Draper memorial; her husband's photographic plates and apparatus are also bequeathed to the observatory. The sum of 90,000*l*. is given to the New York Public Library, 40,000*l*. for a memorial to Dr. John S. Billings, and 40,000*l*. as a memorial to her father, Courtland Palmer. The income of these funds is to be used for the purchase of books, and an additional trust fund of 10,000*l*. is given for the benefit of the employees of the library. There is also a bequest of 5000*l*. to the Smithsonian Institution, and of 5000*l*. to the laboratory of surgical research of New York University, of the medical department of which Dr. Henry Draper was at one time dean.

SOME indication of the cause of the severe floods which have of late been so prevalent in the Thames Valley and in other parts of the country can be gathered from the summary of rainfall issued in the Weekly Weather Reports of the Meteorological Office. In the five weeks ending January 2 the aggregate rainfall was largely in excess of the average in all parts of the United Kingdom. The greatest excess of rain occurred in the south-east of England, where the fall was 318 per cent. of the average. The next highest percentage is 284, in the east of England, followed by 246 in the midland counties. In the Channel Islands the rainfall was 223 per cent. of the average, and in the south-west of England it was 200 per cent. In all other districts the rainfall was less than double the normal, and in the west of Scotland it was only 131 per cent. of the average.

A SUMMARY of the weather issued by the Meteorological Office for the fifty-two weeks ended January 2 shows the aggregate conditions for 1914. The mean temperature for the year was in excess of the average in all parts of the British Isles. In the east and north-east of England and in the midland counties the mean temperature was 2° above the average, whilst in all other districts except the north and south of Ireland and the Channel Islands the excess amounted to 1°. The south-east of England was the only district with an absolute temperature of 90°, but the thermometer exceeded 80° in all other districts. The lowest temperature was 7° in the east of Scotland. The rainfall for the year was largest in the north of

Scotland, where the amount was 49·31 in., and it was least in the north-east of England with 24·82 in. The only districts with an appreciable deficiency of rain were the west and north of Scotland, where the percentage of the average rainfall was respectively 91 and 94. In the south-east of England the aggregate rainfall was 125 per cent. of the average, which is the highest difference from the normal, in the Channel Islands it was 121 per cent. of the average, in the south-west of England 119, in the south of Ireland, 111, in the midland counties 109, and in the east of England 108 per cent. In no other district was the rainfall more than 104 per cent. of the average. The rainy days were not generally very different from the normal. There was a slight excess of sunshine in the eastern districts, whilst the western districts were mostly in agreement with the average.

A few weeks ago we announced with regret the death in Cambridge, on December 9, of Prof. A. van Gehuchten, professor of the anatomy, pathology, and treatment of diseases of the nervous system in the University of Louvain. Sir Clifford Allbutt, in two short communications to the Educational Supplement of the *Times* (January 5) and the *British Medical Journal* (December 26) expressed the grief of many friends at Cambridge, as well as of biologists generally, at the loss which science has sustained by Prof. van Gehuchten's death. To these sources, and an appreciative obituary notice contributed by Dr. F. E. Batten to the latter journal, we are indebted for the following details. In 1887, after a brilliant career as a student under the late Prof. J. B. Carnoy, and in laboratories at Berlin and Frankfurt, van Gehuchten returned, at the age of twenty-six, to Louvain, where he had been appointed instructor in anatomy, especially in the field of neurology, of which subject he became one of the most original investigators and exponents of our time. During twenty-four years the records of his now famous researches into the nervous system appeared in a series of papers in which each challenged the others in interest and importance. His researches dealt especially with the unit of modern neurology—the neuron; with the origin and causes of the motor nerves; the pathology of certain virulent nervous maladies; the phenomena of normal and morbid reflexes; and incidentally but very effectively with the development of methods. It was in 1897 that he began his long and fruitful series of study on methylene-blue staining methods, a report on which he presented to the International Congress of Medicine at Moscow in that year.

A remarkable human skeleton, discovered by Dr. Hans Reck in the Oldoway ravine in German East Africa, is described in the *Antiquary* for January, by Mr. J. Reid Moir. In the layer resting immediately upon the basal basaltic lava, rhinoceros bones were discovered, and in the overlying deposit, that in which the human remains were found, a great number of elephant bones, differing from the present-day African elephant, and a splendid hippopotamus skull were unearthed. Dr. Reck believes that it is impossible to imagine that this skeleton attained its position in the deposit in which it was found otherwise than during its normal accumulation, and that any idea of an artificial grave having been dug into this stratum is untenable. If these facts be accepted, the remains seem to belong to the Pleistocene period. They do not represent a very early or primitive type, and they thus present a close analogy to the celebrated Ipswich man. The obvious conclusion is that man must have been developed at a period much earlier than is generally supposed. But before this startling conclusion is accepted we must have much more precise details of the geological age of the stratum in which the remains were found. A decision on the question may safely be deferred until Dr. Reck's detailed report is available for study.

Prof. Flinders Petrie contributes to *Ancient Egypt*, part i. of 1915, a valuable article on metals in Egypt, in which he brings together all the available information on the use of copper, gold, silver, lead, tin, bronze, and iron. The account of iron is particularly instructive. First, we have the sporadic Iron Age, beginning with the Gerzeh beads and the well-known piece of sheet iron from the pyramid of Khufu at Gizeh. Incidentally, we are told that the supposition that iron might disappear in course of time is a fallacy. A lump of oxide of iron is practically insoluble when buried, and its strong colouring and staining power make it very obvious. The developed Iron Age in Egypt began about 1200 B.C., whereas in Assyria, iron, as a tribute from the Chalybes, dates from 881 B.C. An Ethiopian source for the Egyptian iron may be discarded, as, if it were common there, it would soon have reached Egypt at a very early date; but the Ethiopian slag-heaps are not earlier than the general special culture of that region, which began in the XXVth dynasty, and continued from 700 B.C. onwards. The sources of the European and Euphratean iron would be quite sufficient to account for the general use of iron in Egypt, even apart from the Ethiopian.

The picture-film entitled "The Escape," exhibited by Messrs. Ruffell, at the Alhambra Theatre, on Tuesday, possesses scientific interest. Apparently an ordinary melodrama of low life, with an exceptionally well-ordered and pictured scenario, it is designed for educational purposes in eugenics. Many of Zola's and de Maupassant's novels and stories might be thus eugenically underlined. The kinematograph has already done good educational work, *e.g.* in botany and general biology, and there is no reason why it should not develop its usefulness all round the educational field. A long view and some imagination are needed if the average person is to draw the eugenic moral from tragedies of everyday life, but a picture-film interspersed with explanatory mottoes, easily remembered, is a real educative force. The drama deals largely with evil conditions imposed by heredity and environment. A connection is made between them and criminal behaviour, operating both in the home and in public. Selfish luxury is exposed as well as selfish brutality, and the effects on the new generation of the nation's men and women are vividly indicated. A picture-play like this should help many to visualise

the scientific reality behind domestic happenings seen daily but ignored.

We have received a report of a bacteriological examination of the milk supply of Montreal in 1913–14, by Dr. F. C. Harrison and Messrs. A. Savage and W. Sadler. A large number of analyses were carried out on more than 1000 samples, and the averages show that Montreal milk, both in summer and in winter, is of very poor hygienic quality. Various recommendations are made with the view of improving the supply.

It is shown by Mr. E. Shaw, in the *Victorian Naturalist* for November, 1914, that two supposed species of Australian cockroaches were founded in 1893 on females of a species named in 1869 from males, and representing a genus apart from that to which the two former were assigned.

In the *American Museum Journal* for December, 1914, Mr. R. C. Andrews records the history of the magnificent collection of whales, porpoises, and dolphins which has recently been brought together in the American Museum, and in the acquisition of which he himself has taken a very large share, having visited whaling-stations in Vancouver, Alaska, Japan, and various Pacific isles, as well as having harpooned white whales during their annual rush up the St. Lawrence. The descriptions of the capture and flensing of the monsters are most vivid, while many of the illustrations are of the greatest interest.

The Report of the Marine Biological Station at Port Erin for 1914 contains a summary of the investigations carried on at the station during the year. Nearly nine million plaice eggs were dealt with in the fish hatchery, of which number about eight million were successfully hatched and the larvæ liberated at an early stage of development. Experiments in lobster rearing were also carried on. Out of 24,500 eggs placed in the hatching boxes, 1823 larvæ were reared to the fourth or "lobsterling" stage. The regular collection of plankton from Port Erin Bay was continued. Biochemical researches on the nutrition and metabolism of marine animals were carried on by Prof. B. Moore and other workers, and various biological researches were also undertaken.

In revising the water-beetles of the group typified by the genus Helophorus in the January issue of the *Entomologist's Monthly Magazine* (the first number of the fifty-first volume and of a nominal third series), Dr. D. Sharp takes occasion to express his objection to the practice of prefixing the letter "H" to derivatives from Greek aspirated words, on the ground that the Greeks did not indicate the aspirate by a letter, and arranged the aspirated and silent vowels in a single alphabetical series. To omit the "H" would, however, destroy all clue to the origin of the words, and in certain instances might lead to difficulty; as, for example, if there were a derivative from ὄρος, a mountain, analogous to horizon, from ὅρος, a boundary. In another article Dr. J. Waterston describes two new species of bird-lice (Mallophaga), representing as many genera, from a Colombian toucan.

Tropical Life for December contains a well-illustrated supplement entitled "Panama and Prosperity," with numerous illustrations of tropical products reproduced from excellent photographs. Coco-nut germination, the picking and curing of cacao, the sugar cane industry, lime-growing, and tobacco in Jamaica are among the subjects illustrated, and should prove of value to those interested in tropical vegetation.

In the *Kew Bulletin*, No. 9, a new oil seed from South America, *Osteophleum platyspermum*, Warb., is described and figured, and an analysis given of the kernel, which contained 55·2 per cent. of fat. Other members of the Myristicaceæ are known to yield yellowish fats containing a large proportion of the glyceride of myristic acid. These seeds, could they be imported in sufficient quantity, would be valuable for commercial purposes.

The Report of the Botanic Station in the Virgin Islands for 1913–14, just received, shows that in these small islands, as in the larger islands under the jurisdiction of the Imperial Department of Agriculture for the West Indies, important work is being done in the improvement of the cultivated crops. The cotton industry, in particular, is well-fostered, and the usefulness of the station is shown by the large demands received for coco-nuts, coffee plants, bay plants, etc. Special attention is being paid to the coco-nut industry, and its progress will be eagerly watched, especially by those owning land in the islands.

The Annotated List of Flowering Plants and Ferns of Point Pelee, Ontario, forming Memoir 54 of the Biological Series, Department of Mines, Canada, is a useful compilation, since Mont Pelee lies on a direct line of north and south bird migration. The object of the paper is to throw light on bird migration and also to add to the knowledge of the distribution of the wild plants of Ontario and Michigan. 583 species of plants were noted on the point. On Pelee Island, a large island to the south in Lake Erie, the Kentucky coffee tree and other plants reach their northern limit. It is unfortunate that Mr. Dodge does not summarise his results or draw any conclusions as to the dispersal of the plants by migratory birds.

The "Fern ledges" of St. John, New Brunswick, form the subject of Memoir 41 of the Geological Survey of Canada, by Dr. M. C. Stopes. These deposits are now recognised as Carboniferous, though formerly described as Devonian, and consist of alternations of sandstones and shales, and it is in the shales that the rich flora of débris occurs. The shales contain impressions of Calamites, Cordaites, etc., and the plants have been for the most part described by Sir William Dawson. A new genus, Pteridospermostrobus is described, the plant being allied to the British Lagenostema, but the preservation is unforfunately very imperfect. The monograph is illustrated by a fine series of plates and useful text figures.

The annual report of the Philippine Weather Bureau (parts 1 and 2), recently issued under the direction of the Rev. J. Algué, S.J., contains hourly observations

made at the Manila Observatory during the calendar year 1912. There is but little variation in the mean values from year to year, and nothing exceptional occurred during the year in question beyond an increase in seismic activity; *e.g.* the annual departures from the normal of forty-eight years were, for temperature, $-0·15°C$.; rainfall, $+3·8$ mm.; it is therefore unnecessary to add to the remarks made in our previous issues. During the fiscal year 1911–12 the earthquakes reported from various parts of the archipelago numbered 230, 90 per cent. above the average. Only five of the shocks were severe; that of July 12, 1911, has been registered all over the world with the characteristics of a "great earthquake." The Manila seismographs recorded 318 disturbances. The relations with other services in the Far East have recently been much improved; the observations are now synchronous, and although not yet simultaneous, the construction of synoptic charts from available data is much more satisfactory.

IN the *Museums Journal* for December Mr. Alan Pollard advocates the practical use of Cartesian co-ordinates for locating objects in a museum or other rectangular room. He suggests that a foot may be a convenient unit for the purpose, and that a rough scale may be sufficient for purposes of localisation, the *centre* of the object being the point specified. As it is necessary to specify which faces of the room are to be taken as co-ordinate planes, the author proposes, the wall containing the door by which the room is entered as plane of (x, z), and the wall to the left of this as plane of (y, z). For a line or plane parallel to one edge or face of the rooms, he proposes to specify numerically the given co-ordinates using letters for the indeterminate ones; for example $(x, 29, z)$ represents a wall 29 ft. from the plane of (x, z).

THERE is a growing tendency among postgraduate students, and indeed mathematical writers generally, to produce papers containing no new ideas, but merely clothing ideas already familiar to readers in slightly different form or notation. As examples we may illustrate the waste of university endowments on students who merely propose to express well-known formulæ of electrostatics or attractions by means of quaternions and elliptic functions. Mr. George Paswell contributes to the Bulletin of the American Mathematical Society for December "An Appeal to Producing Mathematicians" which we hope will be read in very great earnest by all teachers of advanced students and writers of papers. He points out that the profession of civil engineering is teeming with problems awaiting the solutions of a Laplace or a Newton, and he instances the theory of elasticity as requiring the most urgent attention. He further attacks the shallowness of the courses of mathematical instruction given to applied science candidates, and though his strictures apply particularly to America, it is equally true that in Great Britain candidates can obtain University degrees in engineering on work that is scarcely up to intermediate pass standard. A paper by Mr. Sidney Withington on the catenaries of one of the American trolley railways in the Journal of the Franklin Institute for December, 1914, illustrates this point well. The author on page 721 employs the binomial theorem with a reckless waste of neglected terms to prove or rather to fail to prove an obvious geometrical result which he can only accomplish by inserting or omitting a factor 2 from one or other of two quantities to be proved equal, the explanation of this factor being quite different from anything clearly and explicitly stated in the paper. While strongly supporting Mr. Paswell's plea, we greatly regret that he has omitted the subject most urgently requiring research at the present time, viz., aeroplanes. Aeroplane problems are running to waste by the dozen, and they practically never, or at best rarely, figure in mathematical transactions.

THE *Electrician* for December 25, 1914, reproduces the provisional report of the committee of the Physical Society on Nomenclature and Symbols. Some of the most noteworthy features of the report are its proposal to use capitals for the amplitudes, and small letters for the instantaneous values of quantities varying harmonically; its restriction of the termination -ity to specific, and its use of the termination -ance for non-specific, properties. Thus we have the resistance, conductance, and inductance of an electric circuit, but the resistivity, conductivity, and permeability of the material of which it is composed. The term capacity of a condenser is, however, retained, and forms an exception which might be got rid of by the substitution of the word capacitance. In terrestrial magnetism and atmospheric electricity the terminologies are in a chaotic state, and the evil is not likely to be mitigated so long as colourless words like declination and inclination are adopted by theoretical writers for the effects graphically described by the words deviation of the compass and dip respectively. It is much to be desired that the various committees now considering the question of symbols should confer with each other in order if possible to introduce unanimity into their reports (see p. 544).

UNDER the title "Chemistry and Practical Life" has been reprinted an address delivered by Dr. G. T. Beilby before the Chemical Society of the Royal Technical College, Glasgow. Whilst fully recognising the great indebtedness of modern civilised society to science and its discoveries, Dr. Beilby emphasises the enormous debt which had already been incurred to the countless generations of workers who had lived and worked before the advent of chemical science. In reviewing the position of chemical industry in this country, a subject on which Dr. Beilby speaks with authority, it is pointed out that "long after the scientific development of chemical engineering was well under way in Germany, scientific and academic chemists completely ignored the necessity for this new hybrid, the 'chemical engineer,' or openly scoffed at the idea." Too frequently in the colleges of this country "there appears to be an absence of any real conviction that the call for instruction in chemical science with a deliberate view to its application in the

development of the arts and industries is intrinsically sound from the intellectual as well as from the practical point of view." A letter by Mr. C. R. Darling in the Journal of the Society of Arts (December 18) emphasises in a similar way the fact that "if we are to have that co-ordination between the teacher and manufacturer that exists in Germany to the great advantage of both, the teaching of chemistry must not, as at present, be mainly confined to the cloister. We must either introduce courses of instruction in industrial chemistry into our existing colleges and universities, conducted by men of experience, or create new institutions for the purpose. So long as educational authorities regard the possession of a degree as the only criterion of ability, and form their staffs almost exclusively of men who have had no industrial experience, they will never give that effective assistance to the manufacturers which will enable us to hold our own in the sphere of chemical industry."

AMONG the various uses to which oils are put is their employment by electrical engineers for the insulation of oil-immersed transformers and for surrounding the breaking contacts of high-tension switches. Special qualities of oil are necessary and a good deal of research has been going on as to the selection and testing of suitable oils for these purposes. A quantity of information has been collected by a research subcommittee of the Institution of Electrical Engineers, and is embodied in a report just issued. The chief troubles are the deterioration of the oil by the gradual formation of sludge and the lowering of its quality as a dielectric by the absorption of moisture. This sludge now appears to be due to the formation of complex organic acids, dehydrogenated hydrocarbons, and oxidised resinous asphaltones of the mineral oil originally used. The formation of these compounds is accelerated by increase of temperature, and for testing purposes they can be rapidly produced by exposing the oil to ozone. The effect of sludging, although impeding the required circulation of oil in a transformer, does not affect its dielectric quality so much as the absorption of moisture, and this is so serious that the presence of a small percentage of water in the oil is more easily detected by electrical tests than by purely chemical methods.

HITHERTO the manufacture of the well-known antiseptic, thymol, has been practically confined to Germany, notwithstanding the fact that ajowan seeds, the oil from which is almost the sole source of commercial thymol, are grown on a large scale only in India, which has thus been supplying Germany with the raw material of a valuable industry. No further supplies of thymol being forthcoming from Germany owing to the war, the price had increased almost eight-fold by September last, and is even now 21*s.* 6*d.* per lb., as against 5*s.* per lb. before the war. There is every reason why the United Kingdom should now become the chief centre of the manufacture of thymol. The manufacturing process is quite simple, and ample supplies of ajowan seed are available in India. The Imperial Institute, which has devoted attention to this subject, has now made inquiries in India, and is prepared to put intending British manufacturers of thymol in touch with Indian exporters of the seed. Fortunately, too, a British possession can provide a substitute for thymol if such be required. This substance is carvacrol, which is obtained from oils derived from a variety of plants, but particularly from the origanum of Cyprus. At the instance of the Imperial Institute this Cyprus origanum oil is already being produced in commercial quantities from wild plants in Cyprus, and in 1913 was exported thence to the United Kingdom to the value of 980*l.* It is believed that the plant can be cultivated profitably and on a large scale in Cyprus, and experiments in this direction are understood to have been begun.

THE first report of the Board of Trade Committee on bulkheads and water-tight compartments, presided over by Sir Archibald Denny, has now been issued, and forms the subject of the leading article in *Engineering* for January 8. The committee has now been at work for nearly two and a half years, and the first report deals with foreign-going steamers carrying more than twelve passengers. It is not possible even to mention all the points covered by this comprehensive report, but we note that the committee has given a clearly defined method for the construction of flooding curves and tables. Full calculations were made for several actual vessels of widely different types, and from these, together with the general laws governing flooding calculations, a method of preparing flooding curves from simple data was devised. The method was tested by applying it to a number of actual vessels, and comparing the results with those given by full flooding calculations for the same vessels. The Committee is right in claiming that the formulation and enforcement of rules governing subdivision is a contribution of the utmost importance to the subject of safety of life at sea.

WE have received an interesting pamphlet from the Bonecourt Waste Heat Boiler Co., Ltd., of Parliament Mansions, Westminster, in which is described a method of raising steam for power, heating, or other purposes by utilising the heat carried away in the products of combustion of internal-combustion engines and metallurgical furnaces. In general, the exhaust gases from an internal-combustion engine contain from 30 to 45 per cent. of the total heat available in the fuel supply, and these gases leave the engine at a fairly high temperature. In the Bonecourt system the exhaust gases from the engine are passed through internal tubes in a small steam boiler. At full engine load it is claimed that from 3 to 3·5 lb. of water can be evaporated from and at 100° C. per hour per brake-horse-power of the engine, with no additional cost for fuel. In other types of boiler made by the firm, both fuel firing in an ordinary grate and heating by exhaust gases are combined. Small tubes take the products of combustion from the coal-fired grate and separate larger tubes in the same boiler receive the engine exhaust gases. A boiler 7 ft. in diameter by 6 ft. long would be

suitable for a 500 brake-horse-power gas engine, and would evaporate 1500 lb. of water an hour from and at 100° C. from the heat in the exhaust gases alone. Alternatively it would evaporate the same quantity when fired with coal alone, and if worked simultaneously by both methods, the evaporation would be about 3000 lb. an hour from and at 100° C. A large increase in efficiency is claimed by application of the system to open-hearth furnaces.

THE forty-second annual issue, that for 1915, of "Willing's Press Guide and Advertisers' Directory and Handbook" has been received. This yearly book of reference provides a concise and comprehensive index to the Press of the United Kingdom, a list of telegraphic news and reporting agencies, lists of the principal Colonial and foreign journals, and a variety of general information. A classified index of periodicals will prove of special interest to librarians, who, under such titles as "Chemical Science," "Geology," "Astronomy," "Philosophy," will find lists of magazines and journals devoted to different branches of science. The price of this useful "guide" is 1*s*.

OUR ASTRONOMICAL COLUMN.

FIREBALLS IN JANUARY.—Though January is by no means a month presenting special meteoric activity, it has furnished quite an unusual number of large fireballs. An analysis of the dates appears to show that the following periods are rather strikingly indicated:—

Principal Radiants.

Jan. 1–4	230°+52°		
9–13	57°−12°	120° 0°	133°+21°
14–19	110°+23°	130°+33°	130°+48°
25–28	132°+31°	160°+58°	332°+57°

The January fireballs deserve more careful observation and inquiry. There are evidently some rich showers involved, but it is very difficult from the limited state of our knowledge, to single out the richest systems from the large number which apparently supply our January meteors. Apart from the several radiants mentioned above, there are many others fairly well defined in Aries, Taurus, Perseus, Leo, Virgo, Gemini, and Ursa Major. The data already collected appear to prove that the prevalence of large meteors is due rather to a considerable number of showers than to the special activity of two or three, but the investigation can be carried still further when additional materials have accumulated.

THE CAPTURE THEORY OF SATELLITES.—Prof. T. J. J. See's volume entitled "Researches on the Evolution of the Stellar Systems" (vol. ii., "The Capture Theory"), is discussed by Dr. A. C. D. Crommelin in the current number of *Scientia* (vol. xvii., 1915.) Prof. See's contention is that the planets and satellites were independent of the solar system, and have never been evolved from what we consider their primaries, but that they have been captured from outside and made to conform to their present orbits under the secular action of a resisting medium. Dr. Crommelin holds to the view that the matter embodied in the planets was always a part of the solar system, but spread out in the form of huge dust clouds, which finally condensed round certain centres. It is in support of this view that the present article was written, and he brings forth many lines of argument which help to strengthen his view. Dr. Crommelin states that his conclusions do not imply any want of respect for Prof. See's contributions to astronomical theory, for "his suggestions are always stimulating and ultimately help on the attainment of the truth." The new light that the study of the spectroscopic binaries has shed on the question calls nevertheless for a modification of his views.

OBSERVATIONS OF THE MOON.—Prof. W. H. Pickering, in the November number of *Popular Astronomy* (vol. xxii., No. 9, 1914) described some interesting observations on the lunar crater Aristillus, and incidentally made some general statements which no doubt have attracted attention. He points out that nearly everyone who looks at the moon through a telescope confines his attention to those regions near the terminator because they furnish "striking views, are easily identified, and because what is seen is easy to understand." It is for this reason, he says, that the impression that the moon is lifeless has so long maintained its existence. According to him the only time when the moon is really interesting is when its surface is viewed far away from the terminator, that is, during the lunar summer time, for then changes are taking place, changes which are "conspicuous all over the surface to any who will take the trouble to watch and to study them carefully." Here, he suggests, is the opportunity for the amateur to come in, to make his observations and drawings with care, to record the times, compute the corresponding colongitudes, and to publish his results. The necessary observations do not require the highest grade of seeing nor the largest telescopes. Close observation has led Prof. Pickering to conclude that the moon is very far from being a dead planet, and he has advocated the existence of vegetation on the moon for more than twenty years; he hopes by means of the above assistance that his idea will gain ground, and that the textbooks of twenty years hence will not contain the statement that "the moon is without air, water, or vegetation."

COMPANION TO "THE OBSERVATORY" FOR 1915.—The Companion to *The Observatory* for the present year has just come to hand, and its contents are familiar to astronomers, both professional and amateur. The substance of the matter and its arrangement follows for the most part on the lines of former issues. One important alteration is the page devoted to meteor radiants. This year the principal radiant is given for each night during the year, as well as the average hourly number of meteors visible on a clear moonless night. This information is supplied by Mr. W. F. Denning from observations made between 1866 and 1914. Only two eclipses will occur during the year, and these are both annular eclipses of the sun; neither will be visible in Europe.

THE METEOR-FALL OF ENSISHEIM (1492).—A reprint from the Journal of the Royal Astronomical Society of Canada (September-October, 1914) contains some interesting historical references to the meteor-fall of Ensisheim, which occurred in Alsace in 1492. These notes have been brought together by Dr. C. A. Chant in the hope of clearing up several discrepancies between different authorities. According to Wulfing's work on meteorites in collections and literature, sixty-five museums are supposed to possess portions of this meteorite, the original weight being 127 kg. (279 lb.), of which 70·4 kg. have been located. Ensisheim is the fortunate possessor of 54·8 kg., which is preserved in the town hall.

CHEMICAL TESTS AND STANDARDS.

As is well known, the Bureau of Standards of the U.S. Department of Commerce [1] issues from time to time circulars and technological or scientific papers upon various matters which have come before it for investigation. Among a budget of these publications received recently are papers dealing with the questions indicated below.

In Technologic Paper No. 31, Mr. E. T. Montgomery describes experiments made with "Some leadless borosilicate glazes maturing at about 1100° C." In ceramic practice glazes containing lead have certain advantages, but are often potentially poisonous. The object of the experiments was to make a general comparison between lead glazes and leadless glazes for white ware and china at a firing temperature of about 1100° to 1120° C. Seger's work on leadless glazes was taken as the basis. The author concludes that both kinds have special faults and special virtues, but it is not likely that any leadless glaze will be found "which will exactly duplicate the many excellent properties" of glaze containing lead as an ingredient.

Paper No. 33 describes a method of determining the carbonic acid, obtained from the combustion of carbon in iron, by converting it into barium carbonate and titrating this salt. This avoids certain errors to which the use of potash bulbs or soda-lime tubes for weighing the carbonic acid is liable. The principle of the process is well known; the point of the paper lies in the details given for obtaining accurate and fairly rapid results.

In Paper No. 35 Mr. L. G. Wesson explains a "combustion method for the direct determination of rubber." It consists in converting the rubber into a nitrosite, which is then dissolved out with acetone, and a combustion analysis made upon an aliquot part of the solution after expulsion of the solvent. The process promises to be a useful one.

The "Scientific Paper" (No. 221) is a discussion of the "influence of atmospheric conditions in the testing of sugar." During the operations of clarifying and filtering solutions of sugar for polarimetric examination, the liquids, if not kept covered, lose water by evaporation. The concentration of the sugar is thus increased, and the polarisation-value rendered too high. The magnitude of this effect, and the conditions modifying it, have been investigated by the authors of the paper. By keeping the liquids covered during the operations practically all increase in the polarisation-value may be prevented.

Of the "Circulars" in question one (No. 16) is a small pamphlet which describes the testing of hydrometers as carried out by the Bureau of Standards, and gives instructions with a view of promoting uniformity in the construction and verification of these instruments. The other (No. 44, "Polarimetry") treats of the principles which underlie the construction and use of the polariscope and the analysis of sugars. It is written from the point of view of the standards department, and deals at some length with the different systems, scales, and sources of illumination employed in modern polarimetry. This publication is distinctly of value both to polariscope makers and to sugar analysts.

WAR AND THE RACE.

The Manchester Statistical Society has printed an eloquent address by Dr. C. W. Saleeby, "The Longest Price of War." The thesis is the old, but politically ignored, result of war in "reversed selection." Quoting Michelet's epigram that the campaigns of Napoleon lopped a cubit from the stature of the French, and Prof. J. A. Thomson's observation that not even the discoveries of Pasteur could restore the physique which the victories of Napoleon's armies had destroyed, Dr. Saleeby notes the small size of the present-day French soldier, as remarked by many observers. To-day, for our own forces, "the brave, the vigorous, the healthy, the patriotic are taken, and the others left. . . . The rejected recruits recruit the race." The whole question is one which statisticians should investigate in special reference to the present war. Dr. Starr Jordan's study, "The Human Harvest," and the late J. Novikow's "Darwinisme Sociale," are the best of a meagre list of popular expositions of the thesis, of which the decay of the Roman Empire is the classic type. Speeck estimated that of every hundred thousand Romans, eighty thousand were slain. "Vir" thus gave place to "homo"; "the Roman Empire perished," says Seeley, "for want of men."

No scientific mind wishes to eulogise war, in the German fashion, which depends for its argument on the primitive athletic form of war, whereas war of to-day is simply peace riddled with casualties. Darwin's famous sentences refer only to a more or less imaginary conscript army in a country which is always at war—"in every country in which a large standing army is kept up, the finest young men are taken by the conscription or are enlisted. They are thus exposed to early death during war, are often tempted into vice, and are prevented from marrying during the prime of life. On the other hand, the shorter and feebler men, with poor constitutions, are left at home, and consequently have a much better chance of marrying and propagating their kind." It seems a fairly obvious inference that the dysgenic results of modern warfare remain to be proved. The deliberate sacrifice of life by exploiting the mass-formation is a special case needing investigation. The whole subject calls for investigation; until this is carried out, nothing is at all clear either for or against the biological effects of war.

STANDARDISATION OF ELECTROTECHNICAL SYMBOLS.

The International Electrotechnical Commission has recently issued its report (Publication 27 [1]) upon international symbols in electrotechnics. In the preface to the report, it is pointed out that the subject of international agreement in regard to symbols employed in electrotechnics was first brought before the International Electrotechnical Commission at its meeting in London in 1908. In Brussels, in 1910, a few general rules, together with a certain number of symbols, were adopted for circulation to the various national committees. The question of international agreement in regard to the symbols for the algebraic representation of Ohm's law was briefly mentioned, with the result that the following year, at Cologne, certain definite proposals were made by Dr. E. Budde, president of the German committee, which culminated in international agreement being reached in this important matter at the plenary meeting of the commission held in Turin in September, 1911. At the latter meeting a number of other proposals were provisionally adopted, and a special committee was instituted to continue the work and draw up further proposals to be placed before the national committees for their consideration. At the plenary meeting of the Commission held in September, 1913, at which twenty-

[1] London: Published for the Commission by Waterlow and Sons, Ltd., and to be obtained from the General Secretary, 28 Victoria Street, Westminster, S.W. Price 2s. 1d. post free.

four nations were represented, the final recommendations were ratified as given in the report here reprinted. An article on the proceedings of that meeting appeared in NATURE of September 25, 1913 (vol xcii., p. 109).

Introductory Remarks on the Standardisation of Symbols.

In so far as electrotechnics alone are concerned, it would seem possible to standardise symbols, and the following principles have served as the basis of the work of the special committee in the attainment of this object:—

The symbols must be clearly distinguishable one from another when writing with a pen on paper, with chalk on a blackboard, or with a typewriter. In the printed text, it is advisable to use a different type for the symbols from that of the text. It is desirable also that in ordinary handwriting, one should not be obliged to add distinctive signs to symbols to specify the type to be employed. It should be possible to spell out the symbols when writing them on the blackboard. Finally, preference should be given to those symbols already in common use. From this it will be seen that it is impossible to make a distinction, in ordinary handwriting, between Roman letters and italics, and that small roundhand letters, being too difficult to differentiate from the above, cannot be used. It is generally agreed to abandon Gothic type, as requiring too long a time in writing. Finally, many of the Greek capitals are identical with Roman capitals. Taking the above points into account, there remain about one hundred symbols available in Roman, Script, and Greek type, of which several are already used for mathematical symbols and which are necessary for the purposes of the electrician. A list of symbols most frequently needed in electrotechnics is appended herewith. Taking into account certain symbols which are occasionally made use of, it is obvious that there will be none left for purely physical. or mechanical quantities. Thus, in the same formula, electrotechnical symbols may occur in conjunction with other symbols used in mechanics and physics generally; this is especially the case in equations containing mass, moment of inertia, speed, density, temperature, quantity of heat, etc. The I.E.C. recommends, therefore, that in such cases, for physical and mechanical quantities, the symbol habitually used by physicists and mechanical engineers should be employed, if this symbol does not already exist in the formula as an electrotechnical symbol. If, on the contrary, it already exists in the formula, it is desirable that it be accompanied by a distinctive sign or that the notation be changed.

Rules for Quantities.

(*a*) Instantaneous values of electrical quantities which vary with the time to be represented by small letters. In case of ambiguity, they may be followed by the subscript "t."

(*b*) Virtual or constant values of electrical quantities to be represented by capital letters.

(*c*) Maximum values of periodic electrical and magnetic quantities to be represented by capital letters followed by the subscript "m."

(*d*) In cases where it is desirable to distinguish between magnetic and electric quantities, constant or variable, magnetic quantities to be represented by capital letters of either script, heavy-faced, or any special type. Script letters to be only employed for magnetic quantities.

(*e*) Angles to be represented by small Greek letters.

(*f*) Dimensionless and specific quantities to be represented, wherever possible, by small Greek letters.

TABLES OF SYMBOLS ADOPTED.

I.—*Quantities.*

NAME OF QUANTITY	SYMBOL	Symbols recommended for the case in which the principal symbol is not suitable
1. Length	l	In dimensional equations the capital letters L, M, T, are to be employed
2. Mas	m	
3. Time	t	
4. Angles	$\alpha, \beta, \gamma \ldots$	
5. Acceleration of gravity	g	
6. Work	A	W
7. Energy	W	U
8. Power	P	*
9. Efficiency	η	
10. Number of turns in unit of time	n	
11. Temperature Centigrade	t	θ ϑ
12. Temperature absolute	T	Θ
13. Period	T	
14. $2\pi/T$	ω	
15. Frequency	f	ν †
16. Phase displacement	ϕ	
17. Electromotive force	E	
18. Current	I	
19. Resistance	R	
20. Resistivity	ρ	
21. Conductance	G	‡
22. Quantity of electricity	Q	
23. Flux-density, electrostatic	D	
24. Capacity	C	
25. Dielectric constant	ϵ	
26. Self-inductance	L	$\mathfrak{L}$
27. Mutual inductance	M	$\mathfrak{M}$
28. Reactance	X	$\mathfrak{X}$
29. Impedance	Z	$\mathfrak{Z}$
30. Reluctance	S	$\mathfrak{R}$ Script, heavy-faced, or special type
31. Magnetic flux	Φ	$\mathfrak{F}$
32. Flux-density, magnetic	B	$\mathfrak{B}$
33. Magnetic field	H	$\mathfrak{H}$
34. Intensity of magnetisation	J	$\mathfrak{J}$
35. Permeability	μ	
36. Susceptibility	κ	

* A symbol for the second column is to be supplied by the Austrian and German Committees jointly and inserted without further discussion by the I.E.C.

† This symbol will be omitted if the Austrian and German Committees agree to do so.

‡ A symbol for the second column is to be supplied by the Austrian and German Committees jointly and inserted without further discussion by the I.E.C.

The German delegate made a reservation in regard to the symbols 13, 14, 20, 23, 25, 27 to 31, which are

not so far accepted in Germany, but did not oppose the adoption of these symbols by the I.E.C.

II.—*Units. Signs for Names of Units.*

Signs for names of electrical units to be employed only after numerical values :—

NAME OF UNIT	SIGN
1. Ampere	A
2. Volt	V
3. Ohm	*
4. Coulomb	C
5. Joule	J
6. Watt	W
7. Farad	F
8. Henry	H
9. Volt-coulomb	VC
10. Watt-hour	Wh
11. Volt-ampere	VA
12. Ampere-hour	Ah
13. Milliampere	mA
14. Kilowatt.	kW
15. Kilovolt-ampere	kVA
19. Kilowatt-hour.	kWh

m	sign for milli-	μ	sign for micro- or micr-
k	sign for kilo-	M	sign for mega- or meg-

* As a sign for the ohm, one of the two letters O or Ω is provisionally recommended. The letter Ω should no longer be used for megohm.

III.—*Mathematical Symbols and Rules.*

NAME	SYMBOL	Symbols recommended for the case in which the principal symbol is not suitable
Total differential	d	d
Partial differential	∂	
Base of Napierian logarithms	e	ϵ
Imaginary $\sqrt{-1}$	i	j
Ratio of circumference to diameter	π	
Summation	Σ	
Summation, integral	$\int$	

1. Ordinary numerals as exponentials shall exclusively be used to represent powers. (In consequence, it is desirable that the expression $\sin^{-1}x$, $\tan^{-1}x$, employed in certain countries be expressed by arc $\sin x$, arc $\tan x$.)

2. The comma and the full-stop shall be employed for separating the decimals according to the custom of the country but the separation between any three digits constituting a whole number shall be indicated by a space and not by a full-stop or a comma (1 000 000).

3. For the multiplication of numbers and geometric quantities, indicated by two letters, it is recommended to use the sign ×, and the full-stop only when there is no possible ambiguity.

4. To indicate division in a formula, it is recommended that the horizontal bar or the colon be employed. Nevertheless the oblique line may be used when there is no possibility of ambiguity; when necessary, ordinary brackets ( ), square brackets [ ], and braces { } may be employed to obtain clearness.

IV.—*Abbreviations for Weights and Measures.*

Length :—m; km; dm; cm; mm; μ=0·001 mm.
Surface :—a; ha; m²; km²; dm²; cm² mm².
Volume :—l; hl; dl; cl; ml; m³; km³; dm³; cm³; mm³.
Mass :—g; t; kg; dg; cg; mg.

V.—*Name for Electrical Unit.*

The I.E.C. will recommend to the International Congress of the Applications of Electricity, to be held in San Francisco in 1915, the adoption of the name "Siemens" for the unit of conductance.

GERMAN METHODS IN COMMERCE.

A PAPER on the organised methods employed by Germany in commerce, prepared by Sir William Ramsay for the Institute of Industry and Commerce, was referred to in a paragraph in NATURE of December 24 (p. 457). By permission of the institute, the article is here reprinted in full.

It has not been generally known that in commerce, as in war, the methods employed by Germany have been completely organised for many years. Instead of looking on commerce as an arrangement for mutual benefit, the German nation has regarded it as a war, And just as in the present war all methods of attack are regarded by the military advisers of Germany as legitimate, so we are slowly awaking to the knowledge that German commercial and industrial methods have for years been aggressive. The war in which we are now engaged is, indeed, a war for the liberation of nations from commercial and industrial brutality, as well as for their deliverance from an attempted enslavement to German "Kultur," as exemplified by the practices of their army.

At the annual meeting of the Society of Chemical Industry in 1903 I pointed out that the German military organisation had its counterpart in their commercial organisation; that there exists an Imperial Council whose proceedings are kept quiet, but which takes into consideration all obtainable statistics, and as far as possible legislates, or endeavours to legislate, on the basis of these statistics. Where fiscal duties are found to be required, such a council puts them on; where there is an advantage in taking them off, they are removed. Where cheap transit is possible they give it; for the railways are the property of the State. I then said :—"Is it to be expected that any country can fight such a combination as that without adopting, at all events, something of their methods, or without studying their methods, and without combining together, if not to imitate them, at least to thwart them? There is a military campaign against us, and we must defend ourselves."

The competition in the colour trade, for instance, has almost prohibited the manufacture of dyes in England. In Germany the management is in the hands of well-trained men, who, aided by an efficient staff of engineers and chemists, are continually engaged on the problems of utilising any discovery made in their own laboratories or elsewhere, and making it commercial, whether by securing cheap raw material, cheapening the process of manufacture, or creating a public demand for the object to be manufactured. Agencies are maintained all over the world whereby the article is introduced to the notice of foreign purchasers; and an extensive credit system is encouraged. All this is legitimate; but the maintenance of a trained legal staff, not merely to advise as to the validity of patents, but to advise whether the infringement of

another's patent is likely to be successful, and whether it may not be possible, by infringing a patent, so to saddle an opponent with legal expenses as to break his competition, is not easily defensible. Fair competition between individuals lies at the bottom of all trade; unfair competition, backed by all the resources of the State, is what we have had to face with Germany.

We have recently had brought to our notice German methods applied to the shipping industry, and the Australians have been pointing out that the control of the "base metal market" is almost entirely in German hands.

It is necessary to go further; just as the German State has shown itself to be no respecter of treaties, just as the leaders of the German army have revealed themselves as breakers of every humane law, treacherous and deceitful, so long as they think they can gain their ends, so it is foolish not to be warned that the German nation as a whole, is completely unworthy of trust; that commercial agreements are regarded by members of that nation as binding only so long as some advantage is to be gained by keeping to them, and that dishonesty is excusable if only it appears to lead to German prosperity. For there is a sort of debased patriotism in the average German mind, "Deutschland, Deutschland über alles, über alles in der Welt," no matter how the supremacy of "Deutschland" is secured.

We were shocked at the beginning of the war by the disregard towards treaties displayed by our opponents; we were amazed at the treatment of Belgian non-combatants; and we are slowly realising that every trick, from firing on the Red Cross to the false display of the white flag of surrender, is made use of by the enemy, and not, be it observed, by individual groups of our opponents, but by command from high quarters. We are slowly and incredulously awakening to the knowledge that German commercial tricks are on a par with their tricks in war: that the whole nation is infected by the microbe of dishonour and dishonesty.

Of course, there are honest men among our opponents; from time to time we read of kind acts to our wounded; and from a lifelong experience of Germany and the Germans I have no hesitation in stating there are Germans as kindly, as honest, and as upright as there are among ourselves, the French, the Americans, and among the inhabitants of all other nations. That is not the point. What we have to face is a nation organised for a policy of dishonesty; and a nation which, as a nation, approves of that policy. Moreover, this nation believes that the policy of dishonesty is likely to be a successful one, and it has the will, and believed itself to have the power, to enforce this policy on the whole world. Conscientious Germans have been impressed more by the end than by the means adopted to gain that end: the prosperity of their "Vaterland."

I conceive that the main purpose of the Institute of Industry and Commerce is to take counsel and evolve some means for combating this attack. Just as it is clear that peace can never be declared until the chance of another Teutonic outburst is made impossible, by the total disbandment of the German army, so it must be evident that the commercial system of Germany cannot be allowed to continue. It is probable that it is better to make a beginning by an alliance of science, industry, and commerce, such as the institute contemplates; but it will be necessary, if the future German State is allowed to retain the power of waging an industrial war, to combat it by the action of the organised British nation, that is, by the State. Once that conquest is achieved, however, we should do well to remember that commerce should be co-operative and not competitive; that it is to our interest not only that we ourselves should prosper, but that others should also prosper; that, indeed, our own prosperity is bound up in the prosperity of our fellow-creatures.

WILLIAM RAMSAY.

STATE AID FOR SCIENCE.[1]

Introductory.

ELEMENTARY education and the training of teachers for work in elementary schools have been the object of State solicitude for the past eighty years. Increasing sums of money have been devoted to these two purposes; rules and regulations in rich variety have been framed for the proper disposal of this money, and some of the ablest and most energetic administrators have spent their lives in the endeavour to carry them out; a vast system of officials and organisations has arisen to see that no possible flaw or fault remains in the effective distribution of the sums annually voted by the State; and yet the general consensus of opinion among those best qualified to judge is that the results achieved are very poor, that they are transient in effect and occasionally even harmful rather than beneficial. Gigantic efforts have been and are being made, yet the results are plainly incommensurate with the outlay; very few indeed being satisfied that the State and the locality are getting money's worth for their expenditure.

This then being the present position as regards the problem of elementary education let us now see how far the same position is true in regard to the small portion of the State's annual expenditure on education of all types and degrees which is specifically earmarked for the promotion of science teaching, scientific training, and research. It may perhaps turn out to be true that the ineffectiveness of much of our educational system is due to the absence of the scientific spirit among our administrators and teachers, to lack of definite knowledge of the capabilities of the child mind, and neglect of the conclusions which science, if properly studied, could have supplied.

Taking as the basis of our investigations the various sums voted by the State for the promotion of science during the past sixty years, we can from the variations in the amounts, and in the particular objects for which these amounts were granted, observe how the encouragement given to science has fluctuated. For this purpose the Estimates annually presented to Parliament are the most trustworthy guide—a guide who, however, frequently leads one astray.

The task of following any particular item of the Vote from year to year is rendered difficult from the various reorganisations and rearrangements occasioned by the changes made from time to time in the organisation of the various offices, as, for example, when the control of science instruction in Scotland was transferred to the Scottish Education Department in 1897–8, and that for Ireland in 1899–1900 to the Board of Agriculture and Technical Instruction. Nor is this the only source of confusion. Sub-heads dealing with science are sometimes kept separate from and sometimes amalgamated with those relating to art, so that it is not possible to say with certainty whether a particular form of aid has increased, diminished, or disappeared.

This difficulty becomes accentuated in the year 1900, when the Science and Art Department became amalgamated with the Education Department, and the two started anew on their official career as the Board of Education. In subsequent Estimates votes were

[1] Abridged from a paper read before Section L of the British Association at Melbourne, by C. A. Buckmaster.

rearranged, amalgamated, or split up until their history can no longer be followed with accuracy.

It will thus be seen that the determination of the exact amount contributed by the State for the furtherance of science is not altogether an easy matter. Moreover it cannot be settled by turning to Class IV. of the Estimates, which deals with the amount allotted for education, science, and art—three subjects probably entirely distinct in the official mind. For in Class II. of the Estimates dealing with public offices there will be found under the head of the Board of Agriculture items for agricultural education and for advances to societies for experimental purposes and for research. This is only one example to show that the money voted annually for education, science, and art does not represent the total of the State's assistance either to education or to science. We need not inquire on the present occasion if it is more complete in regard to art.

Again, from time to time the State, goaded into action by outside pressure, grants sums of money for specific scientific inquiries, such as the 1000*l.* allotted in 1873 and following years to the Sub-Wealden Exploration, the 15,000*l.* granted for observing the transit of Venus in 1882, the annual grants for successive years of varying sums from 2000*l.* to 5000*l.* for the Deep-Sea Exploring Expedition in 1877–87. The recent National Antarctic Expedition also received the substantial help of 45,000*l.* The International Geodetic Conference was aided for a number of years, and so also was, and is, the North Sea Fisheries inquiry. These are genuine examples of the aid given by the State for science purposes, but they are from their very nature variable in amount, and not assigned as part of a definite policy of encouraging systematic scientific research as a continuous and necessary part of national organisation. They owe their existence to external forces, and if these were withdrawn or lessened they would disappear.

The grants of this character are generally, but not universally, to be found under Class IX. of the Estimates labelled "Miscellaneous or Temporary."

Another series of grants are to be found under the heading "Public Buildings," where the sums voted for the Natural History Museum, the Royal College of Science, the Edinburgh Industrial Museum, the National Physical Laboratory, the Edinburgh Observatory, and other buildings may from time to time be discovered and their progress followed by noting the sums annually voted towards their commencement, continuation, and completion. These sums also are not voted as part of a settled, thought-out scheme of scientific equipment for the nation, but are granted more or less piecemeal, according to the pressure which can be brought to bear to get a particular vote included in the Estimates.

Class IV. (Education, Science, and Art) does not therefore, include anything like all the State aid given to science, nor does it include all that is given for educational purposes. The War Office Vote includes large sums spent, not merely on the technical training of officers, but also on the general elementary education of the rank and file of the Army, and of their children, both in day schools and in evening classes. Similarly, the Admiralty Vote includes the sums spent on the educational institutions at Osborne and Dartmouth, and less important places. The Vote for educational purposes in the Army Estimates for 1914–15 amounts to more than a quarter of a million, while that for the Navy is slightly less than this amount. Probably a greater proportion of the Navy Vote is spent on science instruction than is the case with the Army. This might naturally be expected. Nor is this all. From time to time a Government Department embarks on a little scientific investigation on its own account. Though started with a purely utilitarian aim, the results cannot but be of some permanent scientific value. The expense attending these investigations must be sought for among the votes taken for the office specially concerned in the inquiry. Such cases will be found under the Public Health Department of the Privy Council, the Chief Secretary for Ireland's Department, the Board of Trade, and the Local Government Board.

For the sake of completeness mention should be made of the sums expended by Royal Commissions and Select Committees, such as the Royal Commission on Scientific Instruction, which was appointed in 1870, that on Technical Instruction in 1881, and the Select Committee to report on the Museums of the Science and Art Department in 1898.

All these have the same characteristic of indefinite variability, and a consideration of their annual fluctuations would lead to no definite result. Without, therefore, ignoring or depreciating the valuable if erratic assistance the State gives from time to time for scientific purposes by providing buildings, appointing commissions, financing expeditions, and carrying out inquiries, it is only by restricting attention to the sums voted year by year in pursuance of a more or less settled scheme that we can truly determine if science instruction is really increasing in volume and effectiveness, and is being made more and more available for all who could derive profit from it. In this connection it may be worth while to recall the words of the Queen's Speech in 1853:—"The advancement of the fine arts and of practical science will be readily recognised as worthy the attention of a great and enlightened Nation, and I have directed that a comprehensive scheme should be laid before you having in view the promotion of these objects towards which I invite your aid and co-operation."

The Rise and Fall of the Science and Art Department.

Before the first International Exhibition of 1851 State aid to education of any type had been practically restricted to an annual grant for elementary schools, which in 1850 had reached the modest sum of 125,000*l.*; to a grant to the University of London of about 4000*l.* spent on examiners, scholarships, exhibitions, and prizes, with practically nothing on salaries; grants for the teaching of drawing in schools of design; and grants to the Royal Dublin Society. The grants for schools of design had crept up year by year from 1300*l.* in 1838 to 14,755*l.* in 1850. The Royal Dublin Society received annually about 6000*l.*, sometimes a little more, sometimes less, and this was supposed to be expended very largely in the promotion of science and art.

In 1853 the new Department of Science and Art was launched, and the Geological Survey, the Geological Museum, and the Museum of Industry, Dublin, put under its charge. The infant South Kensington Museum and the well-established School of Design were also included, and the new organisation began its task of encouraging science instruction. But whatever may have been the views of far-sighted men like Sir Henry Cole, who then, as Mr. Cole, was making history as director, those in actual control were singularly blind to the future. Thus the Board of Trade in a letter to the Treasury in March, 1853, state that "in the proposed Department of Science and Art the motive power will be local and voluntary—the system in the main self-supporting."

In regard to the Geological Survey, it is stated:—"It is important to bear in mind that the expenses incurred on account of the Geological Survey are not permanent in their character, and will ultimately cease

to be a charge upon the public." "Ultimately" is a good word, seeing that the expenses of the survey were in 1852–3 approximately 5500*l*., while sixty years later, in 1913–14, they were about 17,875*l*.

This short-sightedness was not confined to the Board of Trade, for the Treasury with due solemnity replied that in their opinion "the utility of (science and art) institutions is great in proportion as they are self-supporting."

If this test were applied to our existing science institutions there are few which could claim to be really of great utility.

Of more value was the statement made by the Board of Trade further on in the letter already mentioned that the "assistance received from Parliament will be applied to the general good of all."

With these expressions of policy the Science and Art Department started on its career. The sums annually taken in the Estimate for its manifold activities gradually grew from year to year from 44,476*l*. in 1853–4 to 600,781*l*. in 1898–9. In the following year the amount granted is included in the Estimate for the Board of Education.

For many years the science grants were awarded on the results of examination and attendance. Before a school could claim payment for its work the students had to receive a certain minimum amount of instruction from a recognised teacher, this amount of instruction being spread over a certain number of weeks, so as to enable the instruction to be given systematically, with time for home-work and home-reading. Nothing was paid on account of those students who did not pass the examination at the end of the course, and the amount paid depended upon the grade of success, varying from a minimum of 1*l*. to a maximum of 5*l*. On the results of these examinations the National Scholarships, Royal Exhibitions, Whitworth Scholarships and Exhibitions, were also awarded and the examinations are still temporarily retained for this purpose.

It is of course easy to criticise this system but at the time it was instituted, examination was much more popular as a universal test of attainment than it is at present. At a time when children of tender years were being coached to pass an individual examination in reading, writing, and arithmetic not to mention a number of additional subjects, it was only natural that the same tests should be applied to the older students found in evening classes.

A centralised examination meant also the publication of official syllabuses for each of the branches of science in which examinations were held. These no doubt in time tended to cramp and stereotype the teaching but this ill effect was minimised by the fact that the examination papers always contained more questions than the candidate was permitted to answer and he was thereby enabled to select those parts of the subject which had formed the principal portion of his instruction or in which he was specially interested. It should also not be forgotten that in the case of the great majority of the candidates, certainly in the case of those above 16 years of age, the examination was looked forward to as a necessary crown to the session's work. With much that was feeble and almost worthless, and in spite of cramming and learning by rote, there was a substantial amount of good grain winnowed from the chaff and many a man can trace back his love of science or his success in life to what he learnt in science classes and to the rewards he gained through this much maligned examination system.

It must also be remembered that with few exceptions the examinations were in pure and not applied science, the underlying idea being to foster the study of the scientific principles on which our productive industries depend and to leave the practical working out of these principles to an enlightened self-interest. Nowadays applied science seems to have swept all before it and in the desire for quick results the need of a firm foundation of scientific principles is apt to be ignored.

The Science and Art Department stuck steadily for many years—perhaps too tenaciously—to the pure sciences and only extended its assistance generally to applied science when the system of payment on attendance and results gave way to the system of payment on attendance alone.

One of the early results of the change was distinctly beneficial. Under the examination system the only practical work in science for which grants were obtainable was in chemistry and metallurgy. When payment on attendance alone was established grants for practical work in physics were obtainable and physical laboratories began to be built and equipped. Especially was this the case in the day schools which had grown out of the science classes established in the elementary schools. In these schools—the organised science schools or schools of science as they were called—13 hours each week had to be devoted to mathematics, science, drawing, and manual instruction and the science had to include a definite proportion of laboratory work. The success of these schools so far as their rapid increase in number and in attendance was concerned was undoubted. Not only did the so-called higher grade elementary schools adopt the system but numbers of endowed secondary schools followed suit. For these latter the requirement of a definite amount of time per week for science and art work was often irksome and the close similarity of the curriculum in the higher grade and in the secondary school led to fears of competition and overlapping.

Inquiry showed that these fears were largely imaginary, but as at the time the State was developing its scheme of assistance to secondary education, the organised science school became officially unpopular and the discovery that school boards could not legally carry on such schools was the deathblow to systematised science teaching in connection with elementary day schools. The attempts to soften the blow by the establishment of higher elementary schools was unsuccessful in spite of much official pressure. The original minute under which these schools were to work was a marvel of restrictive officialism and though the stringency of the original regulations was subsequently relaxed the higher elementary school never prospered and nothing has yet effectively taken the place of the defunct organised science school. It remains to be seen whether the new junior technical schools, which after years of repression have forced their way into official recognition and favour, will fill the gap in the education of the elementary school boy or girl who, having gone through the ordinary elementary school course, has had neither the desire nor the opportunity to carry his training further in a secondary school.

Building Grants for Local Science Schools.

Aid was first granted towards the building of science schools in 1868, grants in favour of schools of art having been in existence since 1856. The rate of grant was half-a-crown per sq. ft. of floor space up to a maximum of 500*l*. The grant was withdrawn in 1897, but applications for aid received before that decision was published were accepted, and the claims so acknowledged were not finally liquidated until 1902. Thus, for a period of thirty-four years State aid was given towards the provision of suitable buildings for science instruction. It is of interest to

see how this aid was appreciated. During the first half of the time 1868–1884 the grants paid amounted to 4,862*l*. 15*s*., representing about 39,000 sq. ft. of floor space; during the second half of the term 1885–1902 the grants paid amounted to 43,183*l*. 15*s*., representing 345,470 sq. ft. of floor space, or more than eight times as much as in the earlier period. In fact, before the edict went forth withdrawing this help the annual expenditure had crept up to nearly 4000*l*. a year, representing at least eight additional technical schools per annum. The remarkable increase during the latter half is due partly to the stimulus afforded to local authorities by the various Technical Instruction Acts, but public subscription provided no inconsiderable portion of the total, and it must be remembered that the State aid was only a small fraction of the total cost. It would be no exaggeration to say that this expenditure of public money of 48,000*l*. represented half a million of local funds devoted to building and equipping science and technical schools and institutes.

In addition to the aid given to science teaching by the payment made to teachers or to local committees on examination results, the science and art department promoted science instruction in a number of ways, which, without much expenditure of State funds, stimulated local interest and encouraged local expenditure for science purposes.

Among these minor influences the chief place must be given to the Royal Exhibitions and National and Local Scholarships, and with these should be coupled the Whitworth Scholarship and Exhibitions founded in 1867, which the department administered under Sir Joseph Whitworth's trust. These, fortunately—with the exception of the Local Scholarships—still continue, but it is doubtful if under present regulations they give the same opportunity to the working artisan as in the early days of their first establishment.

Grants towards the provision of laboratory fittings and toward the purchase of apparatus also served to encourage proper provision for experimental teaching at better total cost to the State. These also have disappeared, although it is still possible in certain circumstances to get aid toward the purchase of museum objects.

Prizes and medals were also in the early days found useful in encouraging students and incidentally in distributing among the successful competitors books which were of use in further prosecution of their science work.

These rewards, like the fittings, the apparatus, and the building grants, have now disappeared, and the amounts spent on them no longer appear separately in the estimates. It is doubtful, however, if the country has been saved the expenditure; like the recent savings resulting from the partial abolition of the May examinations, it may possibly reappear in the guise of an increase in the number of officials.

Science in Elementary Schools.

In the early years of State aid to elementary education no attention was paid to the claims of science beyond a pathetic desire that budding teachers should be encouraged to come forward for examination in land-surveying.

But with the rise of class subjects and the addition of "specific subjects" to the code in 1867, science teaching in elementary schools awoke. Special grants were made both for "class subjects" and for "specific subjects" on each child who passed the examination in the subject held annually by H.M. inspector. But very few inspectors either had much knowledge of or much love for science. Nearly all had been appointed for their literary or mathematical attainments, and it is not, therefore, surprising that the majority of the inspectors discouraged schools and teachers from taking science among the specific subjects. This was so generally evident that the British Association appointed a committee in 1879 specially to inquire into the matter. This committee was re-appointed with slightly varying functions from year to year until 1904, when it was reconstructed and the scope of its operations modified. Its annual reports contain statistics as to the various branches of science taken as specific subjects and as to the number of children taught, and it added from time to time some well-deserved criticisms on the general system.

In spite of general official discouragement, much admirable work was done, Liverpool and Birmingham being especially active in this respect. Those who had the opportunity of seeing some of the science teaching at these places can testify to the soundness with which it was given and to the genuine interest taken in it by the children.

By the year 1878–9 there were 29,459 children examined in physical geography, 20,506 in animal physiology, 1621 in mechanics, and 1332 in botany. Ten years later physical geography had disappeared, apparently having ceased to be a "specific subject" and become a "class subject" under the guise of elementary science. Animal physiology shows a falling off to 15,893 children examined, mechanics a big rise to 9651, botany a slight increase to 1944, while chemistry was taken by 1531 pupils, sound, light, and heat by 1076, magnetism and electricity by 1669, and principles of agriculture by 1199. We again pass on ten years, and find that in 1898–9 the numbers in animal physiology had grown to 41,244, in mechanics to 50,324, and in botany to 8833. Chemistry shows almost a tenfold increase to 14,737, magnetism and electricity had grown to 7697, sound, light, and heat to 1943, while principles of agriculture remains inactive at 1163. Various other branches of science also appear, with among them nearly 10,000 more. Science teaching in the elementary school seems to be flourishing, but a few years later the system of payment is altered; "specific subjects" disappear, and the teaching of science rapidly changes and then dies down.

The breaking down of the system by which the grants were made to depend upon class subjects and specific subjects, and the merging of these in the general course of the elementary-school curriculum, was no doubt educationally sound, but it certainly has had one effect: the reduction in the amount and the standard of science instruction; while the policy itself has not yet been effectually completed, since separate grants are still obtainable for "special subjects" such as handicraft, cookery, laundry-work, gardening, and dairywork.

There can be no doubt that there is less real systematic science teaching in our elementary schools than was the case twenty years ago, and that the proportion of the total expenditure on elementary education which can be looked upon as spent in promoting science instruction is decidedly less not only in proportion but in amount.

State Aid for Science in the Secondary Schools and the Universities.

State aid to secondary education grew out of the grants made to science classes. These classes were held at first only in the evening, but after a little some began to meet in the daytime. Some of the

private schools and less well endowed grammar schools, attended partly by children of parents who might be described without much inaccuracy as belonging to the "industrial classes," began to realise that they might get help from the Science and Art Department. On its side the department promised an additional grant, first of 10*s*. and then of 1*l*. per head for pupils taking a definite course of science work, and passing successfully in at least one of the subjects of the course. Thus arose the organised science school. As has already been stated, most of the grammar schools found that the requirements of the department for an organised science school were too severe, and continued to get aid for separate science classes, and the organised science school scheme was for a time mainly worked either by schools of a more or less private character, by schools held in mechanics' institutes as at Leeds and Keighley, or by school boards. In fact, the organised science schools promoted and carried on by the bigger boards, as at Manchester, Salford, Bolton, Sheffield, and many other places, were so successful as to cause alarm to the grammar and endowed schools. A lively controversy arose in which the catchwords of overlapping and co-ordination made a frequent appearance.

By various modifications in the regulations, the purview of the Science and Art Department in the organised science schools was extended, first to requiring a certain amount of non-science work, secondly insisting on the teaching of at least one language other than English, and finally by requiring the whole of the secular portion of the curriculum to be submitted to inspection. This, with the alteration of the grant from one depending on results and attendance to one on attendance alone completed the process by which a large number of secondary schools found themselves in receipt of State aid and open to State inspection.

But this change was no sooner complete than the insistence on science instruction, which was the basis of the early system, was relaxed, till in the present day, when a grant of 774,000*l*. is taken for aid to secondary schools, none of it can be said to be specifically devoted to science instruction, although science must, as a general rule, form part of the school course. It is not too much to say that the weight of official recognition has passed from the scientific to the literary side of the secondary school, and that the time and energy devoted to instruction and practical work in science have shown a remarkable decrease. So much for the secondary school. We now come to the universities and the university colleges. Here the State aid has taken a variety of forms. The grant to London University began in 1839 with a modest 5,050*l*. for the expenses of examiners in various branches of knowledge, among which science held a worthy place. Expenses of administration were from time to time brought within the scope of the vote.

After the year 1891–2 the special vote for the London University practically disappears from the estimates. There had always been considerable receipts paid into the Exchequer, so that the sums actually voted had long ceased to represent a clear grant from the State, and in the succeeding ten years only modest sums from 100*l*. downwards are entered under this vote. At the same time, gradually increasing sums were voted for distribution among the universities and university colleges and the constituent colleges of the London University received, and still receive, substantial sums in this way.

The universities and the university colleges have enjoyed State assistance in a number of ways. First and for long the most important of these aids was the annual grant administered by the Treasury, and applied to what was considered by the Treasury advisers the proper work of universities—literature, mathematics, and pure science, excluding rigidly any applied science or technology, if such there chanced to be within the sacred precincts. This aid began in 1883–4 with a modest grant of 4000*l*. for the University College of Wales. It was increased to 8000*l*. in 1884–5, to 11,500*l*. in 1885–6, to 12,000*l*. in 1886–7, and to 14,000*l*. in 1887–8 and 1888–9. In the following year England begins to participate in the grant under this vote, and its subsequent fortunes are as follows:—

	£		£		£
1889–90	44,785	1898–99	104,507	1907–8	201,400
1890–91	71,000	1899–1900	105,700	1908–9	221,800
1891–92	71,000	1900–1	105,500	1909–10	217,400
1892–93	71,000	1901–2	116,700	1910–11	218,100
1893–94	83,000	1902–3	121,706	1911–12	303,800
1894–95	86,098	1903–4	119,100	1912–13	314,200
1895–96	98,339	1904–5	151,200	1913–14	314,300
1896–97	102,179	1905–6	197,300		
1897–98	104,059	1906–7	200,400		

A portion of this vote, about 28,000*l*., is, however, specifically voted for the purpose of Welsh intermediate education, and should, in fact, not appear here but in the vote for secondary education.

In addition, the universities and university colleges have received considerable benefit from the grants paid for the training of elementary-school teachers in the day training colleges.

Some instruction in science has always been a necessary portion of the training course, though it it must be admitted that the emphasis laid upon it in the day training colleges was always less than in the better residential colleges, and has in recent years evolved or degenerated (according to the views taken of its importance as a branch of training) into nature study or general experimental science. The principal value of this variety of State aid has been, not in any stimulus given to science instruction, but in the support it afforded in the early years of these colleges and universities to their arts side, a side which, without these day training students, would often have been non-existent.

The earliest mention of the State solicitude for the training in science of the future teachers in State-aided schools appears, as already stated, in the directions to inspectors in 1845 that inquiries should be made as to the attainments of the teacher in land surveying—an attempt presumably to give a rural bias to elementary education—the rural bias which, after seventy years, we are still seeking to impart. A more serious attempt was made in the newly-founded training colleges of St. Mark's, Chelsea, St. John's, Battersea, and Chester, where from the first some one or more subject of science—and we may also add—of handicraft, were included in the training course, and we may be certain that the inspector who reported on these colleges—Canon Moseley—was not unsympathetic to this infant attempt at a real general education.

Science teaching continued to flourish at the training colleges for many years. Laboratories were gradually built and fitted up, systematic practical work undertaken, and in the more powerful and well-equipped colleges an increasing proportion of their students were enabled to obtain the B.Sc. degree or the Inter B.Sc. of the University of London. Then came a period of official repression, when rightly or wrongly the attempt was made to devote the training college time more exclusively to the professional side

of the schoolmaster's calling, and to discourage the working for degrees.

The growth of the day training colleges and their intimate connection with the universities has, however, rendered of slight effect the attempt to divert students from the degree studies, and the present tendency seems to be rather to encourage this university training by the grant of facilities for lengthening the training college course beyond its normal two years' duration.

The universities and university colleges had a third source of income from the State, although a very small and variable one, in the fees paid by the Science and Art Department for the attendance of teachers at science courses, and in the aid given toward the establishment of local exhibitions tenable at the colleges. Though the amount of the aid has been trifling so far as the actual sums are concerned, the effects have been remarkably good. Many a man now holding a good position in the scientific or industrial world can trace his success to the opportunities given him by these local exhibitions to pursue a course of systematic study in a fairly well-equipped institution of university rank. This is still more true of the Whitworth scholarships and exhibitions which were at one time generally held at an institution of this type.

But the most elastic source of Government aid to science work in the university was tapped for the first time when it was made clear to the university authorities that the Regulations of the Technical Branch of the Board of Education definitely offered assistance to "any institution in which systematic instruction in science or science and art was given." It only remained for the university to place, under the supervision of the Board of Education, the work in the applied sciences which the Treasury officers declined to recognise. After the first plunge was made one after another succumbed to the fascinating bait, and now all the universities in the country receive aid from the Board of Education for at least some portion of their work. The fears at first naturally felt that the acceptance of the Board's aid would result in fettering the teaching or the administration have so far proved in practice to be unfounded.

Following the example of the universities came the medical schools attached to the London hospitals, and the same elastic regulations enabled them, too, to be admitted to their share in the sums available for technical instruction. The first grant under this head was one of 1,000*l.* to St. Mary's Hospital Medical School in the year 1908–9. For the last financial year for which figures are available, a sum of 15,600*l.* was distributed among eleven medical schools—a very substantial and acceptable increase—while the total grant, including the universities and the university colleges, was 44,600*l.*—a sum, be it remembered, in addition to the Treasury grant.

It will therefore be seen that State aid towards science teaching of university standard has shown a distinct upward tendency, but a tendency more marked in regard to applied science, less obvious in regard to pure science.

State Aid for Agricultural Education.

State aid towards agricultural education began in 1888–9 with a grant of 5,000*l.* to the Agricultural Department of the Privy Council, and in 1890–1 the Board of Agriculture came into being. In the year following the creation of the new Department the amount voted had grown to 8,000*l.* It remained at this figure till 1895–6 when 1700*l.* was transferred to the Scottish Education Department.

By 1897–8 the expenditure had risen again to 7200*l.* In 1901–2 it was 8900*l.*, and ten years later had grown still further to 19,500*l.* In this year the Board of Agriculture captured the president of the Board of Education, and shortly after completed its triumph by annexing almost all the agricultural instruction formerly aided by the Board of Education and 6000*l.* of its grant. The Board of Education still controls and aids the pleasing and harmless fad of school gardens in connection with elementary schools and with evening schools for youths not over sixteen years of age. Thus, one whole branch and that not the least in importance has been definitely removed from the control of the State Department specially created to deal with education and put under another responsible for swine fever and cattle disease, ordnance survey, and the regulation of commons.

The change appears to have commended itself to the country and to the farming interest, for the grants for the present year are on a scale far in advance of anything before. The vote for agricultural education is 98,250*l.*, for forestry education 1000*l.*, for general agricultural research 43,815*l.*, for forestry research 1200*l.*, and for animal and plant pathology 18,650*l.*, making a total grant of 163,000*l.*, as against one of 78,000*l.* for the preceding year. But this is not all the State aid to agriculture. Scotland gets 51,184*l.* and Ireland 49,750*l.* In addition, there is a grant of just over 7000*l.* for fishery investigations. The obvious moral of these figures seems to be that technical instruction and research develop rapidly when confided to the care of an authority specially entrusted with this duty, instead of to one immersed in other and more immediately popular types of education.

State Aid for Scientific Research and to Learned Societies.

Finally we come to the aid given by the State towards scientific research. The total amount of the aid is, however, uncertain, and it is easy to omit items in various votes which might conceivably be properly classified under this heading. For our purpose the most important portions of this aid are (1) the research grant administered by the Royal Society. This began in 1850 with a sum of 1000*l.* and continued, in spite of some alarms of a possible withdrawal, till 1876, when an additional grant of 4000*l.* for five years was made. In 1882 the original grant of 1000*l.* and the additional grant of 4000*l.* were replaced by a single sum of 4000*l.*, and it has remained at that sum to the present time. An application for an increase was made in 1894, but not granted, but, possibly as a compromise, a grant of 1000*l.* was made towards the expense of the publication of scientific researches, and this grant still continues to appear annually in the estimates.

State aid to the various scientific societies of the country may be best dated from the year 1854–5, when a grant of 500*l.* was made to the Royal Geographical Society, and the grant has continued at the same amount. As already stated, the Royal Society grant of 1000*l.* was in 1856–7 definitely inserted in the Annual Estimates, but similar amounts had in fact been granted since 1851, the amounts for the succeeding years to 1855 being looked upon as special and not necessarily annual. In 1866–7 the Royal Society of Edinburgh secured 300*l.*, and in 1869–70 these three votes, with the grants for scientific investigations, were classified together as Votes for Learned Societies with a total of 12,300*l.* The subsequent history of this Vote is shown in the following table:—

	£			£			£
1870–71	12,370	...	1885–86	21,400	...	1900–01	50,724
1871–72	12,450	...	1886–87	24,400	...	1901–02	53,154
1872–73	12,450	...	1887–88	23,900	...	1902–03	68,396
1873–74	12,450	...	1888–89	21,900	...	1903–04	90,780
1874–75	13,300	...	1889–90	27,603	...	1904–05	46,407
1875–76	12,550	...	1890–91	25,253	...	1905–06	53,900
1876–77	12,550	...	1891–92	25,790	...	1906–07	57,650
1877–78	15,550	...	1892–93	25,896	...	1907–08	54,479
1878–79	17,050	...	1893–94	26,163	...	1908–09	56,295
1879–80	17,050	...	1894–95	26,247	...	1909–10	57,964
1880–81	17,050	...	1895–96	26,827	...	1910–11	74,228
1881–82	21,600	...	1896–97	28,154	...	1911–12	61,603
1882–83	20,900	...	1897–98	27,984	...	1912–13	125,523
1883–84	23,650	...	1898–99	28,452	...	1913–14	99,708
1884–85	23,400	...	1899–00	36,724			

On the whole, this may be looked upon as evidence that there is a recognised body of feeling in favour of annual subsidies of this character. The large fluctuations in the amounts are due to the initiation or the completion of the principal expenditure on various new branches of work, *e.g.* the National Library of Wales, the Antarctic Expedition, the Sub-Wealden Exploration, the North Wales University College, and so on. The vote is in fact the collection of miscellaneous items of expenditure, all of which may be said to be in some degree scientific in character, and which are, therefore, appropriately grouped under Class IV., Education, Science, and Art.

It has not been found possible to trace the grants specially allotted to Scotland and Ireland with any approach to accuracy. In the earlier years they were included in those for England and Wales. First one and then another item was removed and committed to the control of a department of the nation concerned. In this way the vote for Scottish Education appeared separately for the first time in 1875–6, and that for the Irish Department of Agriculture and Technical Instruction in 1899.

For the current financial year 1914–15, the votes for Scientific Investigation, etc.—the Societies being presumably the etc.—is apportioned as follows:—

		£
1.	Royal Society Scientific Investigations...	4,000
	Royal Society Scientific Publication ...	1,000
	Royal Society Magnetic Observatory, Eskdalemuir	1,000
	Royal Society National Physical Laboratory	7,000
	Royal Society National Physical Laboratory, Aeronautical Section ...	12,550
2.	Royal Society, Edinburgh	600
3.	Meteorological Office	20,000
4.	Scottish Meteorological Society	100
5.	Royal Geographical Society	1,250
6.	Royal Geographical Society of Scotland	200
7.	Marine Biological Association	1,000
8.	Royal Zoological Society, Ireland ...	500
9.	International Geodetic Association ...	300
10.	Solar Physics Observatory	3,000
11.	North Sea Fisheries Investigation ...	1,250
12.	British Antarctic Expedition	5,000
13.	Edinburgh Observatory	1,637
14.	International Seismic Association ...	210

Either the Scientific Investigation or the etc. also covers grants to the Royal Academy of Music, the Royal College of Music, Royal Irish Academy of Music, the Royal Irish Academy, the Royal Hibernian Academy, the British School at Athens and at Rome, the British Academy, and the National Library and National Museum of Wales. Among them they take 40,100*l.* of the total.

The conclusions to be drawn from these facts are simple and evident. The aid given by the State towards the advancement of science has increased in amount and variety so far as applied science is concerned. Questions dealing with matters of immediate utility connected with physics, biology, pathology, or agricultural practice have secured the attention of the State with a fair measure of success. But the support and encouragement formerly given to pure science have dwindled down till they are now almost lost among the grants given for the study of Shakespeare and tailors' cutting, the practice of cooking and Morris dancing, or the cultivation of languages from ancient Greek to modern Esperanto. All excellent objects, and all deserving of the nation's support, but in their rapid growth they bid fair to choke the tender plant of pure science, to the prior existence of which they owe their own flourishing condition, and the early struggles of which ensured their own success.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—A course of six lectures on the international crisis in its ethical and psychological aspects will be given at Bedford College, Regent's Park, on Fridays, at 5.15, beginning on February 5. The lectures have been arranged by the council of Bedford College in co-operation with the Committee of Imperial Studies of the University of London, and are open to the public without charge. Viscount Haldane, visitor of the college, will be in the chair at the first lecture, when Mrs. Henry Sidgwick will speak on the morality of strife in its relation to the war. The other lecturers will be Prof. Gilbert Murray, Dr. A. C. Bradley, Dr. L. P. Jacks, Prof. Stout, and Dr. Bernard Bosanquet.

SEVERAL bequests for higher education are chronicled in the issue of *Science* for December 25 last. Mr. J. Arthur Beebe has bequeathed 30,000*l.* to the building club of the Harvard Club of Boston; 2000*l.* to the fund of the Harvard class of 1869, of which class he was a member, and 1000*l.* to Dr. F. C. Shattuck for investigations of tropical diseases. The residue of the estate, after some personal bequests have been paid, is bequeathed to Harvard University, the income to be used for the general purposes of the University. The University of Pennsylvania will be the ultimate beneficiary of the 40,000*l.* estate of the late Mr. William B. Irvine, ex-city treasurer, who died December 6. The money will provide either a building for a school of mining engineering or an auditorium.

DURING the second week of the year no fewer than twenty educational associations held meetings in London. The quality of the papers read was in many cases very high, and the attendances were such as fully to justify the organisers in their refusal to listen to those who suggested postponement on account of the war. The sense of national crisis deepened and strengthened the tone of the addresses whenever the subject under discussion was felt to concern national progress. It was the rule that the debates dealt with wide issues, and the fact that a drop in quality and interest affected the exceptional instances when minutiæ of the class-room or examination-hall fell to be discussed is perhaps scarcely a matter for regret. The problems of suitable science work to be undertaken in schools, including the aim of such work and its national influence, obviously rank among the matters which need statesmanlike handling in the near future. In her address to the Science Teachers' Association, Mrs. Bidder discussed the scientific training most suitable for girls, and urged that the work should be manual and scientific, so that girls could handle things and obtain a scientific attitude of mind. Elementary physical and chemical work should lead

to appreciation of scientific method and scientific accuracy. Domestic work might be taught as an art or craft, and more things might be taught in the home—by which was not meant an increase in "home lessons." Girls could be taught to express themselves clearly through science lessons. The address was practical, and will no doubt be helpful to the science mistresses who heard it. It is a matter for great regret that no other paper on science teaching in schools (above the stage of nature-study) appeared at the conferences during Education Week, 1915. The presidential address delivered by Sir George Greenhill before the Mathematical Association upon the subject of mathematics in artillery science, did, however, deal largely with the unsatisfactory position which science occupies in the training of artillery officers.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, December 18, 1914.—Dr. A. Russell, vice-president, in the chair.—H. R. **Nettleton**: A vacuum guard-ring and its application to the determination of the thermal conductivity of mercury. A specially constructed vacuum vessel heated at the top by steam and cooled at the bottom by flowing water, is used to find the thermal conductivity of mercury. The vacuum acts as a guard-ring, which is at the same time not open to the well-known objection of communicating to the calorimeter a quantity of heat difficult to estimate. So efficient is the vacuum that the temperature gradient, as measured by a single thermo-junction carried by a cathetometer, is probably not in error to the extent of 1 part in 500. The mean value obtained for the thermal conductivity of mercury in a set of twenty-four experiments is 0·01960 c.g.s. units over the range 35° C. to 45° C. The remarkable linear nature of the temperature gradient obtained within the vessel, the cross-section of which was very uniform over the larger range of temperature, 35° C. to 65° C., would indicate at least that there is no diminution of thermal conductivity with rise of temperature.

THE MANUFACTURE OF DYESTUFFS IN BRITAIN.

A Summary and an Appeal.

THE speech of Lord Moulton in Manchester on December 8, 1914, was a notable event, even in these days of strenuousness and surprise. For although he was careful to disclaim any official sanction of the views he expressed, it was common knowledge that the Government had requisitioned his services in investigating the question of the shortage of dyestuffs, and had based its policy largely on the advice he gave as the outcome of his investigation.

The general outline of the crucial position in which the British textile trades are placed at the present time is well known. At least 1,500,000 operatives are engaged in the various branches of the trade, which has an annual value of 200,000,000*l.* Nearly the whole of this vast industry depends for its commercial success upon the use of dyestuffs, which cost about 2,000,000*l.* per annum, and only about 10 per cent. of the necessary quantity of dyestuff is made in this country. Before the war, between 80 and 90 per cent. of our dye-wares was imported from Germany, and this supply is now entirely cut off. Unless, therefore, immediate steps are taken greatly to increase our national output and the supply from neutral countries (chiefly Switzerland), a catastrophe will very quickly overtake the great textile and associated industries.

The magnitude, gravity, and imminence of the crisis clearly pointed to the necessity for Government action, and a "Chemical Supplies Committee" was appointed to confer with the Board of Trade on the position. This committee included a number of well-known chemists, and manufacturers and users of chemicals and dyestuffs. The investigations of Lord Moulton and of this committee are understood to have formed the basis from which the offer of the Government was developed, but the committee was apparently not responsible for the details of the scheme for the establishment of a large Joint-Stock Dye Manufacturing Company, which was made public on December 22, 1914.

Prior to this, on December 10, 1914, a meeting of large users of dyes was held at the Board of Trade, at which a resolution was unanimously passed welcoming the assistance of the Government in a national effort to increase the British supply of dyes. A small committee, representative only of the users of dyes, was appointed, and elaborated the scheme to which reference has already been made for the formation of a manufacturing company.

An influential committee, appointed by the Society of Dyers and Colourists, has also made exhaustive inquiries on the technical side and has accumulated much valuable information.

It is well known that the difficulties involved in establishing on a permanent basis the manufacture of dyes on a scale adequate to supply our needs are enormous, and that without Government or legislative assistance they might well prove insurmountable; and the action of the Government in proffering such broad-minded and generous support has received, as it deserved, the recognition of all parties.

The German colour industry is probably the most complicated, most highly developed, and most profitable of all her great industries. The capital invested in it is about 12,000,000*l.*, and the German exports of dyes and associated products in 1912 were valued at 10,600,000*l.* The organisation, both for production and for marketing and distribution, is wonderfully efficient, and above all the Germans have long realised that in this branch of industry the scientific mind and scientific method must be predominant, not only in the laboratory and in the works, but in the management. The boards of directors of their large works are virtually committees of technical and commercial experts who are in intimate touch with the respective branches of the works of which they have special knowledge. In a word, the trained man of science has in these works come to his own, and a proper recognition of the necessity of this is vital to the development of the British colour industry.

The reasons for the predominance of Germany in this particular industry have been frequently and variously stated, but it is now generally conceded that there is no lack of highly-trained chemists in this country competent to build up a commercially successful enterprise. With regard to other factors, we have, of course, a superabundance of the coal-tar products which form the basis of the manufacture, but the manufacture of certain essential reagents, *e.g.*, fuming sulphuric acid, though already existing, may have to be increased.

Government assistance will be required in regard to the provision of cheap alcohol, and the resources and skill of the chemical engineer will be

heavily drawn upon to provide the essential apparatus. A great number of chemists will be needed to work out the details of known processes, first on the laboratory scale, and later on a bulk basis, and the well-equipped laboratories and staffs of the universities and larger technical institutions might well be pressed into service for much of the preliminary work. Many chemists will also be required for developing new processes and other research work, because of no other industry can it be so truly said that stagnation spells failure.

The great complexity of the manufacture of dyestuffs is not due to the use of a large number of raw materials, the direct products from coal tar being only nine or ten. By chemical treatment these are, however, transformed into 250 to 300 different intermediate products which, in their turn, yield some 1200 chemically distinct dyestuffs. In some processes of manufacture high temperatures and pressures are required; in others the temperature must be reduced, and a large refrigerating plant is an essential feature of a colour works.

Surely, then, it is abundantly evident that the technical expert must be the preponderating element in the dye factory, and that he must have a large share in the management and control. The British custom of entrusting the management of large concerns to financiers, commercial magnates, and "men of affairs" has done much to retard the scientific development of our industries, and the adequate representation of the technical expert on the directorate is vital to the success of the new scheme.

Lord Moulton laid down three propositions with regard to the proposed new British dye manufacturing company. It must be large enough to be able to face severe competition at the end of the war. It must be, and must remain, entirely British, and, it must be co-operative; and all these conditions are fulfilled by the scheme put forward. It is proposed that the share capital shall be 3,000,000*l.*, and the Government offers to supplement this by a loan of 1,500,000*l.* at 4 per cent. and repayable in twenty-five years. The four and a half millions of capital thus proposed is probably ample to establish and develop an industry which would make us independent of imported products.

The proposals with regard to co-operation are that dyers and others associated with the consumption of the products, *e.g.*, spinners, manufacturers, merchants, textile machinists, etc., should take shares in the new company and thus become interested in its success. This is quite sound and receives general acceptance, but certain suggestions in the prospectus with regard to a *pro rata* subscription appear to be unworkable.

The Government reserves the right of appointing two directors of the company, and it is much to be regretted that the opportunity has not been taken of giving a wise lead in regard to the character of the directorate, by stipulating that the scientific technologist should be adequately represented.

Another feature of the scheme propounded by the committee is that certain existing colour works are to be taken over by the new company to form the nucleus of development. The resources of these works are to be extended as rapidly as possible in order to cope with immediate necessities and prevent an actual famine in dye-wares—in fact, large extensions are at the present moment being made.

A point which presents some difficulty in adjustment is the relationship of the new company to existing British dye-producing firms, or such as may be established in the future. It is obviously not desirable to stifle private enterprise by anything in the nature of a monopoly supported by the Government, but the existence of successful German firms which are outside the two great "Interessengemeinschäfte," or rings, indicates that the difficulty is more apparent than real. A somewhat cognate matter is the future relationship of the new company to the Swiss firms which are importing to us during the present crisis.

The various criticisms of the Government scheme which have been offered, refer, not to general principles, but in almost all cases to more or less important details. The general outlines of the scheme—the establishment by co-operation of those specially concerned, of a new company with great resources and financially aided by the Government—has received general approval, and the unprecedented step taken by the Government has been applauded by men of all parties, as meeting an industrial crisis in a bold and statesmanlike manner. In response to this, and in recognition of a national emergency, it is the obvious duty of all who are commercially interested, to deal with the question from the national rather than from the individual point of view. Support of a scheme for the manufacture in Britain of British used dyes is, at its lowest estimate, an essential business insurance, and on a higher plane it is helping forward a movement to free our great textile industry from the danger

of German domination. Apart altogether from the commercial aspect, there is, therefore, a great obligation of patriotism involved. The scheme put forward—possibly as a *ballon d'essai* as regards details—certainly requires modification, but from it can be elaborated a national and co-operative effort which is bound to succeed.

Even to discuss the question of the breakdown of the proposal to make ourselves independent of German products, is almost a triumph for the enemies of our country, and a national humiliation for us. Let us all take as a starting-point of our deliberations that the thing *must be done*, and then the details of how to do it will fall into proper perspective.

Finally it may be pointed out that incidental advantages of enormous national value will accrue as the result of the successful fruition of this dye-ware manufacture scheme. The necessity for dealing with our industries from a national, rather than an individualistic, point of view will be more fully recognised by the Government and by the public. The necessity for the use of scientific method and control of our industries will be strongly emphasised. The claims of patriotism and the value of co-operation in commercial matters will receive fuller consideration, and lastly, the establishment of a powerful company for the manufacture of organic dyestuffs will afford protection to our great industries concerned in the manufacture of inorganic chemicals, an attack on which was beginning to be organised.

Now is our opportunity, and everything is propitious. Patriotism and self-interest are alike clamouring for the establishment of a large dye manufacturing concern, and the Government offers its support. One essential thing may, however, be overlooked—the new company is foredoomed to failure unless a scientific, rather than a purely commercial spirit permeates the management, and an appeal is made to the Government and to the eminent business men forming the committee who have issued the scheme that in its final form it may include a full recognition of this fundamental point. WALTER M. GARDNER.

ELECTROMAGNETIC WAVES.

Electromagnetic Theory. By O. Heaviside. Vol. iii. Pp. ix+519. (London: *The Electrician* Printing and Publishing Co., Ltd., n.d.) Price 21*s*. net.

IT is scarcely necessary to recommend to those interested in electromagnetic theory any book or article written by Dr. Oliver Heaviside. Since 1899 the scientific world has had in possession the first and second volumes of his "Electromagnetic Theory"; and these volumes hold a unique place in the literature of the subject. The first volume was reviewed in NATURE of 1894 (see vol. li., p. 171), and the second in 1899 (see vol. lx., p. 589). Now, after fourteen years of waiting, the world is enriched with the third and presumably the last volume containing the author's views upon the later developments of this ever-growing science.

The third volume is marked by all the characteristics of the earlier volumes. There is shown the same powerful grasp of the great principles of Maxwell's theory, the same intuitive intimacy with the hidden features of the electromagnetic field, the same boldness in materialising the mathematical conceptions, the same fearlessness in attacking really difficult problems, inventing new mathematics if necessary, or ingeniously turning to account old results got in different lines of inquiry. Every now and again he runs off into a side alley, at first sight quite away from the natural highway, but out of which he leads us back with some substantial gain, fitting us the better for the strenuous work to come. And we need all our best powers to follow his lead. There is no shirking of difficulty; there is no yielding to authority. Every new fact or hypothesis in electromagnetism must pass through his critical mind, every new theory be looked at carefully and the evidences for and against balanced against each other. The book is indeed the product of a hard-working and ingenious mind, and bears throughout the unmistakable marks of the personality of the author.

The modified quaternion analysis which Dr. Heaviside introduced into the earlier volumes is used with good effect when occasion demands. There is, of course, nothing talismanic in the particular notation which Dr. Heaviside has adopted; and it seems a pity to stir up old controversy by reproducing letters written last century. When the author accuses Tait of viewing the same thing quite differently according as it is clothed in his (Tait's) favourite quaternion garb or in so-called vectorial vestments, he uses a sword with a cutting edge in the hilt. We have simply to change Tait to Heaviside and interchange the words quaternionic and vectorial, and the truth remains. And the curious thing is that all the change which Dr. Heaviside makes in the Hamiltonian notation is to drop the S for scalar and change the sign. Meanwhile more recent vector analysts equally despise Hamilton and Heaviside, and add to the confusion by inventing their own precious notations.

The subject-matter of the present volume is very simply described. It has to do with the

generation and propagation of electromagnetic waves. There are two chapters which are numbered ix. and x. in continuation of the chapters of the earlier volumes. The sections are also numbered in continuation of the sections of vols. i. and ii. The fifty-three sections which constitute chapter ix. were published originally in the *Electrician* during 1900 and 1901, and are grouped under the title of "Waves from Moving Sources." Largely by synthetic methods the author constructs the solutions of various cases, discussing in his own way the fundamental question of the connection between matter and æther. Some interesting remarks are made concerning the investigations of Larmor and Lorentz. The later sections deal with spherical pulses started by a "jerked electron."

Chapter x. with its forty-one sections occupies about three-quarters of the whole book. It is called "Waves in Ether." The first seven sections, reprinted from the *Electrician* (1902) form a group of connected discussions in which a deformable æther is assumed along with a constant velocity of radiation through it. The assumptions are found to be compatible if the inductivity and permittivity of the æther vary as the density. The remaining sections, some of which appeared originally in NATURE, are more of the character of isolated articles, bearing either directly upon electromagnetic theory or upon mathematical and physical problems suggested by its development. For example, there is a long article on the solution of definite integrals by differential transformation, and one nearly as long on the inversion of operations. Still longer is section 534, on the theory of an electric charge in variable motion, probably one of the most important in the whole book. Here, as elsewhere, Dr. Heaviside strongly affirms the truth of Newton's Third Law of Motion, "an impregnable fundamental principle whose neglect sometimes leads to alarming consequences." Why, he asks at the very end of the volume, is this principle to be taken as fundamental? "Because it is always true when proper examination can be made, and is the guide to fresh knowledge. Besides that, the untruth of the principle in practice would lead to chaos."

Dr. Heaviside is also a firm believer in the existence of the æther. "Through this ether all known disturbances are conveyed electromagnetically or gravitationally. If the first way, the speed is finite. If the second way, it may also be finite, perhaps with the same velocity. . . . As the universe is boundless one way, towards the great, so it is equally boundless the other way, towards the small; and important events may arise from what is going on in the inside of atoms, and again, in the inside of electrons. There is no energetic difficulty. Large amounts of energy may be very condensed by reason of great forces at small distances. How the electrons are made has not yet been discovered. From the atom to the electron is a great step, but is not finality."

To the elucidation of the deep problems involved in this confession of scientific faith, Dr. Heaviside has made great and lasting contributions. The strenuously minded student will find him a stimulating guide through the intricacies of the electromagnetic equations. The book is with great fitness dedicated to the memory of George Francis Fitzgerald. C. G. K.

THE ASCENT OF SAP IN PLANTS.

Transpiration and the Ascent of Sap in Plants. (Macmillan's Science Monographs.) By Dr. Henry H. Dixon. Pp. viii+216. (London: Macmillan and Co., Ltd., 1914.) Price 5*s*. net.

PROF. DIXON first became known as an investigator of the problem of the ascent of water in plants by his work in collaboration with Dr. Joly published in the Proceedings of the Royal Society, 1894, and in the Philosophical Transactions, 1895, and from that time forward he has with admirable patience and efficiency continued to work at this difficult question. The appreciation of his position as an authority in this department is shown by his having been most appropriately chosen as a contributor to the "Progressus Rei Botanicæ," and finally as a writer in the present series of science monographs.

When a second edition is called for, it is to be hoped that Dr. Dixon will see his way to giving the references to literature as footnotes instead of at the end of the chapters, an arrangement that seems to us to have no practical advantages. The only other criticism of a general kind that we have to offer is on the relative space given to the two main divisions of the subject. There is but one chapter on the "nature of transpiration," while the remainder, consisting of about 200 pages, deals with the ascent of sap. But there is so much to be said on the latter subject that the author may well feel justified in his comparatively brief treatment of transpiration. There are many interesting points in chapter i., *e.g.*, the discussion on transpiration considered as a form of secretion, and the allied question of transpiration in air saturated with moistures.

Prof. Dixon does not, we think, quite realise the danger of assuming that the stomata are thrown out of action as far as transpiration is concerned by dull light or darkness. But inas-

much as his interesting experiments on transpiration in oxygen, air, CO_2, ether, and chloroform give values differing *inter se* in practically the same way as the evaporation of a surface of water under like conditions, it must be allowed that there is here no error of the above-mentioned kind.

The second chapter is devoted to the discussion of those hypotheses of the ascent of water in trees which depend on the co-operation of living cells in the water-way, views that may be said to begin with Godlewski's theory (1884), which was followed by the cognate hypotheses of Westermaier, Janse, and others. The whole chapter is good reading, but the most interesting part is the description of Dixon's experiments bearing on the effect of killing the sections of the water-way by heat. In this way it has been shown by Janse and Ursprung that the transpiration current is checked and that the leaves above the heated region wither. This fact was used as an argument for the "vital" theories of the ascent of water. But Dr. Dixon shows clearly that by heat, poisonous substances are developed, and that withering occurring above the injured region may undoubtedly be produced by this cause, and therefore that the argument for vital theories loses its validity.

With chapter iv. begins the kernel of the book, namely, the re-statement of the cohesion theory of the ascent of water. The most interesting features of this section are the discussions on the effect of air bubbles in the water conduits, and the evidence in favour of cohesion theory which is derived from a general discussion on the structure of wood.

This is followed in the next chapter by a discussion of the purely physical problem of cohesion. He confirms and extends Berthelot's estimation of the tensile strength of water containing air, a point of great value. He also works out the tensile strength of sap—a necessary precaution—and records the astonishing tensions of about 132 and 207 atmosphere. The sap used in these experiments was ingeniously obtained by centrifuging, a method likely to be useful in other botanical researches.

Having shown how great is the cohesion of the water columns, Dr. Dixon goes on to the other half of the problem—the resistance offered by wood to the passage of sap. He makes it probable that Ewart's estimate of this element in the problem is much too high, and points out (p. 132) "that if Ewart had obtained my results, the difficulty of resistance, which he finds to be fatal to the cohesion theory of the ascent of sap, would not have presented itself to him."

The rest of the book is mainly devoted to the question whether the leaves can develop traction sufficient for raising the sap, a force which he says (p. 139) "must at least be equal to the pressure produced at the base of a column of water which is twice the height of the transpiring tree." The problem in fact comes to be whether the osmotic pressure in the cells of the leaves is sufficiently great to account for the raising of water in very tall trees. One method employed was to expose leaves to compressed air in a closed vessel; in this way it was shown pressures of 26–38 atmospheres must exist in the leaves. Finally he proceeded to ascertain the osmotic pressure in the leaves by determining the freezing point of the cell sap. This was effected by employing a thermocouple in place of the thermometer used in Beckman's method of cryoscopy. In this way Dixon is able to determine the freezing point of small quantities of fluid—a practical point of considerable importance. The osmotic pressure in the leaves deduced by this method are finally shown to be more than sufficient to account for the ascent of water. F. D.

THE SCHUMANN REGION OF THE SPECTRUM.

The Spectroscopy of the Extreme Ultra-Violet. By Dr. T. Lyman. Monographs on Physics. Pp. v+135. (London: Longmans, Green and Co., 1914.) Price 5*s*. net.

THE remote ultra-violet part of the spectrum, first investigated by Victor Schumann and since known as the "Schumann region," has in recent years become of distinct importance in several directions. A knowledge of the vibrations of short wave-lengths is indispensable in the study of spectral series in relation to theories of emission spectra, and it has further been found that photo-electric, photo-chemical, and photo-abiotic processes become much more pronounced in this region. In the present monograph full accounts of the methods and results of observations are given in an interesting and convenient form by Prof. Lyman, who was among the first to take up and extend the work of Schumann. The first part of the book, referring to the ordinary ultra-violet spectrum included between wave-lengths 4000 and 2000, is a valuable introduction to the larger second part in which the Schumann region is dealt with.

As is now well known, the opacity of air, glass, and quartz to the Schumann rays renders it necessary that the entire spectrograph and source of light should be enclosed in a vacuum, and that special materials should be used for the construction of lenses and prisms; specially prepared photographic plates are also necessary. Schumann's

apparatus was a "vacuum spectrograph" having prisms and lenses of fluorite, but Prof. Lyman has employed a concave grating of one metre radius, which is much simpler in adjustment and has the great advantage of permitting the determination of wave-lengths. A full description of this instrument is given, together with many practical details which have contributed to its successful manipulation. The absorption of various gases and materials in the region of short wave-lengths is fully discussed, and the spectra of the various elements which have hitherto been investigated are described in detail. Complete tables of these spectra, and a bibliography of the whole subject, are also included.

It is interesting to note that the author has lately succeeded in photographing the spectrum to wave-length 905, thus extending it as far beyond Schumann's limit as this was beyond the limit reached by Stokes, about wave-length 1850, if counted on the scale of oscillation-frequencies. Further extension by the direct spectroscopic method is beset by many difficulties, but the author does not consider it hopeless to make further attempts to reduce the gap between the shortest Schumann waves and the waves constituting X-rays, which have a wave-length of about one Ångström unit. In this gap the relation between "light" and matter undergoes a profound change, and further exploration would doubtless lead to results of great value.

The book is a valuable record of successful work in an important field of research, and will be indispensable to those wishing to undertake investigations in the Schumann region, or having occasion to make use of the available data of observation. It may, however, be confidently recommended to the larger circle of readers who are interested in the progress of physical science.

OUR BOOKSHELF.

The City of Dancing Dervishes and other Sketches and Studies from the Near East. By H. C. Lukach. Pp. xi+257. (London: Macmillan and Co., Ltd., 1914.) Price 7*s*. 6*d*. net.

THIS collection of papers, the work of a careful student of the Nearer East, most of which have already appeared in periodicals, is of value at the present time. The treatment, however, is sketchy, and some of the questions discussed do not easily lend themselves to popular writing. The chapter on the jests of the Turkish humorist, Khoja Nasr-ed Din, scarcely deserved re-publication, being a collection of "chestnuts," unless an attempt could have been made to trace their analogues in Western folklore. An interesting paper, based on personal knowledge, describes an interview with the Chelebi Effendi, the leader of the Dancing Dervishes, a Persian by origin, a scholar and theologian, intimately associated with the Turkish Court, his function being to gird each new Sultan with the historic sword of Osman at the Eyub mosque at Constantinople, a ceremony which no Christian is permitted to witness. The best result to be expected from the sketch of the Sunni and Shiah sects and of the origin and influence of the Caliphate may be to attract the reader to the standard authorities, from Gibbon to the Encyclopædia of Islam.

The net result of the book is to show the weakness of the Turkish Sultans' claim to the Caliphate, which will probably now be transferred to the new Sultan of Egypt, and to illustrate the hopelessness of the prospect of a Jehad or holy war preached from Constantinople. The Allies are quite aware of the weakness of the Turkish position, and one result of the war must be that Islam will be revolutionised, much to their advantage.

The Principles of Irrigation Practice. By Dr. J. A. Widtsoe. Pp. xxv+496. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 7*s*. 6*d*. net

As President of the Utah Agricultural College, Dr. Widtsoe has had almost unique opportunities of learning at first hand the results obtained by irrigation in the dry States of America, and in this book he gives a summary of his own investigations and those of others in neighbouring States. The general importance of the subject becomes manifest when it is realised that about 25 per cent. of the earth's surface receives ten inches or less of rainfall annually and can only be reclaimed by irrigation, while another 30 per cent. receives between ten and twenty inches of rainfall and requires irrigation for all intensive cultivation.

The first few chapters deal with theoretical considerations. The soil is likened to a mass of mineral particles, on which hangs a film of water; calculations are given to show its thickness, and some of its properties are sketched out This view is necessarily only approximately correct, because it is now known that the soil has not this simple constitution, but is essentially a colloidal mass. Many of the theoretical considerations founded on the older and simpler idea therefore require modification. Similar remarks also apply to some of the coefficients and constants applied to the soil moisture: their theoretical interest is not great, although they are very important as guides to the practical man in irrigation practice. The chapters, however, give as good a summary as our present knowledge permits, and they clearly show how necessary it is to overhaul the whole subject in the light of modern conceptions.

By far the greatest part of the book is taken up with an account of the effect of irrigation on the crop and on the land, and illustrations and diagrams are given in profusion. The work is admirably done, and gives one of the best summaries of the subject that we have seen for some time.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Electrical Notation.

THE variety of notations for electrical quantities has become a real difficulty in reading international literature. Up to the end of last century the notation of Maxwell was the standard in Great Britain, and such extensions as became necessary were grafted on it. There is no sign of its dying out among the workers, many of them of fundamental importance, who have been accustomed to employ it—in pure science at any rate.

You direct attention (p. 541) to the conflicting recommendations produced simultaneously by two committees, each carrying authority. As the list which you reproduce on p. 545 claims to have international force, it would be interesting to speculate how many readers could guess what are the quantities proposed to be denoted by the symbols η, f, G. ϵ, X, Z, S, Φ. A German equivalent for f is given as ν, which is usually synonymous with n further up in the table; so that f seems to be a duplicate.

Cambridge, January 15. J. LARMOR.

The Influence of Icebergs on the Temperature of the Sea.

THE part of the "Report on the work carried out by the s.s. *Scotia*, 1913," on the above subject, referred to in NATURE of January 14, will, I fear, be a great disappointment to many after the great promise given by the new line of investigation discovered by Prof. H. T. Barnes, of Montreal University. Prof. Barnes found, by means of a very sensitive registering thermometer, that there was always a rise in temperature of the sea on approaching icebergs, and part of the *Scotia's* work was to check this observation. The *Scotia* was fitted with two sensitive registering thermometers, one to be used for trawling near the surface; the other was placed in a box through which the condenser water for the engine was pumped. Unfortunately, both these instruments soon became defective owing to sea water leaking into them. The one used for surface temperatures was repaired on the voyage, but the other does not seem to have been restored to working condition. The result is that all the temperatures taken with the recording instrument are surface temperatures taken at a depth of 2 ft.

The following is the conclusion come to by the observers on the *Scotia*. "An inspection of the records . . . leads to the conclusion that the temperature of the sea near its surface does not furnish a certain method of detecting the presence of an iceberg in the regions over which the *Scotia* made her voyages." Now Prof. Barnes's conclusion was not arrived at from temperatures taken near the surface, but at some depth. His records of the rising temperature on approaching icebergs were made with his first ship, in which the thermometer was placed at a depth of 5 ft., but better results were obtained by his second ship, in which it was placed at a depth of 16 to 18 ft.

In justification of their conclusion that their surface temperatures ought to give results similar to the deeper ones, the observers on the *Scotia* seem to have accepted Prof. Barnes's explanation of the cause of the rise in temperature near the berg. Prof. Barnes says all the water from the melting ice is carried downwards, and that this downward current is supplied by a surface current flowing towards the berg, and that this surface current, in some way not explained, retains all the solar radiation, which he says usually penetrates deeper, but is, he says, prevented by the water being in motion. If that explanation be correct, then the *Scotia's* observers would be quite right in supposing that the rising temperature would be more manifest at the surface than at some depth. Though the *Scotia's* observers accepted Prof. Barnes's explanation of the heating of the water, they do not seem to be satisfied with it, as they say: "This explanation is difficult and seems complicated."

Prof. Barnes's explanation is founded on the supposition that all the water of the melted ice is carried downwards. Dr. Otto Pettersson, on the other hand, says that only the water of the ice melted some distance below the surface is carried downwards, while that melted near the surface flows away from the berg on the surface. In a previous letter (NATURE, January 9, 1913) I showed by two methods of experimenting that all the water of the melted ice comes to the surface. I think it is generally admitted that the salinity of the sea is, as a rule, lower in the vicinity of melting ice than at a distance from it. If so, where does the fresh water come from if not from the melted ice? Outside the rising current of diluted sea-water next the ice there is a descending radiation-cooled current of sea-water drawn from a distance and flowing underneath the ice-cooled water on the surface. This downward current is accepted by Prof. Barnes and Dr. Pettersson, though Prof. Barnes does not admit the existence of the cold-surface current. Accepting the existence of these currents in the water surrounding icebergs, the following explanation was offered in NATURE (March 16, 1913) of the rising temperature observed on approaching icebergs. The surface water at a distance from a berg has a higher temperature than the water immediately underneath it. That is, outside the influence of the berg the temperature decreases with the depth, so that when the surface water is submerged by the cold-surface current, it is sunk to some depth beneath the surface, the result of this being that a thermometer sunk to a depth of, say, 16 ft. when at a distance from the berg registers a lower temperature than if placed in the surface water; but if the deeply submerged thermometer be moved into the water near the berg, it will now register a higher temperature than it did at a distance from it, because it will now be in the submerged-surface water, the temperature of which will probably have fallen to some extent in its passage under the cold-surface water. The effect of the movement of the ship towards the berg is virtually the same as raising the thermometer towards the surface when the ship is outside the influence of the berg. In the letter referred to I suggested the use of two thermometers, one near the surface, the other at some depth, and registering together, when an inversion of the temperature would indicate the approach to ice, if the explanation be correct. If this inversion of temperature really does exist, it might be detected by the ordinary tilting thermometers, one in the water near the surface, and others at depths down to three or four fathoms, as the difference that might be looked for from Prof. Barnes's thermograms amounts at times to a degree or more Centigrade, an amount easily detected by means of thermometers of that kind.

It is a great misfortune that the thermometer in the condensation water of the *Scotia* could not be repaired for the investigation. The depth at which

the inlet of the condensation water was placed is not stated in the report, but from the size of the vessel it could not be very deep, and the best results could scarcely be expected from it, and for the same reason it would be of no use save in fine weather, owing to the rolling of the vessel constantly changing the level from which the water was drawn. Still, under calm conditions, it might have been deep enough to touch in some cases Prof. Barnes's rising temperature.

Prof. Barnes's results are so consistent and definite that they carry conviction, and one can scarcely imagine that the observations taken when sailing towards, and from, an iceberg in many different directions, which enabled him to draw the isotherms all round the berg as given in his report and reproduced in your issue of December 12, 1912, could be the result of chance, and not of something which had a real physical existence. It is possible that the conditions there represented may be rare, as they seem to indicate that the berg and the water had travelled together for a long time. It seems probable that in many cases the distribution of the isotherms will not be so regular owing to the berg and the water moving at different rates and in different directions. One conclusion we may, however, come to from the *Scotia's* observations which is that the explanation of the rising temperature on approaching icebergs is not due to radiation as supposed, as the registering thermometer on the *Scotia*, though not as sensitive as that used by Prof. Barnes, was yet easily capable of detecting changes such as those indicated by Prof. Barnes's thermograms. It is to be hoped that the subject will be further investigated after the war is ended.

JOHN AITKEN.

Ardenlea, Falkirk, January 4.

The Longevity of Seeds.

IN the note in NATURE of January 7 (p. 515) upon Mr. Shull's paper in the *Plant World*, referring to the longevity of seeds, it is stated that this "is a subject on which specific information is always desirable." The following, therefore, may at least contribute suggestion.

In 1862, my father, at a cost of 4000*l*., caused Dowalton Loch, the largest sheet of water in Wigtownshire, to be drained. The operation attracted considerable attention at the time, owing to the subsequent exploration of a number of "crannogs," or lake dwellings of the fascine type which were laid bare. The bottom of the lake, about 200 acres in extent, was for the most part covered with deep mud and peat; but across the centre of it lay a ridge of broken rock, now a dense jungle of dog willow (*Salix caprea*), whereof the seeds were no doubt wind blown.

Six years ago I was clambering among these rocks, and, coming upon an open space in the thicket, found to my surprise that the ground, to the extent of nearly an acre, was thickly covered among the stones with a carpet of *Pyrola minor*. Nowhere, except in Norway, have I seen this pretty plant in such profusion.

Now, although I have given fairly close scrutiny to the phanerogamous flora of this country, I have not found *P. minor* within its bounds, though for forty years I have known of a colony of it in the neighbouring county of Kirkcudbright, about five and twenty miles in a straight line from Dowalton Loch. *P. rotundifolia* also grows on the banks of the Cree about twenty miles distant.

No doubt *P. minor* once abounded in Wigtownshire, but it has disappeared under the plough, though it may linger still in the remote moorland. Dowalton Loch lies in the heart of an arable, closely cultivated district. Whence, then, did the minute seeds come which have produced this surprising crop? Have they lain dormant under the waters of the loch since the days of the lake-dwellers, or—a more moderate guess—since the days when the primeval forest bordering the lake was cleared away and the land broken up for tillage?

I shall be happy to receive a visit from anyone who may desire to verify for himself the topography of the district in connection with this isolated mass of Pyrola.

HERBERT MAXWELL.

Monreith, January 11.

S. T. Coleridge and the Immortality of the Protozoa.

THAT Weismann's aphorism regarding the "immortality" of the Protozoa had been uttered by others before him is not unknown; and Mr. Clifford Dobell in a recent paper ascribes to Ehrenberg the first expression of the idea. Ehrenberg's book was published in 1838; but Coleridge had said the same thing many years before in his "Biographia Literaria," published in 1817 and written a couple of years earlier. In a footnote to chap. iv. (on Wordsworth's "Lyrical Ballads") he says: "There is a sort of minim immortal among the *animalcula infusoria*, which has not naturally either birth or death, absolute beginning or absolute end: for at a certain period a small point appears on its back, which deepens and lengthens till the creature divides into two, and the same process re-commences in each of the halves now become integral." No statement of the case could well be plainer or more precise than this. I wonder whether Coleridge was indeed the first to make it; or whether some one of the eighteenth-century naturalists had already drawn the inference—not, after all, a very profound one—that a creature which multiplies by simple fission "has not naturally either birth or death," and may be called "immortal."

D'ARCY W. THOMPSON.

The Cause of Streaks upon Lath-and-Plaster Walls.

FOR some time past I have been observing the streaks which occur upon lath-and-plaster walls. I have made a survey of the literature and find no adequate treatment of the phenomenon. For that reason I take the liberty of submitting to you the results of my observations in the hope that you may find them worthy of publication. The results of my observations are as follows:—

(1) The striations are accumulations of dust upon the surface of the plaster. They may be wiped off with a cloth.

(2) The phenomenon occurs only on warmer surfaces of walls which are exposed on the other side to out-of-doors or to colder rooms.

(3) The steeper the temperature gradient through the wall, the more pronounced is the phenomenon.

(4) The light streaks, the spaces comparatively free from dust, occur over laths and joists, the dark streaks over the spaces between them.

Poynting and Thomson ("Text-book of Physics: Heat," p. 152) suggest "that the phenomenon is a probable illustration of 'radiometer action.'" The areas of plaster backed up by wood are probably warmer than those areas not so protected. From the supposedly warmer area an approaching dust particle is repelled by a more vigorous molecular bombardment than it encounters upon approaching the supposedly colder area.

I was led to inquire whether this explanation is a complete one upon observing what appears to be a related phenomenon. In a room rather free from dust but quite damp, the areas of plaster which ordinarily would be streaked with dust were quite clean, but were much discoloured by water. This observation

raises the question as to whether condensed water vapour may not be the trap which catches the dust.

I contemplate carrying out a series of experiments to answer the following questions:—

(1) Under given conditions what difference of temperature exists between a plaster area backed up by lath, and an adjacent area not so protected?

(2) What part does the presence of water vapour in the air play in the phenomenon?

(3) Can a "reversal" of the phenomenon be produced? THOMAS D. COPE.

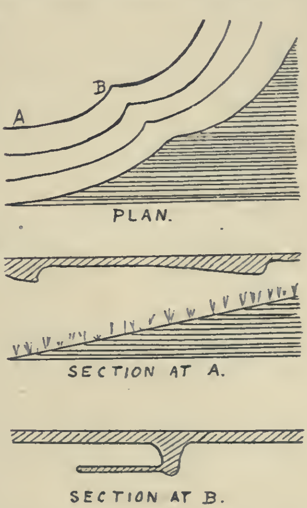
University of Pennsylvania, Philadephia,
December 18, 1914.

Curious Forms of Ice.

ON December 30, 1914, when a heavy rainfall had been followed by a night frost, a layer of prismatic ice was seen immediately below the surface of the heaps of loose clay, in shallow workings in clay-with-flints at the south-west end of Walton Heath, Surrey. The workings are near the crest of the North Downs, at an elevation of about 600 ft. The ice varied from $\frac{1}{2}$ to $1\frac{1}{4}$ in. in thickness, and resembled the form of calcite known as "beef," but even in the most compact portions the prisms were not in close contact with one another. When observed, about midday, the ice was melting, and the sides of some of the heaps were strewn with isolated prismatic and acicular crystals of ice.

This prismatic layer of ice is similar to the ice pillars described in NATURE (vol. lxxiii., 1906, pp. 464, 485, and 534), and analogous to the masses of fibrous ice connected with lumps of chalk, recorded in NATURE (vol. lxxxviii., 1912, pp. 484 and 517).

On the same occasion, shallow pools of rain-water on Walton Heath and Headley Heath were seen to be covered with thin ice, which showed a series of concentric markings parallel to the margin. These markings were formed by ridges on the lower surface of the ice, presenting an abrupt face toward the margin and a gentle slope toward deep water. The ice in the ridges contained air bubbles. The ridges were about 4 in. apart, and in some places as many as seven in number. At points where the direction of a ridge changed, as at B in the figure, a tongue of ice projected downward and sometimes supported horizontal rods of ice half an inch below the surface.



These projections may be analogous to the "bulb formation" referred to by writers in NATURE (vol. lxxxviii., 1912, pp. 414 and 492, and vol. lxxxix., 1912, p. 34). The ridges differ in cross section and direction from those described in NATURE (vol. xc., 1912, p. 411). The pools did not show signs of loss of water by percolation. At first sight I regarded the ridges as earlier shore lines, marking successive extensions of the pools as water flowed into them, but the parallelism and equal spacing of the ridges are perhaps against this view. They may possibly be due to ripples. G. M. DAVIES.

Birkbeck College, London, January 12.

The Fireball of December 31, 1914.

I AM writing to tell you that I also observed the fine meteor described in NATURE of January 7 (p. 517) as having been seen at Bexley Heath on December 31 at about 11.15 p.m. I saw it from my window, facing the west, and I cannot better your description of it as "a fireball, much brighter than Venus."

Its course was from north to south, rather low down, and the sky at the time was clear above, but misty below. The meteor disappeared without leaving a luminous track behind, and seemed to dip into the mist.

I did not notice what stars it passed near, as the moon was shining; possibly there were not many just then distinctly visible. FRANCES M. HARVEY.

15 Purland Chase, Ross, Herefordshire.

THE PHILADELPHIA MEETING OF THE AMERICAN ASSOCIATION.

THE sixty-sixth meeting of the American Association for the Advancement of Science was held at Philadelphia, Pa, on December 28, 1914—January 2, or, as it is termed, during the Convocation Week, 1914–15, under the presidency of Dr. Charles W. Eliot, President Emeritus of Harvard University. The Section on Education of the A.A.A.S. is a comparatively new one, and this was the first meeting at which a member of this section has been president of the Association.

The meetings were, almost without exception, held in the commodious buildings of the University of Pennsylvania; the only exceptions being the meetings of Section E of the Geological Society of America and the Palæontological Society of America, which were held at the Academy of Natural Sciences in the central part of the city.

At the opening session, December 28, 1914, the meeting was opened by the retiring president, Prof. E. B. Wilson, of Columbia University, who introduced president-elect Eliot. Addresses of welcome were given by Dr. E. F. Smith, Provost of the University of Pennsylvania, by Dr. W. W. Keen, President of the American Philosophical Society, by Dr. S. G. Dixon, President of the Academy of Natural Sciences, and by Mr. J. M. Dodge, representing the Franklin Institute.

Dr. Eliot replied to these addresses, and the retiring president, Dr. Wilson, then delivered his address on the subject "Some Aspects of Progress in Modern Zoology," which is printed elsewhere in this issue of NATURE.

After the adjournment of the meeting, the provost of the University and Mrs. Smith received the association and its affiliated societies in the University Museum.

The meeting was a very large one, possibly the largest in the history of the association. Registration figures indicate that there must have been more than two thousand scientific men and women in attendance. The number of affiliated societies meeting at the same time and place was also unusually large. It included the following societies:—

Society of American Bacteriologists, Entomological Society of America, American Association of Economic

Entomologists, Botanical Society of America, American Phytopathological Society, American Psychological Association, Society of American Zoologists, American Society of Naturalists, American Microscopical Society, American Physical Society, Geological Society of America, Palæontological Society of America, American Folk-Lore Society, American Fern Society, Sullivant Moss Society, American Nature-Study Society, School Garden Association of America, American Alpine Club, American Anthropological Association, Southern Society for Philosophy and Psychology, Society for Horticultural Science, American Federation of Teachers of the Mathematical and the Natural Sciences, Society of Sigma Xi.

The meeting as a whole emphasised more than ever the importance of symposia for broad topics which bring together men of different sections. A number of these were held during the week, as follows:—

Section B and the American Physical Society, on the subject, "On the Use of Dimensional Equations."

Botanical Society of America and the American Phytopathological Society, on the subject, "Genetic Relationship of Organisms."

Section of Agriculture, "The Field of Rural Economics."

Section F, the American Society of Zoologists, and the American Society of Naturalists, "The Value of Zoology to Humanity."

Society of American Bacteriologists and Section K, on the subject of ventilation.

Sections C and K and the Society of American Bacteriologists, on the subject, "The Life of Lower Organisms in Relation to Man's Welfare."

There were two especially notable incidents of the meeting. The first of these was the first large meeting of the newly-established Committee of One Hundred on Scientific Research, of which Prof. E. C. Pickering, of the Harvard College Observatory, is chairman, and Prof. J. McKeen Cattell, of Columbia University, the secretary. Reports were received from a number of sub-committees, other sub-committees were established, and the work of the committee as a whole was systematised in order to cover the whole field of scientific research in America with the view of the ultimate ascertaining of its needs. The listing and classification of research funds, the needs of research students, the co-ordination of research among educational institutions, private endowments and industrial research, and a number of other topics will be taken up by this committee.

The second notable event of the meeting was the first session of the newly-established Section of Agriculture (Section M). This opening meeting was presided over by the president of the association, Dr. Eliot. The vice-president, Dr. L. H. Bailey, formerly Director of the College of Agriculture of Cornell University, gave his address on the subject: "The Place of Research and of Publicity in the Forthcoming Country Life Development." The symposium which followed consisted of the following addresses: "Rural Economics from the Standpoint of the Farmer," by Hon. Carl Vrooman, Assistant Secretary of Agriculture; "Credit and Agriculture," by Prof. G. N. Lauman, of Cornell University; "Marketing and Distribution Problems," by C. J. Brand, Chief of the Office of Markets, U.S. Department of Agriculture; and "Distinction between Efficiency in Production and Efficiency in Bargaining," by Prof. T. N. Carver, of Harvard University.

The following addresses of the presidents of sections were delivered during the week:—

(*a*) F. Schlesinger, "The Object of Astronomical and Mathematical Research"; (*b*) A. D. Cole, "Recent Evidence for the Existence of the Nucleus Atom"; (*c*) C. S. Alsberg, "Theories of Fermentation"; (*d*) O. P. Hood, "Safety Engineering"; (*e*) J. S. Diller, "The Relief of Our Pacific Coast"; (*f*) A. G. Mayer, "The Research Work of the Tortugas Laboratory of the Carnegie Institution at Washington"; (*g*) H. C. Cowles, "The Economic Trend of Botany"; (*h*) W. B. Pillsbury, "The Function and Test of Definition and Method in Psychology"; (*i*) J. G. Wall, "Social and Economic Value of Technological Museums"; (*k*) T. Hough, "The Classification of Nervous Reactions"; (*l*) P. P. Claxton, "The American Rural School"; (*m*) L. H. Bailey, "A Place of Research and of Publicity in the Forthcoming Country Life Development."

Following the example of the British Association for the Advancement of Science, two public evening lectures complimentary to the citizens of Philadelphia and vicinity were given. Dr. D. C. Miller, of the Case School of Applied Science, lectured on Tuesday evening, December 29, on "The Science of Musical Sounds," illustrating his lecture by a large number of striking experiments. The second was given on Wednesday evening by By Dr. W. H. Nichols, of the General Chemical Company, on "The War and Chemical Industry." These lectures were rather largely attended, but the American Association has not as yet succeeded in making these lectures as important, viewed as social functions, as has the British Association.

No strikingly important matters of business were considered by the council. A few small research grants were made, and the assistance of the association was continued to the Concilium Bibliographicum Zoologicum of Zurich. It was decided to hold a summer meeting in 1915 at San Francisco under the auspices and management of the Pacific Coast Division of the American Association, the dates to be August 2 to 7. For the place of the next Convocation Week meeting (December 27, 1915, to January 1, 1916), Columbus, Ohio, was chosen. It will be remembered that the association had virtually accepted an invitation from the University and City of Toronto, Canada, for this last-named meeting, but on account of conditions arising from the war, Toronto begged to be allowed to postpone this meeting to some future and more favourable date.

At the close of the meeting the following officers were elected for the coming year:—

President: Prof. W. W. Campbell, Lick Observatory, University of California.

Presidents of Sections: A, *Mathematics and Astronomy*, Prof. A. O. Leuschner, University of California; B, *Physics*, Prof. Frederick Slate, University of California; C, *Chemistry*, Prof. W. McPherson, Ohio State University; D, *Engineering*, Mr. Bion J. Arnold, of Chicago; E, *Geology and Geography*, Prof.

C. S. Prosser, Ohio State University; F, *Zoology*, Prof. V. L. Kellogg, Stanford University; G, *Botany*, Prof. W. A. Setchell, University of California; H, *Anthropology and Psychology*, Prof. G. M. Stratton, University of California; I, *Social and Economic Science*, Dr. Geo. F. Kunz, of New York; K, *Physiology and Experimental Medicine*, Prof. F. P. Gay, University of California; L, *Education*, Prof. E. P. Cubberley, Stanford University; M, *Agriculture*, Prof. Eugene Davenport, University of Illinois.

Permanent Secretary: Dr. L. O. Howard, Smithsonian Institution, re-elected for a five-year period from August 20, 1915.

General Secretary: Dr. Henry Skinner, Academy of Natural Sciences. Philadelphia, Pa.

Secretary of the Council: Prof. W. E. Henderson, Ohio State University.

Secretaries of the Sections: A, Forest R. Moulton, University of Chicago, Chicago, Ill.; B, W. J. Humphreys, U.S. Weather Bureau, Washington, D.C.; C, J. Johnston Geophysical Laboratory, Carnegie Institution of Washington, Washington, D.C.; D, A. H. Blanchard, Columbia University, New York; E, G. F. Kay, State University of Iowa, Iowa City, Iowa; F, H. V. Neal, Tufts College, Mass; G, W. J. V. Osterhout, Harvard University, Cambridge, Mass.; H, G. G. MacCurdy, Yale University, New Haven, Conn.; I, S. C. Loomis, 69 Church Street, New Haven Conn.; K, C. E. A. Winslow; L, S. A. Courtis, Liggett School, Detroit, Mich.; M, E. W. Allen, Office of Experiment Stations U.S. Department of Agriculture, Washington, D.C.

Treasurer: R. S. Woodward, Carnegie Institution of Washington, Washington, D.C.

Assistant Secretary: F. S. Hazard, Office of the A.A.A.S., Smithsonian Institution, Washington, D.C.

THE EARTHQUAKE IN CENTRAL ITALY.

THE earthquake of January 13 was by no means one of the first order of magnitude, but it was the most destructive of which we possess any record. In Avezzano, which formerly contained 11,000 inhabitants, the death-rate amounts to 90 per cent., while it rises still higher in some of the adjoining villages, in Cese to 94 per cent., and in Lapelle to 97 per cent. Before this, the highest known death-rate was 81 per cent. at Avendita during the Norcian earthquake of 1703. There can be little doubt that the disastrous character of this earthquake was as usual due to the faulty construction of the houses, which consisted of stones with little or no binding of cement. Partly, also, it was due to the comparative immunity of the central district from great earthquakes in the past, which has allowed such buildings to survive.

Few details of scientific value have as yet reached this country. The earthquake occurred at 7.53 a.m. (or 6.53, Greenwich mean time). At Rome, it lasted from 15 to 20 seconds. Near the epicentre, there was one shock of great violence, followed by three others. In other neighbouring places, two prolonged shocks were felt. The principal epicentre was no doubt close to Avezzano, probably within five miles of that town. It was in this district that the high death-rates occurred. There was apparently, however, a secondary epicentre including Sora, where 500 persons lost their lives, and Isola Liri; and it is possible that the double shock noticed at some places was due to impulses in two corresponding foci, about twenty or twenty-five miles apart. The area of perceptible damage to buildings extends almost across the peninsula, from Rome on the west to Chieti on the east, these places being 110 miles apart. Towards the north, the shock was felt at Ancona, Perugia, and Grosseto, and, towards the south, at Naples and Potenza; that is, over an area roughly 300 miles long, 240 miles wide, and containing about 56,000 square miles. The shock was recorded at many distant observatories, including those in this country and at Washington. The after-shocks must have been very numerous in the epicentral area. More than 120 were registered at Rome during the first two days, all of them slight, with the exception of one at 8.14 a.m. on January 14.

Earthquakes are neither frequent nor severe in the district chiefly affected. Dr. Baratta, in his "I terremoti d'Italia," defines in it two distinct seismic zones, one including Sora and Isola Liri, the other, less important in the past, extending from Avezzano to Anticoli. To the former zone belong the strong earthquakes of August 19, 1777, and May 9, 1891; and, to the latter, the earthquake of April 10, 1885. The recent shock must have been far stronger than any of these earthquakes, and, as pointed out above, it seems to have consisted of almost simultaneous impulses in both the Avezzano and Sora centres.

C. DAVISON.

VICE-ADMIRAL SIR GEORGE NARES, K.C.B., F.R.S.

BORN at Aberdeen in 1831, G. S. Nares entered the Navy on board H.M.S. *Canopus*, an old battleship captured from the French, in 1845, and was transferred to the *Havannah*, a frigate for service in the Pacific, in 1847. He passed his examination for lieutenant in 1851, and, coming home shortly afterwards, was appointed to the *Resolute*, and sent to the Arctic in the expedition under Captain Sir E. Belcher in search of the Franklin Expedition. His service up to the time he was a lieutenant was entirely in sailing vessels, the motive power of which was the wind applied to the propulsion of vessels by masts, yards, and sails, and this early training made him a thorough master of managing vessels in all circumstances of wind and weather, and although during his service after returning from the Arctic in 1854 he was employed in vessels that were furnished with auxiliary steam power, he was always pleased when he could navigate his vessel under sail alone. One instance of this may be given. When at Malta in the *Newport* in 1869 the chief engineer of that vessel, who was anxious not to go to sea on the day named because he wanted to attend some function on shore with his wife, asked to be given forty-eight hours to take off the cylinder covers, Captain Nares, as he then was, replied: "By all means." The chief engineer was jubilant,

but on the day originally named, after the usual morning muster by division, the order was given "Hands make sail," and the ship sailed out of the harbour, much to the chagrin of the engineer staff. This was a good lesson given with tact and judgment.

During his service in the *Resolute* he took part in the sledge journeys in search of any remains of Franklin. It is not generally known that Arctic sledging was introduced in order to search all the coasts which could not be reached by the vessels for any token of the Franklin Expedition. The ice near the coast is, as a rule, comparatively smooth, consisting of new ice found on the surface between the grounded bergs and the shore line, and this ice is less difficult to travel over than the hummocky ice found in areas off the shore where floes get piled up one on the other from various causes, consequently the sledge parties were able to cover long tracts and to delineate the coast line of numerous islands and straits.

Returning from the Arctic in 1854 he was promoted to lieutenant on October 21, and was sent to one of the armour-plated bombs, constructed specially for the war, 1854–6, for service in the Mediterranean.

From the Mediterranean Nares was transferred to the training-ship for naval cadets, then recently established (1) in the *Illustrious*, and (2) in the *Britannia*, and whilst so serving compiled "The Naval Cadet's Guide and Seaman's Companion." Promoted to commander at the end of 1862 he served in the *Boscawen*, another training-ship, and was then sent to a paddle-wheel vessel, the *Salamander*, engaged in keeping open communication with a party of marines established at Cape York. In his voyages backwards and forwards between Sydney and Cape York he did some useful surveying work and on his return to England in 1867 was selected for the command of the *Newport*, a vessel commissioned for surveying service in the Mediterranean. The opening of the Suez Canal in 1869 necessitated a survey of the Gulf of Suez, and the *Newport* was selected for this service, and was engaged in it during the winter of 1870–71, but in May, 1871, she was sent to England, and her officers and crew turned over to the *Sheerwater*, which vessel, under Nares, proceeded to the Gulf of Suez in the autumn of 1871, and completed the survey from Suez to Koseir by April, 1872.

On the voyage out the *Sheerwater* was instructed to investigate the Gibraltar Strait current, and Dr. W. B. Carpenter embarked on board to assist in that investigation on behalf of the Royal Society. The work was so well done as to mark out Nares for other scientific work, and when, early in 1872, the Admiralty decided to commission a vessel for exploration of the oceanic basins of the world, Nares was chosen to command the ship, and was ordered home to prepare the *Challenger* for her voyage. Leaving England in December, 1872, the *Challenger* executed a series of sections across the Atlantic, and it was then that the system of sections showing the temperature of the ocean from the surface to the bottom was first introduced. Before that time the temperatures were merely plotted in curves. This system of sections gradually revealed the fact that over certain areas the temperature at the bottom remained the same, but that in other areas, adjacent to the first area, the bottom temperature differed, although remaining constant over another considerable space. From this fact it seemed likely that in areas where at equal depths the temperature at the bottom differed in areas adjacent to each other, the difference was caused by a submarine ridge which prevented free circulation. Thus it was known that whilst the Mediterranean had a uniform temperature of from 55° to 56° below a depth of 100 fathoms, the water of the Atlantic adjacent to the Mediterranean decreased in temperature gradually to 36°. The soundings in Gibraltar Strait, just outside the entrance between Cape Spartel and the Spanish coast, revealed the existence of a submarine ridge, and it was then considered probable that in all areas differing much in temperature at equal depths the difference could only be accounted for by the existence of submarine ridges.

The *Challenger* reached the Cape of Good Hope in November, 1873, and in December left for Kerguelen Island to examine a suitable spot for observing the transit of Venus in 1874. This necessitated a triangulation of Kerguelen and a determination of its position. Three weeks were occupied in the work, and records were deposited in cairns to inform the transit of Venus party of the spots considered suitable for the observations. Leaving Kerguelen at the end of January, the *Challenger* then proceeded to the southward as far as the Antarctic Circle to investigate temperatures and depths, and during that cruise, all on board had an opportunity of appreciating the skill of Captain Nares in handling his vessel amongst the icebergs. Gales and snowstorms were not infrequent, and Captain Nares, after consideration, adopted the plan of keeping close to a berg under steam, during night, or in mist or snowstorms, and thus preventing the vessel drifting or sailing into danger. Arriving in Melbourne in March, 1874, and at Sydney in April, the ship was docked and re-fitted, and it was curious to observe how the copper on the bottom was quite corrugated from the strains encountered during the southern voyage. From Sydney the *Challenger* took other oceanic sections across the southern part of the Western Pacific, from Sydney to Wellington, N.Z., from Wellington to the Fiji Islands, and from the Fiji Islands to Raine Island, Australia. From Raine Island the vessel proceeded through the Arafura Sea, the Banda Sea, the Sulu Sea, and the China Sea to Hong Kong, at which port she arrived in November, 1874. On this voyage it was again noticed that the area of some parts of the Sulu Sea differed greatly in temperature at the bottom from the adjacent seas.

At Hong Kong Captain Nares was recalled to England to take command of an expedition about to be organised for Arctic research.

That expedition consisted of two vessels, the *Alert* and *Discovery*, and its primary object was to reach, if possible, the North Pole. Leaving England in the summer of 1875, the vessels proceeded through Davis Strait to Smith Sound, where a secure harbour was found in which to moor the *Discovery*, to form a base of retreat, whilst the *Alert* pushed northward as far as was possible. The ice in the northern part of Smith Sound presented unexpected obstacles, and subsequent observations showed that the polar basin northward of Smith Sound produced masses of icebergs and floes which, being drifted against the coast, were piled one on the top of the other and closed all navigation excepting between the coast and the ice grounded near it. Here, again, the skill of Captain Nares guided the vessel into a fairly secure position between the coast and the grounded ice, a position which it would have been unsafe to take excepting for the *Discovery* left in a secure harbour as a base to fall back on. The winter of 1875–6 was spent in organising sledge parties, one of which, under Commander Markham, was to get as far northwards as possible, one under Lieutenant Pelham Aldrich was to proceed along the coast line in a north-westerly direction, and the third, under Lieutenant Beaumont, was to cross Smith Sound and proceed northward along the Greenland coast. The expeditions along the coast line were successful, as there the ice offered comparatively little obstruction to sledge work, but the rough, hummocky ice encountered by the party under Commander Markham proved to be of such a nature that progress to the northward was very slow and difficult, and the hardships which his party underwent can scarcely be exaggerated.

The sledge parties returning to the vessels towards the end of the summer, Captain Nares decided that it was useless trying to reach the pole from Smith's Sound, and proceeded homewards. The manner in which the *Alert* was extricated from her perilous position and brought safely to England with the *Discovery* was a feat of seamanship any man might be proud of.

After his return from the Arctic Captain Nares was made K.C.B., in recognition of his services, and in 1878 was again given command of the *Alert* to prosecute surveying work in Magellan Strait, but was recalled from that ship in 1879 to act as Marine Adviser to the Board of Trade. This appointment he held for about twenty years. During his retirement, like many another sailor, he took up gardening and was very successful in growing roses.

He died on January 15 and was buried at Long Ditton Church on January 19. The funeral was attended by Captain J. F. Parry, R.N., the hydrographer, who represented the Admiralty, and by several naval officers, most of whom received their first instruction in seamanship from him on board H.M.S. *Britannia*, and many of whom were associated with him in his Arctic Expedition or in the *Challenger* exploring expeditions.

NOTES.

The Executive Committee of the proposed Meteorological Conference at Edinburgh has handed over to the Scottish Meteorological Society the balance of the funds subscribed for the expenses of the meeting with the hope that when the opportunity once more arises the society will take the initiative in carrying the project into execution. It has been decided that the committees in London and Edinburgh shall be kept in being.

We learn from *Science* that Prof. J. H. Pettit, professor of soil fertility in the college of agriculture and chief of soil fertility in the experiment station of the University of Illinois, died on December 30 at Pasadena, California; and that Prof. S. B. Christy, professor of mining and metallurgy in the University of California and dean of the college of mining, died in Berkeley, California, on November 30, 1914, at the age of sixty-one years.

Prof. George Forbes, who has been entrusted by Lady Gill with the duty of preparing a memoir of her late husband, asks us to announce that he would be glad to be favoured with any letters which have been preserved by Sir David Gill's numerous correspondents; and would greatly appreciate any notes—narrative, historical, appreciative, or anecdotal—relating to Sir David's life and personality. All original letters or other documents will be carefully preserved, and returned to the senders at as early a date as possible. Such communications should be addressed to Prof. Forbes at 11 Little College Street, Westminster.

Owing to the war, the fifth International Congress of Philosophy, arranged to be held in London next September, has been abandoned. The General Organising Committee has expressed an earnest hope that the confederacy of the entire philosophical world, which has subsisted since the inauguration of the series of congresses in 1900, and seemed to have attained the rank of a permanent institution, will not be set aside for a longer time than outward circumstances render absolutely imperative. The committee has pledged itself as soon as possible after peace is restored to promote the continuance of this international bond, either by renewing the invitation to meet in this country or by obtaining an invitation from a neutral country.

A Reuter message from New York states that at a dinner given on January 14 at the Aero Club of America, Government officials announced a plan of the Post Office Department to introduce into the postal service 2000 airmen, who would carry sacks of first-class mails. The routes have already been selected by the Department, and it is hoped that the Bill authorising this scheme of aerial transportation of mails will pass next Congress. It may be recalled that, with the sanction of the Postmaster-General, an aerial postal service, for the idea and organisation of which Mr. D. Lewis Poole was chiefly responsible, was carried out successfully between Hendon and Windsor on September 9, 1911, that is, in Coronation year. A sack of letters was conveyed between these

two places in thirteen minutes, and the experiment created great interest at the time. It may be some years before a regular aerial service is established for the transportation of mails, but the report from New York suggests that we are getting within measurable distance of it.

THE *Chemist and Druggist* announces the death on December 28, 1914, at seventy-three years of age, of Prof. Karl Liebermann, professor of chemistry in the Technical High School, Charlottenburg, Berlin.

THE death of Mr. J. S. Harding on January 11, in his seventy-sixth year, has deprived science of a life-long meteorologist. He had been connected with the Meteorological Office since its establishment in 1854, and was private secretary to Admiral FitzRoy—the meteorological pioneer. He retired in 1906, after a service of more than half a century, leaving behind him an abiding memory, having secured the hearty appreciation of the committee and council of the office and the sincere friendship of his colleagues. All who knew Mr. Harding have reason to remember his ever-courteous personality and willingness to help inquiry into meteorological literature in any direction. He had been a member and fellow of the Royal Meteorological Society since 1866, and had contributed valuable work to the researches of the society. He had mastered the chief European languages—a notable asset for the study of international meteorology—and was an esteemed contributor to the columns of NATURE to the very week of his passing into silence.

DR. DE FILIPPI has reported to the Royal Geographical Society at some length upon the work of his expedition in northern Kashmir. Two parties, led respectively by himself and by Major Wood, have gone far to establish knowledge of the topography of the Remo glacier basin and the watershed between it and the Karakoram pass. Their researches appear to necessitate the substantial modification of existing maps, in regard not only to the extent of glaciers, but also to the position of the watershed and defluent valleys. The Remo glacier-field is found to feed both the Indus and the Yarkand systems, and thus to send some of its water down either slope of the Himalayan system, to the Arabian Sea on one hand, and to the Tarim depression in the Central Asian desert on the other. The expedition is continuing its work, which has been extended into Chinese Turkestan.

THE Russian Supplement which accompanied the *Times* of January 15 dealt mainly with economic aspects of the war as especially affecting that country, and some of them, such as the question of the position of the chemico-pharmaceutical industry, call for scientific attention. The possible development of British and Russian commercial relations is treated of at considerable length, and among other interesting commercial discussions are those dealing with the sudden strain placed upon the port of Archangel, with the arctic sea route to Siberia, and with other facts and problems of communication. In another department we find a study of the distribution of Germans in Russia, accompanied by an instructive map, which shows how Germans have established themselves in greatest numbers in some of the best provinces (not necessarily nearest their own frontier), and how they largely populate also some of the great towns, with important political results. Another article discusses the tribes of the Yenisei valley.

ON several occasions recently, writers in the daily Press have suggested that the barbarous methods of warfare adopted by German forces represent the natural result of close attention to scientific teaching, and we are warned against letting our educational institutions be dominated by the same materialistic spirit. It would be juster to associate the humanities rather than science with the cause of the present war, and to say that whatever success has been achieved by the enemy is due to the application of scientific knowledge. There is, unfortunately, little danger that science will be given a prominent or important place in our schools or universities, or that our public men, officials, and writers will understand that it is not only essential to national welfare, but also in addition an intellectual outlook and a standard of truth. The only literary man who knows these things and endeavours to impress them upon the public mind is Mr. H. G. Wells; and for his efforts to awaken the British people to a sense of what their neglect of systematised natural knowledge signifies, we cannot be too grateful. An article by Mr. Wells in the *Daily Chronicle* of January 19 describes truthfully the discouraging conditions attached to scientific study in this country, and the mental inertia which has to be overcome before use is made of scientific knowledge or expert opinion. He pleads for the organisation of a thinking department for collecting, testing, and developing new ideas, such as was referred to by Lord Selborne in the House of Lords a few days ago, and his forcible words may perhaps stimulate interest in intellectual activity for the benefit of the State. It has never been more necessary than it is now to insist upon fuller recognition of the claims of science in education and in public affairs, and for that reason we hope that Mr. Wells will make further and similar contributions to national enlightenment.

THE evidences in favour of the protective treatment against typhoid fever are of many kinds. There is the analogy between this protective treatment and the protective treatments against cholera, anthrax, and plague. There is the authority of the years of hard work spent by men of science over the bacteriology of the fever. There is the whole strength of the medical profession; Sir William Osler and Sir Lauder Brunton have well said, in the *Times*, what their brethren are saying everywhere. Above all, there is the final and irreversible judgment of nature herself. We read, only a fortnight ago, how she has tested this treatment, in northern France and Belgium. Our men in the field may be divided into three classes: (*a*) fully protected, (*b*) partly protected, (*c*) non-protected. The proportion of cases has been 1, 6, and 16; that is to say, the non-protected have been punished sixteen times more than the protected. We read, only a few days ago, how nature made a similar experiment among the French troops in the field. That seems to be her invariable rule, to pick out the unprotected. How could she do otherwise? What else do we

expect of her? For we have got this protective treatment straight from her; it has been copied out of her book. We protect our men from having typhoid once, by giving them a dose of the very stuff which she gives them to protect them from having typhoid twice. The treatment is not perfect; but it does protect our men from the misery of illness or death, and from the grave offence of spreading infection among their friends. Meanwhile, the anti-vivisection societies are hard at work, doing all that they can to rob our men of this protection; and that by methods which are singularly repugnant to public opinion.

THE announcement that the King has been pleased to approve the grant of a Royal Charter of Incorporation to the Institution of Mining and Metallurgy, is one of interest and importance to those interested in the mining industry, as well as to the profession represented by the institution. Its objects are defined in the charter as for "the advancement of the science and practice of mining in respect of minerals other than coal and of metallurgy in respect of metals other than iron." The institution was founded in 1892, and its founders wisely based qualification for membership upon strictly professional lines, avoiding the temptation, which some other kindred societies were unable to withstand, to open the door wide from considerations of finance. This test for admission to its ranks has been maintained and strengthened in the intervening years, and a high professional standard has been attained by rigidly scrutinising the statements of candidates for admission and by direct inquiry with a view to their confirmation. The council also has the right, which is exercised, to investigate cases of alleged breach of professional conduct, and to expel any member against whom such a charge has been substantiated. In 1905 the membership of the institution was 1324, and at the end of 1914 it was 2500. The institution occupies its own freehold house at No. 1 Finsbury Circus, E.C., and has an ordinary income of more than 5000*l*. Its influence for good in the educational, technical, and professional world has well merited the recognition bestowed upon it by the Crown.

AMETHYSTS were used extensively by the ancient Egyptians, and it has hitherto been a puzzle whence they obtained the stone. In the *Cairo Scientific Journal* for August, 1914, Mr. G. W. Murray reports that he and Mr. C. M. Firth recently found a piece in Wadi Bahan in lower Nubia, and in May this year Mr. G. B. Crookston discovered considerable workings for amethyst near Gebel Abu Diyeiba, and practically on the footpath between the phosphate mines of Wasif and Um Huetat. The workings are very extensive, and the amethysts occur lining cavities in a kind of red granite. These cavities occur along veins in the granite, which run in remarkably straight lines for hundreds of yards.

WITH reference to Dr. Bastian's paper on the production of fungus-germs and other living forms from Zooglœal masses (NATURE, December 24, 1914, p. 462) Dr. Margaret C. W. Young directs attention to work she has carried out on the apparent development of very different forms of living organisms from a single parent one. Thus by heating spores of *Bacillus subtilis* in a weak alkaline solution to 110° C., colonies of cocci, streptococci, and yeasts were observed to develop. By other treatment *subtilis* cultures seemed to pass into protozoal stages. Dr. Young holds that bacteria of the *B. subtilis* and *mesentericus* groups are really sporozoites of a protozoon the life-history of which embraces amœboid, flagellate, sporulating, and granular forms. In this, the sexual part of the cycle, the organism is almost invariably parasitic. Outside the host, it exists in fungal forms which may range from a coccus to an aspergillus (*British Medical Journal*, September 25, 1909, and October 3, 1914).

To Captain Stanley Flower, director of the Giza Zoological Gardens, we are indebted for a copy of a new issue of his list of the zoological gardens of the world, apparently published at Cairo. In normal times the list should have been revised up to the end of 1914, and published in January, 1915; but the war rendered this impracticable, and it is therefore corrected only down to the end of July last. The entries include 166 different establishments, public and private.

IN NATURE of July 9, 1914 (p. 478), a letter was published from Mr. Lydekker in which it was stated that an okapi sent home by Dr. Christy from the Belgian Congo had been mounted with true horny sheaths on the bony horn-cores. To make sure that there had been no mistake Mr. Lydekker wrote to Dr. Christy, who is now in the Congo, asking whether the animal had been correctly mounted in this respect. We understand that in a reply just received Dr. Christy says, "quite correct."

THE opening article in the January number of the *Museums Journal* is devoted to the Royal Natural History Museum of Belgium (see p. 404). Although Belgium possessed natural history collections of considerable value at a much earlier date, it was not until 1846 that the museum in Brussels was placed on a permanent footing, Vicomte du Bus, who did such good work on the fossil whales of the Antwerp Crag, being the first director. A new era in the history of the institution was inaugurated when Dr. E. Dupont was appointed director in 1868. In 1891, under the same director, the transference of the collections to a building in the Parc Leopold, originally constructed for the offices of the old zoological gardens, was completed, and the new museum, as it had now become, was opened by H.M. King Leopold II. The accommodation was soon, however, found to be altogether inadequate for the proper housing and display of the collections; and a comprehensive scheme of additions was planned. Only a portion of this scheme has, however, yet been carried out—the remainder is likely to remain *in nubibus* for many a long year.

THE last number of the Journal of the Quekett Microscopical Club is especially interesting in containing a report of the 500th ordinary meeting. Mr. A. E. Hilton has a useful note on the continuous cultivation of the Mycetozoon *Badhamia utricularis* on moistened bread, to which from time to time there may be

profitably added a mixture of ammonium phosphate and cane-sugar. The minimum visibile (apart from the ultra-microscope) is discussed by Mr. A. A. C. Eliot Merlin, who finds that the diameter of a particle just visible under a 1/12th apochromat with a working aperture of 1·4 is 1/377,358th of an inch. The diameter of the flagellum of *Bacterium termo* was estimated by Dallinger at 1/204,700th of an inch, but Merlin finds it to be about double that, namely, 1/112,200. C. F. Rousselet has a note on the sexual stages of two African species of Volvox, *Volvox africanus* and *V. rousseleti,* the vegetative colonies of which were previously described by Prof. G. S. West. Mr. E. M. Nelson discusses various forms of binocular microscope, a much-needed low-power condenser, and a new object glass produced by Zeiss in which a near approach has been made towards apochromatism without the use of fluorspar. Just as oil immersions have eclipsed water immersions, so will this new lens, according to Mr. Nelson, supersede the wide-angled dry lenses, which should all be scrapped.

THE Kew Bulletin, No. 10, 1914, contains a paper on *Hedychium coronarium* and allied species, which is of value in connection with the interest aroused in these plants as a source of material for paper-making. The eight allied species are chiefly distinguished by the floral characters, of which illustrations are given. It seems probable that all these Hedychiums would be useful for paper-making. It will be remembered that the paper made from this plant is self-sized, and can be written upon with ink directly it leaves the machine without further treatment.

THE native plants of the Azores are discussed by Dr. H. B. Guppy in *Kew Bulletin,* No. 9, 1914. The vegetation of the mountain of Pico, 7613 ft., was particularly studied, with its European flora on the higher levels—ling, St. Dabeoc's heath, thyme, etc.—and the characteristic Azorean plants below 5000 ft., such as *Erica azorica, Juniperus oxycedrus,* and the Azorean holly, *Ilex perado.* The Faya tree, *Myrica faya,* is a dominant tree in the lower woods, but the forest trees generally are small, owing to the depredations of the wood-cutters. The indigenous plants are few, the flora is largely European in character, with a few affinities with Africa and the Canaries, *Myrsine Africana* affording the most remarkable connection with the continent. It seems probable that the flora of the Azores is relatively recent and can be accounted for by existing agencies of dispersal in contrast to the Canaries and Madeira, the flora of which is ancient, dating back probably in part to Miocene times.

THE occurrence of pitchblende in the Quartz Hill district, Gilpin Co., Colorado, is described by Mr. E. S. Bastin in Professional Paper, 90 A, United States Geological Survey (1914). The ore is found in veins with pyrite and copper pyrites, and is connected by the author with Cainozoic intrusions of monzonite (diorite with orthoclase).

SINCE the reference made in NATURE of November 26, 1914 (vol. xciv., p. 348) to the Upper Jurassic fauna of the Spiti Shales of the Himalayas, the study of the mollusca has been continued by Miss Paula Steiger in Vienna (*Palaeontologia Indica,* series xv., vol. iv., fasc. No. 5). The author wisely remarks that the comparison of the brachiopods with Mediterranean forms is due to our far too scanty knowledge of members of the group from other parts of the world. Here we have a hint to palæontologists and collectors.

THE 792 pages of the Annual Report of the Geological Survey of Iowa for 1913, which has just been issued, are almost entirely occupied by an elaborately illustrated account of the materials for roads and concrete throughout the State. This systematic report provides much information about the nature of the glacial and interglacial beds. In places, the imported boulders of gneiss and granite in the thin Iowan drift are as valuable as those in the North German plain, and are similarly collected for use on the macadamised roads.

IN the December number of the *Agricultural Students' Gazette,* Prof. G. S. Boulger discusses some problems of ecology as illustrated by Gloucestershire flowering plants. He divides the factors of ecology into three main groups, (*a*) the inherent characters of the plants, (*b*) the environment, and (*c*) the relations of (*a*) and (*b*). Many species of plants, commonly regarded as characteristic of a particular feature in their normal environment, are found flourishing under conditions where this very feature is notably weak or even absent. Thus, the calcicole or lime-loving Pasque-flower (*Anemone pulsatilla,* Linné) will grow well in a rich garden soil poor in lime; the Bee Orchis (*Ophrys apifera,* Hudson), most commonly found in England on limestone, is also luxuriant on the Upper Lias, near Leckhampton. Again, the Fritillary (*Fritillaria meleagris,* Linné) occurs habitually in meadows liable to inundation, but has been found in a wood near Fairford fully twenty feet above the water level. Another species of riverside plant, the Meadow Crane's-bill (*Geranium pratense,* Linné), abundant by Severn and Avon at Tewkesbury, is not uncommon in seemingly dry hedgerows on the Cotteswolds. Little is known of the precise conditions that determine the topographical distribution of common species, and a plea is put forward for the investigation of these and other interesting problems suggested in the paper.

WE have been favoured with a copy of an interesting address by Dr. F. A. Carpenter (local forecaster) entitled "Flood Studies at Los Angeles," reprinted from the U.S. *Monthly Weather Review* of June last. The object of the paper (which is accompanied by tables and diagrams) is to explain, generally, some of the causes and pertinent features of such rain storms, and to investigate more particularly that of February 18–21, 1914. The rainfall of South California is subject to great variations; the average annual fall at Los Angeles is 15·5 in., the extremes being 5·6 in. (1898–9), and 38·2 in. (1883–4). Rain only occurs during parts of the year; South California would be practically rainless were it not for the southern deflection of the paths of some of the

northern storms. During the past thirty-seven years the harbour of San Pedro (near Los Angeles) has only been silted up five times by floods, although the latter are of frequent occurrence. When the first rain is steady it soaks into the land, and no floods occur; but during the next period of rainy weather they generally take place. Dr. Carpenter's useful paper should be read in conjunction with Prof. A. G. McAdie's elaborate memoir on the "Rainfall of California" (NATURE, October 15, 1914).

IT is not so long ago that *Punch* published a cartoon of artists painting pictures intended to represent "old masters," of which one-half had been restored by a particular process. In the *Museums Journal* Mr. I. J. Williams, of the Welsh National Museum, describes his experiences in cleaning pictures himself after vainly attempting to obtain satisfactory results by employing outsiders. The process is, of course, comparatively simple, involving nothing more than rubbing off the old varnish with cotton-wool dipped in a mixture of four parts of methylated spirit to one of turpentine, but he finds that considerable skill is required in stopping the process at exactly the right stage. With a view to the future preservation of the pictures it would, however, be desirable to make very careful inquiries as to the character of the varnish subsequently used, as it is not improbable that the old varnishes were better than any now obtainable.

OWING to the decreased output of scientific work in consequence of the war the concluding numbers of *Science Abstracts* for the year 1914 are somewhat less extensive than usual. The physics part consists of forty pages of abstracts and four of index, and the electrical engineering part of thirty-one and four pages respectively. The actual number of abstracts in the two parts is 104 and sixty-two. The average length of the engineering continues to be greater than that of the physics abstract, mainly on account of descriptions of engineering plant. Both sections of the publication continue to supply up-to-date and trustworthy information as to the advances made in many fields, and it is difficult to see how any scientific or technical worker in either subject could now dispense with *Science Abstracts*.

ACCORDING to an editorial note in the *Scientific American* for December 26, 1914, a series of articles will be published early in the present year dealing with the necessity of encouraging in every possible way the scientific researcher in order to make the industries of America more independent of Europe. The editor is of opinion that many manufacturers who at present depend on Europe for some portion of their raw material for technical processes could, by stating their difficulties to a man of science willing to undertake the necessary research, obtain at a relatively small cost information which would place them on a much firmer footing. We have no doubt these articles will be read with interest in this country, as the attitude of the British manufacturer towards research is by no means so cordial as it ought to be.

A POPULAR edition of Prince Kropotkin's "Mutual Aid: A Factor of Evolution," has been published by Mr. William Heinemann, at the price of 1s. net. This cheap re-issue of an important work appears at an opportune moment. Many German writers are excusing the horrors of the war by representing them as unavoidable consequences of the struggle for existence. As our review of the first edition of "Mutual Aid," in the issue of NATURE for January 1, 1903 (vol. lxvii., p. 196), pointed out, Prince Kropotkin shows that in the case of animals, there is very little evidence of any struggle for existence among members of the same species, and no justification can be found for the crude conception of Darwinism which places selfish interests among the desirable attributes of the human race. We welcome this cheap edition of Prince Kropotkin's noteworthy exposition of evolutionary ethics, and we hope it will have the wide circulation its lucidity and charm deserve.

THE Cambridge University Press will shortly issue a new edition—the third—of "Zoology," by Drs. Shipley and MacBride. The work has been thoroughly revised, many portions being re-written, and several new illustrations added.—Messrs. Methuen and Co., Ltd., announce the forthcoming publication of a further selection of Sir E. Ray Lankester's popular science articles. It will be entitled "Diversions of a Naturalist."

OUR ASTRONOMICAL COLUMN.

SPECTRAL LINE DISPLACEMENTS AT THE SUN'S LIMB.—As a further research in connection with the work carried on at the Kodaikanal Observatory on the displacement of spectrum lines at the sun's limb, Mr. A. A. Narayana Ayyar contributes to Bulletin No. 44 of the Kodaikanal Observatory the results of his work on the displacements at the sun's limb of lines sensitive to pressure and density. It is pointed out that certain lines, particularly those of calcium and sodium, are much more sensitive to pressure and density than iron lines, and that therefore the limb shifts of such lines should provide a much more rigorous test as to whether there is a large difference of pressure and density between the sun's limb and centre. The paper gives the experimental details, and the result arrived at is that the difference of pressure and density between the limb and centre is very small, a conclusion in agreement with that derived by Messrs. Evershed and Royds. The balance of evidence, as the author states, is in favour of slightly lower pressure and density at the limb than at the centre of the disc.

STATISTICS OF SPECTROSCOPIC BINARY STARS.—In the *Arkiv för Matematik, Astronomi och Fysik* (vol. x., No. 6) of the Stockholm Academy, Dr. Sven Wicksell contributes a paper on the statistics of spectroscopic binary stars. Referring in the first instance to the important investigations and discussions by Campbell, Schlesinger, Baker, Ludendorff, etc., he attempts to find out other interesting properties of spectroscopic binaries. Constructing a card-catalogue of 440 binaries, he found it was composed of 104 systems, of which the period was known, seventy-nine in which the semi-amplitude of radial velocity was known and seventy-five in which the excentricity was known. All these he divided into four classes, according to their spectral type, and arranged them in tabular form. The investigation is devoted to the study of the frequency curves of the period, the explanation of the existence of two groups of periods, a reference to Shapley's investigation of eclipsing binaries, etc.,

and, finally, the distribution of spectroscopic binaries as regards the Milky Way.

THE NATURE AND CAUSE OF CEPHEID VARIATION.—Dr. Harlow Shapley, in the December number of the *Astrophysical Journal* (vol. xl., No. 5, p. 448) presents a discussion on the nature and cause of Cepheid variation, in which he investigates the question of whether or not the usually accepted double-star interpretation of Cepheid variation should be abandoned. From the spectroscopic point of view alone, he states, the Cepheids stand out as unexplainable anomalies. There are persistent peculiarities in the spectroscopic elements, a universal absence of a secondary spectrum, and minute apparent orbits. They do exhibit definite periodic oscillations of their spectral lines, as is the case with ordinary spectroscopic binaries, which may be interpreted as periodic orbital motion. In the present discussion, which the author considers only as preliminary, no complete explanation of Cepheid variation is offered as a substitute for the existing inadequate theories, but he points out the direction in which he thinks the real interpretation seems to lie. The sections of the present paper are devoted to the principal results which he has obtained from an extensive investigation, details of which will be published in subsequent papers. The main conclusion which he has reached is summed up by him as follows :—"That the Cepheid and cluster variables are not binary systems, and that the explanation of their light-changes can much more likely be found in a consideration of internal or surface pulsations of isolated stellar bodies."

THE PREHISTORIC SOCIETY OF EAST ANGLIA.

MR. MILLER CHRISTY, in the Proceedings of the Prehistoric Society of East Anglia, 1913–14, discusses the curious engraved shell from the Red Crag at Walton-on-the-Naze, which has formed the subject of much controversy since it was exhibited at the York meeting of the British Association in 1881. It is a crude and inartistic attempt to depict a human portrait. It is much ruder in its execution than the celebrated drawings of the human figure from the French caves and the Bushman drawings from South Africa. It also differs from other drawings of this kind as it represents, not a profile, but a full face. The characteristics of this supposed portrait have been investigated by a special committee, and on the whole Mr. Christy is disposed to agree with its members that the evidence is insufficient to enable us to reach any definite conclusion regarding its age.

Under the title of "An Early Norfolk Trackway: The Drove Road," Messrs. W. G. Clarke and H. D. Hewitt describe a supposed ancient trackway, fourteen miles in length, connecting the fenland at Blackdike, Hockwold, with Peddar's Way on Roudham Heath. There are some indications that this was an ancient route, but the evidence adduced in support of the conclusion that it is of extreme antiquity is not quite conclusive. In its original state it possesses many points of resemblance to known prehistoric trackways in East Anglia and other parts of England; it is subsidiary to Peddar's Way, and it is also connected with the Pilgrim's Walk; in relation to the Fendyke it resembles the Icknield Way, which is certainly prehistoric; roads from Saxon settlements were in some cases diverted from their natural course by the Drove; there are barrows in the vicinity, and flint implements and ancient pottery have been found in the neighbourhood. Another similar road near Norwich is described by Mr. Walter Rye in the same issue of the Proceedings.

ANNUAL MEETING OF THE PARIS ACADEMY OF SCIENCES.[1]

THE year just ended has been broken by a formidable discontinuity. In the first period our work has followed its usual course; in the second, it has been dominated by the constant thought of national defence.

The importance of the rôle of our academy grows from year to year. Nearly all the development of modern civilisation takes its roots in scientific research; that is to say, in the study, the co-ordination and the generalisation of those facts and ideas which lend themselves to exact measurements or precise comparisons. The domain of science thus understood is unlimited; it ranges from the highest abstractions to the most practical applications, from the world of stars and nebulæ to that of atoms and molecules; from the mechanics of worlds to factories, to armoured vessels, and to aeroplanes; from the delicate phenomena of physics and chemistry to the great industries, to telephony, to wireless telegraphy, and to explosives; from the most complex living organisms in the present and the past to microscopic beings; from the experiments of physiology and microbiology to agriculture, medicine, and surgery. If, at all times, the evolution of philosophy has followed that of science, modern work on the principles of geometry and mechanics, the examination of the ideas of space and time, the daring attempts to connect simultaneously these two ideas with the theory of groups of transformations, have opened entirely new paths in the study of the foundations of our knowledge.

The search for scientific truth by a mind enamoured of moral beauty is the noblest aim of mankind. But the study of science, deflected from the steady ideal of right and humanity, confined to the path of a narrow specialisation, disciplined with a view to domination and reduced principally to practical use, leads rapidly to a civilisation of selfishness, hardness, and materialism, to a kind of learned barbarity like that which has gradually overgrown the Germany of the present day. Granted that the acquisition of the scientific spirit is indispensable to education, other elements should be joined to it to form a man worthy of the name, and these are presented to us by the "humanities," which are studied by our colleagues of the other academies; philosophy and history, religious and social science, the rights of individuals or of nations, the creations of thinkers or of artists.

Instruction and erudition must not be confused with education, the laborious work of acquiring knowledge with the development of civilisation. True education ought to create a personal religion, a conscience increasing in sensitiveness and loftiness of ideal, the love of clearness, the power of forming general ideas, devotion to justice, respect for other men.

This is the well-balanced culture after which France has always sought; it is this which is threatened to-day; at the sight of this danger Prof. Murray Butler, of Columbia University, has said :—

"What are we to think? Is science a sham? Is philosophy a pretence? Is religion a mere rumour? Is the great international structure of friendship, good-will, and scholarly co-operation upon which this university and many of its members have worked so long, so faithfully, and apparently with so much success, only an illusion? Are the long and devoted labours of scholars and of statesmen to enthrone Justice in the place of Brute Force in the world, all without effect? The answer is No; a thousand times, No!"

The American conscience has thus formulated the

[1] Translation of the main part of the address delivered on December 21, 1914, by the president, M. Paul Appell.

universal reply, which is a certain proof of victory for our ideal.

Amongst the scientific events of the year, prominent mention is due to the unveiling of the monument of our colleague Marey, one of those men to whom modern physiology owes so much. As M. Richet has said ("Inauguration du monument élevé à la memoire de Etienne Jules Marey, au Parc des Princes, à Boulogne-sur-Seine, le mercredi 3 Juin, 1914"; Paris: Gauthier-Villars), he is one of those who leave a work so firm, so fruitful, so perfect that every year adds to its renown. In fact, time takes no toll on a well-founded scientific work. The pages of Descartes on "la Géométrie analytique," of Harvey on "the contractions of the heart," of Lavoisier on "les combustions respiratoires," remain intact and intangible, like the Greek marble statues, the beauty of which remains unchanged after a lapse of twenty centuries. The idea conceived by Marey in his youth and realised by him in his work was the creation of methods permitting the direct and precise inscription of motion, either by graphical records, or by photographs taken at intervals so short as to appear continuous. A running man, a galloping horse, a flying bird, a beating heart, execute movements only a confused average of which can be seized by the eye. The photographs of Marey give an exact analysis of them; it is only necessary to realise the synthesis of the successive images by the aid of a method employed a long time ago in certain toys to obtain a kinematograph. This apparatus, possessing innumerable scientific applications, has then its origin in the work of Marey.

It presents the great philosophic interest of giving control of the time, which, until then, had been the one independent variable. Once a phenomenon is recorded it can be repeated in its successive phases, accelerating or retarding at will. Thus deceleration permits the study at leisure of the beats of the heart, the movements of a bird's wings, and acceleration shows in a few minutes the germination of a plant or the hatching of an egg. It is even possible to change the sign of the variable and reverse the order of events. Marey then was an inventor of genius, a man who extracted something from nothing; the improvement of a discovery is a small matter, the essential point is to make it.

This year French physicists have been actively occupied with the construction of a huge electromagnet, in which the intensity and dimensions of the field were to be much greater than those of the most powerful apparatus in current use. A magnet of this nature would permit of absolutely new researches on the magnetic properties of matter at different temperatures, on the constitution of crystals, on Zeeman's phenomenon, rotatory magnetic polarisation, and, in another order of work, on modifications of vital phenomena under the action of the magnetic field. The council of the Faculty of Science of Paris, struck with the importance of these researches, had reserved from the funds placed at its disposition by the liberality of M. Commercy for the advancement of science a sum of 50,000 francs, as a first contribution, although small, to the total expenditure required for the realisation of the scheme. Prince Bonaparte, who is always ready with active generosity to support great French scientific enterprises, has taken an active interest in this question. At his request an official committee, composed of the most competent members of our academy, was constituted, in order to study under what conditions France could be endowed with an instrument that should be unique in the world. This committee has held numerous meetings to discuss the various suggestions and hear the best-known specialists; its results have been published in a pamphlet which is a credit to our academy. Without quoting any names, the conclusions may be summarised thus: it is desirable that an important laboratory of magnetic research should be created; this laboratory should be placed under the patronage of the academy, and administered by the University of Paris; in this laboratory should be installed the most powerful electromagnets of the types chosen.

While we are thus dreaming of a gigantic magnet destined to enlarge the field of human knowledge, Germany, carried away by its dream of world-domination, prepared in secret enormous mortars in view of a sudden overwhelming attack on Belgian and French fortresses; when the time was thought favourable, war was declared against Russia and France, and Belgian neutrality was violated. Since the first days in August our academy has had but one thought, to assist the Government in the defence of the country and liberty.

At the meeting of August 3, the academy notified the Government that all its members who were not mobilised in the public service held themselves in readiness to aid in the national defence, each according to his speciality. After the meeting six large committees were constituted under the following denominations:—(1) Mechanics (including Aviation); (2) Wireless Telegraphy; (3) Radiography; (4) Chemistry (including Explosives); (5) Medicine, Surgery, Hygiene; (6) Food. All these committees have worked their hardest; the time has not come to speak of the reports which they have presented and the results they have obtained.

On August 10 the academy addressed to its correspondants in Belgium, M. Boulvin at Ghent, and M. Francotte at Brussels, the expression of its brotherly friendship and its profound admiration for the Belgian people and army. We solemnly renew to-day the expression of these sentiments, adding our indignant protest against the destruction of the treasures of art and science; the acts of violence on the liberty, life, and property of the non-combatants, committed deliberately in order to punish noble nations because they did not hesitate in their choice between the laws of honour, the respect for treaties, the love of independence, and the base suggestions of material interest or of fear.

MATHEMATICS IN ARTILLERY SCIENCE.

SIR GEORGE GREENHILL, president of the Mathematical Association, delivered an address upon "Mathematics in Artillery Science" at the annual meeting of the association on January 9. We have been unable to obtain a copy of the address from the officials of the association, though we think that one of the chief purposes of a scientific society should be to secure as wide a publicity as possible for its papers and addresses. Sir George Greenhill's remarks have, however, been summarised in the daily papers, and from the *Times* report the subjoined abstract has been derived. We may add that as Sir George was formerly professor of mathematics in the Artillery College, Woolwich, his opinions upon the position which science occupies in our technical training for modern warfare must be given careful consideration.

Six months ago artillery officers would have said there was no such thing as mathematics in artillery science; but that outlook was now ancient history, for at the present time we are engaged in what is, in fact, a mathematical war. Drawing upon his experience as a professor of artillery theory for in-

stances where science would prove itself useful on service, he explained how particulars of the enemy's guns could be deduced from fragments of the wall of a shell and photographic pictures. From a fragment they could determine whether a shell came from one of the 42-centimetre howitzers, the very existence of which still appeared in doubt. Dealing with the calculations for ascertaining how far men should stand from a gun to avoid the danger of permanent deafness, he said they need not fear to stand 12 yards behind the 42-centimetre howitzer; and so the story was discounted of the firing party taking cover 100 to 200 metres away when this howitzer was fired. An application of the theory of the conduction of heat would have reassured our men that life in the trenches would not be too cold, or would at least be warmer than in the frost above, provided only the floor could be drained dry under foot. It had also to be borne in mind that the trench gave better cover than a tent.

Five years ago he had an invitation to Berlin, to visit the Military Technical Academy there. It was a magnificent institution such as we could not afford, so our rulers assured us. Prof. Cranz showed how in his department no money was spared in recent equipment, including a bomb-proof range available for artillery fire and yet in the heart of a big city. There were plenty of outdoor artillery ranges also to visit, where instructive work was in progress. The Perry system of education was adopted in Berlin. After a lecture on wireless telegraphy, the class was set to work, as he saw, in making the antennæ which had played such an important part in the war. Sixty officers were under instruction at a time for a course of three years, and he was assured their zeal was admirable. It was considered such bad form not to give the best in return for the honour and glory of the Fatherland. But our Regular was apathetic by comparison. We must put our trust in the junior ranks to push old Apathy from his stool and carry us through this war.

It was a mournful contrast to revert to Woolwich. There they had been evicted and were told to found a new artillery college with the choice of a cellar under some stables or a kitchen and scullery and bare walls in a deserted hospital, there to organise victory and at no expense. With the courage of an Austrian general compelled to maintain his muzzle-loading musket a match for the Prussian needle-gun, the Military Director assured them that there was nothing superior to be found at Greenwich, in the Naval College there lodged in the old Palace. Such dismal, penurious surroundings had a disastrous effect on the *genius loci,* and they never really recovered from a downhearted spirit not calculated for victory. Our military science was under the rule of Thumb, the official genius. His fumbling method was considered a match for disciplined theory.

We saw already how the cost had been well laid out in this war of the Berlin Military Technical Academy, the German jumping off with a lead he was able to keep so far. The finished article of the academy was employed in the dissemination of true theory and in the scientific direction of warlike preparation as at Krupps. Assuming everything for the best for the Allies, and if we lived to go in again at Antwerp, an interesting match would be watched between our artillery science and the German, to see how long it would take us to get the other side out, compared with our own innings and the time we kept our wicket up. No long-range fire, he had been assured, was ever going to be of any use again, involving theoretical calculation. The word was "Gallop up close, to 400 yards, and let them have it."

The country was furious at the way our poor fellows were pounded mercilessly at the start by long-range accurate howitzer fire with no protection from our own side. King George's stirring appeal, "Wake up, England," was intercepted by our rulers, and it was England the Unready again when our Senior Lethargy bumped into the Titanic Energy of the German Empire.

SOME ASPECTS OF PROGRESS IN MODERN ZOOLOGY.[1]

IT is our privilege to live in a time of almost unexampled progress in natural science, a time distinguished alike by discoveries of the first magnitude and by far-reaching changes in method and in point of view. The advances of recent years have revolutionised our conceptions of the structure of matter, and have seriously raised the question of the transmutation of the chemical elements. They have continually extended the proofs of organic evolution, but have at the same time opened wide the door to a re-examination of its conditions, its causes, and its essential nature. Such has been the swiftness of these advances that some effort is still required to realise what remarkable new horizons of discovery they have brought into view. A few years ago the possibility of investigating by direct experiment the internal structure of atoms, or the topographical grouping of hereditary units in the germ-cells, would have seemed a wild dream. To-day these questions stand among the substantial realities of scientific inquiry. And lest we should lose our heads amid advances so sweeping, the principles that guide scientific research have been subjected as never before to critical examination. We have become more circumspect in our attitude towards natural "laws." We have attained to a clearer view of our working hypotheses—of their uses and their limitations. With the best of intentions we do not always succeed in keeping them clear of metaphysics, but at least we have learned to try. We perceive more and more clearly that science does not deal with ultimate problems or with final solutions. In order to live science must move. She attempts no more than to win successive points of vantage which may serve, one after another, as stepping stones to further progress. When these have played their part they are often left behind as the general advance proceeds.

In respect to the practical applications of science we have almost ceased to wonder at incredible prodigies of achievement; yet in some directions they retain a hold on our imagination that daily familiarity cannot shake. Not in our time, at least, will the magnificent conquests of sanitary science and experimental medicine sink to the level of the commonplace. Science here renders her most direct and personal service to human welfare; and here in less direct ways she plays a part in the advance of our civilisation that would have been inconceivable to our fathers. Popular writers delight to portray the naturalist as a kind of reanimated antediluvian, wandering aimlessly in a modern world where he plays the part of a harmless visionary; but what master of romance would have had the ingenuity to put into the head of his mythical naturalist a dream that the construction of the Panama Canal would turn upon our acquaintance with the natural history of the mosquito, or that the health and happiness of nations—nay, their advance in science, letters, and the arts—might depend measurably on the cultivation of our intimacy with the family lives of house-flies, fleas, and creatures of still more dubious antecedents!

[1] Presidential address delivered to the American Association for the Advancement of Science, Philadelphia, December 28, 1914, by Prof. E. B. Wilson.

I.

Fourteen years ago to-night it was my privilege to deliver an address before the American Society of Naturalists, entitled "Aims and Methods of Study in Natural History,"[2] in which I indicated certain important changes that were then rapidly gathering headway in zoology. To-night I once more ask attention to this subject as viewed in the fuller light of the remarkable period of progress through which biology has since been passing. I will not try to range over the whole vast field of zoology or to catalogue its specific advances. I will only permit myself a few rather desultory reflections suggested by a retrospect upon the progress of the past twenty-five years. If my view is not fully rounded, if it is coloured by a long-standing habit of looking at biological phenomena through the eyes of an embryologist, I will make no apology for what I am not able to avoid. Let me remind you also at how many points the boundaries between this and other branches of biology have become obliterated. The traditional separation between zoology and botany, for instance, has lost all significance for such subjects as genetics or cytology. Again, the artificial boundary often set up between zoology and animal physiology has wholly disappeared, owing to the extension of experimental methods to morphology and of comparative methods to physiology. I trust therefore that our brethren in botany and physiology—perhaps I should include also those in psychology—will not take it amiss if I include them with us under the good, old-fashioned name of *naturalists*.

The sum and substance of biological inquiry may be embodied in two questions: What is the living organism, and how has it come to be? We often find it convenient to lay the emphasis on one or the other of these questions, but fundamentally they are inseparable. The existing animal bears the indelible impress of its past; the extinct animal can be comprehended only in the light of the present. For instance, the palæontologist is most directly concerned with problems of the past, but at every step he is confronted by phenomena only to be comprehended through the study of organisms as they now are. Our main causal analysis of evolution must be carried out by experimental studies on existing forms. All this seems self-evident, yet the singular fact is that only in more recent years have students of evolution taken its truth fully to heart. And here lies the key to the modern movement in zoology of which I propose to speak.

I do not wish to dwell on matters of ancient history; but permit me a word concerning the conditions under which this movement first began to take definite shape as the nineteenth century drew towards its close. In the first three decades after the "Origin of Species" studies upon existing animals were largely dominated by efforts to reconstruct their history in the past. Many of us will recall with what ardour naturalists of the time threw themselves into this profoundly interesting task. Many of us afterwards turned to work of widely different type; but have our later interests, I wonder, been keener or more spontaneous than those awakened by the morphological-historical problems, some of them already half forgotten, which we then so eagerly tried to follow? I am disposed to doubt it. The enthusiasm of youth? No doubt; but something more, too. Efforts to solve those problems have in the past often failed; they no longer occupy a place of dominating importance; but they will continue so long as biology endures, because they are the offspring of an ineradicable historical instinct, and their achievement stands secure in the great body of solid fact which they have built into the framework of our science. Says Poincaré: "The advance of science is not comparable to the changes of a city, where old edifices are pitilessly torn down to give place to new, but to the continuous evolution of zoologic types which develop ceaselessly and end by becoming unrecognisable to the common sight, but where an expert eye finds always traces of the prior work of the centuries past. One must not think then that the old-fashioned theories have been sterile and vain."

After all, science impresses us by something more than the cold light of her latest facts and formulas. The drama of progress, whether displayed in the evolution of living things or in man's age-long struggle to comprehend the world of which he is a product, stirs the imagination by a warmer appeal. Without it we should miss something that we fain would keep—something, one may suspect, that has played an important part of the higher levels of scientific achievement.

I seem to have been caught unawares in the act of moralising. If so, let it charitably be set down as an attempt to soften the hard fact that thirty years after the "Origin of Species" we found ourselves growing discontented with the existing methods and results of phylogenetic inquiry and with current explanations of evolution and adaptation. Almost as if by a preconcerted plan, naturalists began to turn aside from historical problems in order to learn more of organisms as they now are. They began to ask themselves whether they had not been over-emphasising the problems of evolution at the cost of those presented by life-processes everywhere before our eyes to-day. They awoke to the insufficiency of their traditional methods of observation and comparison and they turned more and more to the method by which all the great conquests of physico-chemical science had been achieved, that which undertakes the analysis of phenomena by deliberate control of the conditions under which they take place—*the method of experiment*. Its steadily increasing importance is the most salient feature of the new zoology.

Experimental work in zoology is as old as zoology itself; nevertheless, the main movement in this direction belongs to the past two decades. I will make no attempt to trace its development; but let me try to suggest somewhat of its character and consequences by a few outlines of what took place in embryology.

The development of the egg has always cast a peculiar spell on the scientific imagination. As we follow it hour by hour in the living object we witness a spectacular exhibition that seems to bring us very close to the secrets of animal life. It awakens an irrepressible desire to look below the surface of the phenomena, to penetrate the mystery of development. The singular fact, nevertheless, is that during the phylogenetic period of embryological research this great problem, though always before our eyes, seemed almost to be forgotten in our pre-occupation with purely historical questions—such as the origin of vertebrates or of annelids, the homologies of germ-layers, gill-slits or nephridia, and a hundred others of the same type. Now, these questions are, and always will, remain of great interest; but embryology, as at last we came to see, is but indirectly connected with historical problems of this type. The embryologist seeks first of all to attain to some understanding of development. It was therefore a notable event when, in the later 'eighties, a small group of embryologists, headed by Wilhelm Roux, turned away from the historical aspects of embryology and addressed themselves to experiments designed solely to throw light upon the mechanism of development. The full significance

[2] *Science*, N. S., xiii., No. 314, January 4, 1901.

of this step first came home to us in the early 'nineties with Driesch's memorable discovery that by a simple mechanical operation we can at will cause one egg to produce two, or even more than two, perfect embryos. I will not pause to inquire why this result should have seemed so revolutionary. It was as if the scales had fallen from our eyes. With almost a feeling of shock we took the measure of our ignorance and saw the whole problem of development reopened.

The immediate and most important result of this was to stimulate a great number of important objective investigations in embryology. But let me pause for a moment to point out that at nearly the same time a similar reawakening of interest in the experimental investigation of problems of the present became evident in many other directions—for example, in studies on growth and regeneration; on cytology and protozoology; on economic biology; on ecology, the behaviour of animals and their reactions to stimuli; on heredity, variation, and selection. The leaven was indeed at work in almost every field of zoology, and everywhere led to like results. It was a day of rapid obliteration of conventional boundary lines; of revolt from speculative systems towards the concrete and empirical methods of the laboratory; of general and far-reaching extension of experimental methods in our science.

But I will return to embryology. It may be doubted whether any period in the long history of this science has been more productive of varied and important discoveries than that which followed upon its adoption of experimental methods. In one direction the embryologist went forward to investigations that brought him into intimate relations with the physicist, the chemist, the pathologist, and even the surgeon. A flood of light was thrown on the phenomena of development by studies on differentiation, regeneration, transplantation, and grafting; on the development of isolated blastomeres and of egg-fragments; on the symmetry and polarity of the egg; on the relations of development to mechanical, physical, and chemical conditions in the environment; on isolated living cells and tissues, cultivated like micro-organisms, outside the body *in vitro*; on fertilisation, artificial parthenogenesis, and the chemical physiology of development. In respect to the extension of our real knowledge these advances constitute an epoch-making gain to biological science. And yet these same researches afford a most interesting demonstration of how the remoter problems of science, like distant mountain-peaks, seem to recede before us even while our actual knowledge is rapidly advancing. Thirty years after Roux's pioneer researches we find ourselves constrained to admit that in spite of all that we have learned of development the egg has not yet yielded up its inmost secrets. I have referred to the admirable discovery of Driesch concerning the artificial production of twins. That brilliant leader of embryological research had in earlier years sought for an understanding of development along the lines of the mechanistic or physico-chemical analysis, assuming the egg to be essentially a physico-chemical machine. He now admitted his failure and, becoming at last convinced that the quest had from the first been hopeless, threw all his energies into an attempt to resuscitate the half-extinct doctrines of vitalism and to found a new philosophy of the organism. Thus the embryologist, starting from a simple laboratory experiment, strayed further and further from his native land until he found himself at last quite outside the pale of science. He did not always return. Instead, he sometimes made himself a new home—upon occasion even established himself in the honoured occupancy of a university chair of philosophy!

The theme that is here suggested tempts me to a digression, because of the clear light in which it displays the attitude of modern biology towards the study of living things. It is impossible not to admire the keenness of analysis, and often the artistic refinement of skill (which so captivates us, for instance, in the work of M. Bergson) with which the neo-vitalistic writers have set forth their views. For my part, I am ready to go further, admitting freely that the position of these writers *may* at bottom be well grounded. At any rate, it is well for us now and then to be rudely shaken out of the ruts of our accustomed modes of thought by a challenge that forces upon us the question whether we really expect our scalpels and microscopes, our salt-solutions, formulas, and tables of statistics, to tell the whole story of living things. It is, of course, impossible for us to assert that they will. And yet the more we ponder the question the stronger grows our conviction that the "entelechies" and such-like agencies conjured forth by modern vitalism are as sterile for science as the final causes of an earlier philosophy; so that Bacon might have said of the former, as he did of the latter, that they are like the Vestal virgins—dedicated to God, and barren. We must not deal too severely with the naturalist who now and then permits himself an hour of dalliance with them. An uneasy conscience will sooner or later drive him back into his own straight and narrow way with the insistent query: The specific vital agents, *sui generis*, that are postulated by the vitalist—are they sober realities? Can the existence of an "élan vital," of "entelechies," of "psychoids," be experimentally verified? Even if beyond the reach of verification may they still be of practical use in our investigations on living things, or find their justification on larger grounds of scientific expediency. However philosophy may answer, science can find but one reply. *The scientific method is the mechanistic method.* The moment we swerve from it by a single step we set foot in a foreign land where a different idiom from ours is spoken. We have, it is true, no proof whatever of its final validity. We do not adopt the mechanistic view of organic nature as a dogma but only as a practical programme of work, neither more nor less. We know full well that our present mechanistic conceptions of animals and plants have not yet made any approach to a complete solution of the problems of life, whether past or present. This should encourage us to fresh efforts, for just in the present inadequacy of these conceptions lies the assurance of our future progress. But the way of unverifiable (and irrefutable) imaginative constructions is not our way. We must hold fast to the method by which all the great advances in our knowledge of nature have been achieved. We shall make lasting progress only by plodding along the old, hard beaten trail blazed by our scientific fathers—the way of observation, comparison, experiment, analysis, synthesis, prediction, verification. If this seems a prosaic programme we may learn otherwise from great discoverers in every field of science who have demonstrated how free is the play that it gives to the constructive imagination and even to the faculty of artistic creation.

II.

Thus far I have desired to emphasise especially the reawakening of our interest in problems of the present, and the growing importance of experimental methods in our science. It is interesting to observe how these changes have affected our attitude towards the historical problem as displayed in the modern study of genetics. Even here we are struck by the same shifting of the centre of gravity that has been remarked in other fields of inquiry. In the Darwinian era

studies on variation and heredity seemed significant mainly as a means of approach to the problems of evolution. The post-Darwinians awoke once more to the profound interest that lies in the genetic composition and capacities of living things as they now are. They turned aside from general theories of evolution and their deductive application to special problems of descent in order to take up objective experiments on variation and heredity for their own sake. This was not due to any doubts concerning the reality of evolution or to any lack of interest in its problems. It was a policy of masterly inactivity deliberately adopted; for further discussion concerning the causes of evolution had clearly become futile until a more adequate and critical view of existing genetic phenomena had been gained. Investigators in genetics here followed precisely the same impulse that had actuated the embryologists; and they, too, reaped a rich harvest of new discoveries. Foremost among them stands the re-discovery of Mendel's long-forgotten law of heredity—a biological achievement of the first rank which in the year 1900 suddenly illuminated the obscurity in which students of heredity had been groping. Another towering landmark of progress is De Vries's great work on the mutation theory, published a year later, which marked almost as great a transformation in our views of variation and displayed the whole evolution problem in a new light. In the era that followed, the study of heredity quickly became not only an experimental, but almost an exact science, fairly comparable to chemistry in its systematic employment of qualitative and quantitative analysis, synthesis, prediction, and verification. More and more clearly it became evident that the phenomena of heredity are manifestations of definite mechanism in the living body. Microscopical studies on the germ-cells made known an important part of this mechanism and provided us with a simple mechanical explanation of Mendel's law. And suddenly, in the midst of all this, by a kaleidoscopic turn, the fundamental problem of organic evolution crystaliises before our eyes into a new form that seems to turn all our previous conceptions topsy-turvy.

I will comment briefly on this latest view of evolution, partly because of its inherent interest, but also because it again exemplifies, as in the case of embryology, that temptation to wander off into metaphysics (*sit venia verbo!*) which seems so often to be engendered by new and telling discoveries in science. The fundamental question which it raises shows an interesting analogy to that encountered in the study of embryology, and may conveniently be approached from this side.

To judge by its external aspects, individual employment, like evolution, would seem to proceed from the simple to the complex; but is this true when we consider its inner or essential nature? The egg *appears* to the eye far simpler than the adult; yet genetic experiment seems continually to accumulate evidence that for each independent hereditary trait of the adult the egg contains a corresponding *something* (we know not what) that grows, divides, and is transmitted by cell-division without loss of its specific character and independently of other somethings of like order. Thus arises what I will call the puzzle of the microcosm. Is the appearance of simplicity in the egg illusory? Is the hen's egg fundamentally as complex as the hen, and is development merely the transformation of one kind of complexity into another? Such is the ultimate question of ontogeny, which in one form or another has been debated by embryologists for more than two centuries. We still cannot answer it. If we attempt to do so, each replies according to the dictates of his individual temperament—that is to say, he resorts to some kind of symbolism; and he still remains free to choose that particular form which he finds most convenient, provided it does not stand in the way of practical efforts to advance our real knowledge through observation and experiment. Those who must have everything reduced to hard and fast formulas will no doubt find this rather disconcerting; but worse is to follow. Genetic research now confronts us with essentially the same question as applied to the evolutionary germ. The puzzle of the microcosm has become that of the macrocosm. Were the primitive forms of life really simpler than their apparently more complex descendants? Has organic evolution been from the simple to the complex, or only from one kind of complexity to another? May it even have been from the complex to the simple by successive losses of inhibiting factors which, as they disappear, set free qualities previously held in check? The last of these is the startling question that the president of the British Association propounds in his recent brilliant address at Melbourne, asking us seriously to open our minds to the inquiry: "Whether evolution can at all reasonably be represented as an unpacking of an original complex which contained within itself the whole range of complexity which living things exhibit?" This conception, manifestly, is nearly akin to the theory of pangenesis and individual development, as elaborated especially by De Vries and by Weismann. It inevitably recalls also, if less directly, Bonnet's vision of "palingenesis," which dates from the eighteenth century.

We should be grateful to those who help us to open our minds; and Prof. Bateson, as is his wont, performs this difficult operation in so large and masterly a fashion as to command our lively admiration. It must be said of his picturesque and vigorous discussion that we are kept guessing how far we are expected to take it seriously, or at least literally. We have always a lurking suspicion that possibly his main purpose may, after all, be to remind us, by an object-lesson, how far we still are from comprehending the nature and causes of evolution, and this suspicion is strengthened by the explicit statement in a subsequent address, delivered at Sydney, that our knowledge of the nature of life is "altogether too slender to warrant speculation on these fundamental questions." Let us, however, assume that we are seriously asked to go further and to enter the *cul de sac* that Prof. Bateson so invitingly places in our way. Once within it, evidently we are stalemated in respect to the origin and early history of life; but as to that, one form of total ignorance is perhaps as good as another, and we can still work out how the game has been played, even though we can never find out how the pieces were set up. But has the day so soon arrived when we must resign ourselves to such an ending? Are we prepared to stake so much upon the correctness of a single hypothesis of allelomorphism and dominance? This hypothesis—that of "presence and absence"—has undoubtedly been a potent instrument of investigation; but there are some competent students of genetics who seem to find it equally simple to formulate and analyse the phenomena by the use of a quite different hypothesis, and one that involves no such paradoxical consequences in respect to the nature of evolution. Are we not then invited to strain at a gnat and to swallow a camel?

But I pass over the technical basis of the conception in order to look more broadly at its theoretic superstructure. Is not this, once again, a kind of symbolism by which the endeavour is made to deal with a problem that is for the present out of our reach? Neither you nor I, I dare say, will hesitate to maintain that the primordial Amœba, if we may so dub the

earliest of our ancestors) embodied in some sense or other all the potentialities, for better or for worse, that are realised before us at this moment in the American Association for the Advancement of Science. But if we ask ourselves exactly what we mean by this we discover our total inability to answer in more intelligible terms. We cannot, it is true, even if we would, conquer the temptation now and then to spread the wings of our imagination in the thin atmosphere of these upper regions; and this is no doubt an excellent tonic for the cerebrum provided we cherish no illusions as to what we are about. No embryologist, for example, can help puzzling over what I have called the problem of the microcosm; but he should be perfectly well aware that in striving to picture to his imagination the ultimate organisation of the egg, of the embryological germ, that is actually in his hands for observation and experiment, he is perilously near to the habitat of the mystic and the transcendentalist. The student of evolution is far over the frontier of that forbidden land, in any present attack upon the corresponding problem of the macrocosm; for the primordial Amœba, the evolutionary germ, is inconceivably far out of our reach, hidden behind the veil of a past the beginnings of which lie wholly beyond our ken. And why, after all, should we as yet attempt the exploration of a region which still remains so barren and remote? Surely not for the lack of accessible fields of genetic research that are fertile and varied enough to reward our best efforts, as no one has more forcibly urged or more brilliantly demonstrated by his own example than Prof. Bateson himself.

Perhaps it would be the part of discretion to go no further. But the remarkable questions that Prof. Bateson has raised concerning the nature of evolution leave almost untouched the equally momentous problem as to what has guided its actual course. In approaching my close I shall be bold enough to venture a step in this direction, even one that will bring us upon the hazardous ground of organic adaptations and the theory of natural selection. I need not say that this subject is beset by intricate and baffling difficulties which have made it a veritable bone of contention among naturalists in recent years. In our attempts to meet them we have gone to some curious extremes. On the one hand, some naturalists have in effect abandoned the problem, cutting the Gordian knot with the conclusion that the power of adaptation is something given with organisation itself and as such offers a riddle that is for the present insoluble. In another direction we find attempts to take the problem in flank, to restate it, to ignore it—sometimes, it would almost seem to argue it out of existence. It has been urged in a recent valuable work—by an author, I hasten to say, who fully accepts both the mechanistic philosophy and the principle of selection—that fitness is a reciprocal relation, involving the environment no less than the organism. This is both a true and a suggestive thought; but does it not leave the naturalist floundering amid the same old quicksands? The historical problem with which he has to deal must be grappled at closer quarters. He is everywhere confronted with specific devices in the organism that must have arisen long after the conditions of environment to which they adjusted. Animals that live in water are provided with gills. Were this all we could probably muddle along with the notion that gills are no more than lucky accidents. But we encounter a sticking point in the fact that gills are so often accompanied by a variety of ingenious devices, such as reservoirs, tubes, valves, pumps, strainers, scrubbing brushes, and the like, that are obviously tributary to the main function of breathing. Given water, asks the naturalist, how has all this come into existence and been perfected? The question is an inevitable product of our common sense. The metaphysician, I think, is not he who asks but he who would suppress it.

For all that it would seem that some persons find the very word adaptation of too questionable a reputation for mention in polite scientific society. Allow me to illustrate by a leaf taken from my own notebook. I once ventured to publish a small experimental work on the movements of the fresh-water Hydra with respect to light. What was my surprise to receive a reproof from a friendly critic, because I had not been content with an objective description of the movements but had also been so indiscreet as to emphasise their evident utility to the animal. I was no doubt too young then—I fear I am too old now—to comprehend in what respect I had sinned against the light. That was long ago. I will cite a more recent example from a public discussion on adaptation that took place before the American Society of Naturalists a year or two since. "The dominance of the concept of adaptation," said one naturalist, "which now distinguishes our science from the non-biological ones, is related to the comparatively youthful stage of development so far attained by biology, and *not to any observed character in the living objects with which we deal.*" Here, we almost seem to catch an echo from the utterances of a certain sect of self-styled "scientists" who love to please themselves with the quaint fancy that physical disease is but one of the "errors of mortal mind."

Now, it is undoubtedly true that many adaptations, to cite Prof. Bateson once more, are "not in practice a very close fit." Even the eye, as Helmholtz long ago taught us, has some defects as an optical instrument; nevertheless, it enables us to see well enough to discern some food for reflection concerning adaptations among living things. And it is my impression that efforts to explain adaptations are likely to continue for the reason that naturalists as a body, perhaps influenced by Huxley's definition of science, have an obstinate habit of clinging to their common sense.

At the present day there is no longer the smallest doubt of the great outstanding fact that many complex structural adaptations—it would probably be correct to say all such—have not come into existence at a single stroke but have moved forward step by step to the attainment of their full degree of perfection. What has dominated the direction and final outcome of such advancing lines? We cannot yet answer this question with any degree of assurance; but procrastinate as we may, it must in the end squarely be faced. We have seen one theory after another forced back within narrower lines or crumbling away before the adverse fire of criticism. I will not pause to recount the heavy losses that must be placed to the account of sexual selection, of neo-Lamarckism, of orthogenesis. Some naturalists, no doubt, would assign a prominent place in this list of casualties to natural selection; but probably there are none who would hold that it has been destroyed utterly. The crux lies in the degree of its efficacy. Stated as an irreducible minimum the survival of the fit is an evident fact. Individuals that are unfitted to live, or to reproduce, leave few or no descendants—so much, at least, must be admitted by all. But does this colourless and trite conclusion end the matter or adequately place before us the significance of the facts? Just here lies the whole issue. Does destruction of the unfit accomplish no other result than to maintain the *status quo*, or has it conditioned the direction of progress? Accepting the second of these alternatives, Darwin went so far as to assign to it a

leading rôle among the conditions to which the living world owes its existing configuration. Since his time the aspect of the problem has widely changed. We must rule out the question of the origin of neutral or useless traits. We must not confuse the evolution of adaptations with the origin of species. We must bear in mind the fact that Darwin often failed to distinguish between non-heritable fluctuations and hereditary mutations of small degree. We are now aware that many apparently new variations may be no more than recombination-products of pre-existing elements, We should, no doubt, make a larger allowance for the rôle of single "lucky accidents" in evolution than did many of the earlier evolutionists. And yet, so far as the essence of the principle is concerned, I am bound to make confession of my doubts whether any existing discussion of this problem affords more food for reflection, even to-day, than that contained in the sixth and seventh chapters of the "Origin of Species" and elsewhere in the works of Darwin.

Undeniably there is a large measure of truth in the contention that natural selection still belongs rather to the philosophy than to the science of biology. In spite of many important experimental and critical studies on the subject Darwin's conception still remains to-day in the main what it was in his own time, a theory, a logical construction, based, it is true, on a multitude of facts, yet still awaiting adequate experimental test. Simple though the principle is, its actual effect in nature is determined by conditions that are too intricate and operate through periods too great to be duplicated in the experimental laboratory. Hence it is that even after more than fifty years of Darwinism the time has not yet come for a true estimate of Darwin's proposed solution of the great problem.

But there is still another word to be said. Too often in the past the facile formulas of natural selection have been made use of to carry us lightly over the surface of unsuspected depths that would richly have repaid serious exploration. In a healthy reaction from this purblind course we have made it the mode to minimise Darwin's theory; and no doubt a great service has been rendered to our study of this problem by the critical and sceptical spirit of modern experimental science. But there is a homely German saying that impresses upon us the need of caution as we empty out the bath lest we pour out the child too. This suggests that we should take heed how we under-estimate the one really simple and intelligible explanation of organic adaptations that has thus far been placed in our hands. And in some minds—if I include my own among them let it be set down to that indiscretion at which I have hinted—the impression grows that our preoccupation with the problem as it appears at short focus may in some measure have dimmed our vision of larger outlines that must be viewed at longer range; that we may have emphasised minor difficulties at the cost of a larger truth. To such minds it will seem that the principle of natural selection, while it may not provide a master key to all the riddles of evolution, still looms up as one of the great contributions of modern science to our understanding of nature.

I have taken but a passing glance at a vast and many-sided subject. I have tried to suggest that the tide of speculation in our science has far receded; that experimental methods have taken their rightful place of importance; that we have attained to a truer perspective of past and present in our study of the problems of animal life. The destructive phase through which we have passed has thoroughly cleared the ground for the new constructive era on which we now have entered. All the signs of the times indicate that this era will long endure. And this is of good augury for a future of productive effort, guided by the methods of physico-chemical science, impatient of merely *a priori* constructions, of academic discussions, of hypotheses that cannot be brought to the test of experimental verification. The work ahead will make exacting technical demands upon us. The pioneer days of zoology are past. The naturalist of the future must be thoroughly trained in the methods and results of chemistry and physics. He must prepare himself for a life of intensive research, of high specialisation; but in the future even more than in the past he will wander in vain amid the dry sands of special detail if the larger problems and general aims of his science be not held steadfastly in view. For these are the outstanding beacon lights of progress; and while science viewed at close range seems always to grow more complex, a wider vision shows that her signal discoveries are often singularly simple. This perhaps may help us to keep alive the spirit of the pioneers who led the advances of a simpler age; and it is full of hope for the future.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—The Huxley Lecture will be delivered on January 21 by M. Emile Verhaeren (the national poet of Belgium), who has chosen as his subject "L'Esprit Belge."

LONDON.—Among the opening lectures in the Lent Term at the Bedford College for Women are several which are open free to the public without ticket. In the department of geology a series of four lectures on minerals used as gem stones will be given on Thursdays at 5.15 p.m., beginning on January 28, by Dr. A. Hutchinson and Dr. H. H. Thomas. In the botany department Mr. W. Neilson Jones will lecture on Mondays at 5 p.m., beginning on January 18, on phenomena of heredity. There will also be lectures on hygiene, mathematics, physiology, and chemistry.

A COURSE of lectures to the University of London Officers Training Corps on military subjects is being given by the members of the staff of Birkbeck College, London, on Tuesdays, at 8 p.m. The first lecture, on the economics of war, was given on January 19 by the principal of the college, Dr. G. Armitage-Smith. Forthcoming lectures on succeeding Tuesdays are as follows:—"Bacteria," Dr. H. C. I. Gwynne-Vaughan; "Some Past Fights for Freedom," Mr. L. Ricci; "Trench Making," Dr. J. W. Evans; "Report Writing," Mr. J. H. Lobban; "International Law of War on Land," Mr. G. C. Rankin; "Map Making and Map Reading," Dr. J. F. Unstead; "Range Finding," Dr. A. Griffiths; "Explosives," Dr. G. Senter; "War Clouds of Modern Europe," Mr. A. Jones; "An Ancient Drill Book," Mr. F. A. Wright. The lectures are intended primarily for cadets of the Officers Training Corps, but are open to all persons interested, without fee.

A COPY of the "General Information Number" of the Bulletin of the Armour Institute of Technology has been received from Chicago. Full particulars are given of the courses offered in mechanical, electrical, civil, chemical, and fire protection engineering, as well as those in architecture and the industrial arts. Each of these four-year courses represents a carefully balanced group system of studies, combining a thorough and broad scientific training with the elements of liberal culture, and all lead to the degree of bachelor of science.

THE president, vice-president, and council of the Royal College of Surgeons in Ireland have decided to place in the college a permanent record of the names of all the students, licentiates, and fellows of the college who are at present serving with his Majesty's Navy and Expeditionary Forces, and further to erect a suitable memorial to all such as fall in the war. The president, vice-president, and council will be glad if the relatives and friends would communicate the names of such students, licentiates, and fellows to the registrar of the college.

IN an article in *Science* for December 25, Mr. John C. Burg, of North-Western University, Chicago, examines and summarises the registration statistics for November 1, 1914, of some thirty universities in the United States. The largest gains for the year in the number of students were as follows:—Columbia, 1365; California, 1109; Pittsburgh, 1069; Ohio State, 832; Wisconsin, 806; Harvard, 784; New York, 634; Minnesota, 552; Pennsylvania, 536. The eight universities with the largest total number of students are given in the article as:—Columbia, 11,294; California, 8180; Chicago, 7131; Wisconsin, 6696; Pennsylvania, 6505; Harvard, 6411; Michigan, 6319; New York University, 6142. In the scientific schools, that is, including the schools of mines, engineering, chemistry, and related subjects, Illinois takes the lead with 1406 students, followed by Cornell, 1363, Michigan, 1347, Yale, 1056, Pennsylvania, 906, Ohio State, 851, Wisconsin, 796, and California, 763.

IT is announced in the issue of *Science* for January 8 that the sum of 486,000*l.* was obtained for Wellesley College in the fourteen months ended in December, 1914, according to a statement given out by the treasurer. Of this amount 86,000*l.*, including a conditional pledge of 40,000*l.* from the General Educational Board, was raised before the fire of March 17, when College Hall was burned. The remaining 400,000*l.* includes a pledge from the Rockefeller Foundation of 150,000*l.* Only three gifts of more than 2000*l.* were received since last August. One of these was a gift from Mr. Carnegie of 19,000*l.* for the enlargement of the library. From the same source we learn that the Massachusetts Institute of Technology received in gifts during the past year the sum of 80,000*l.*, besides two items wherein the institute is residuary legatee, and the amounts have not been determined. Among the gifts may be mentioned: bequest of Caroline L. W. French (outright), 20,000*l.*; (residue), 20,000*l.*; Lucius Tuttle, 10,000*l.*; and Nathaniel Thayer, 10,000*l.*

THE issue for January of the Technical Journal of the Association of Teachers in Technical Institutions contains an interesting article on the Massachusetts Institute of Technology. This article is written by Dr. Tyler, Walker professor of mathematics, and Mr. R. C. Maclaurin, president of the college. It may be noted that not only is admission to the college regulated by means of entrance examinations, but there is a continual weeding out of those students who do not display the requisite ability and application. New students are examined periodically, and if their work proves to be unsatisfactory they are required to withdraw. Some of our own colleges could copy this system, and thereby show a considerable improvement in their produce. In the same journal there is an article on laboratories for building trade students, by Mr. G. Arnall. This article suggests that the time is ripe for the institution of separate laboratories for such students, in which the testing of cements, timber, ferro-concrete, etc., could be studied practically. The scheme will probably involve considerable modification of building courses, and the author invites his colleagues in this branch of teaching to submit model syllabuses of laboratory experiments.

IN Circular 885, issued on January 11, the Board of Education states that there is likely to be some difficulty in procuring in this country adequate supplies of chemical laboratory glassware. These articles have ordinarily been imported from Germany and Austria, and they have not hitherto been manufactured in this country except in negligible quantities. Steps to ensure the production of chemical glassware in this country are being taken, but in view of the technical and other difficulties which have to be overcome it must necessarily be some considerable time before there can be production on a large and sufficient scale. Having regard to the extent to which many of the manufacturing industries of the country, including some of special value at the present crisis, require chemical glassware for analytical and other purposes connected with the various industrial processes, it is important that every effort should be made to economise in the use of stocks of such ware now in the hands of educational establishments. These stocks should be examined and a careful record kept of quantities and consumption. Every effort should be made to avoid breakages, and it will probably be found possible to economise in the consumption of "Jena" vessels by the substitution in certain cases of other kinds of glass receptacles. Fresh orders should not be given to manufacturers or supplying agencies for the present, where this can possibly be avoided. The Board of Education is confident that local education authorities and schools and colleges will do their best to assist the Government in the matter.

SOCIETIES AND ACADEMIES.

LONDON.

Mathematical Society, January 14.—Sir Joseph Larmor, president, and afterwards Prof. A. E. H. Love, vice-president, in the chair.—Prof. H. M. **Macdonald**: A class of diffraction problems.—H. E. J. **Curzon**: Halphen's transformation.—Dr. A. **Young**: A Christmas problem in probabilities.—W. E. H. **Berwick**: The condition that a quintic equation should be soluble by radicles.—Sir J. **Larmor**: The variation of the earth's angular velocity of rotation.

PARIS.

Academy of Sciences, January 4.—M. A. Perrier in the chair.—G. **Bigourdan**: The rapid testing of small telescopes. The method proposed, which is easily and rapidly carried out, is a relative one, comparison being made with a standard telescope. The instrument is focussed on a square, one centimetre in the side, containing a group of black lines ruled at equal distances. The number of lines in the centimetre varies from 4 to 20, and the white interspaces are equal in width to the black lines. Details of the mode of testing separating power, astigmatism and field are given.—L. **Landouzy**: a flexible and non-inflammable gelatine film, suitable for radiology. A description of the preparation and use of thin gelatine plates designed to replace the ordinary glass-coated plates. The unexposed plates, with cardboard supporting frame, weigh 8 per cent. of the weight of the ordinary plate, and after exposure and removal of the film from the frame, this is reduced to 2·8 per cent. Additional advantages as compared with glass plates are cheapness, non-fragility, flexibility, enabling the plate to be inserted into awkward positions without damage, and as compared with celluloid, non-inflammability and perfection of detail.—Edouard **Heckel**: *Solanum*

Caldasii and the cultural bud mutation of its subterranean parts. This variety has received several names, and in the author's opinion the classification is too artificial. Proofs are given of the mutation of this wild potato.—MM. **Camichel, Eydoux,** and **Lhériaud**: The Venturi meter. A discussion of the accuracy of the Venturi water meter. The theoretical formula is $q = \lambda a \sqrt{p_1 - p_2}$, in which q is the quantity, $(p_1 - p_2)$ the difference of pressure between the main tube and the construction, and λ a factor less than unity depending on the internal friction of the liquid. Experimental results with a Venturi gauge of 300 mm. diameter, contraction $\frac{1}{4}$, and flow varying from 60 to 160 litres a second. The value of λ was found to be 1, the error of experiment being under 1 per cent. Similar results were obtained with a larger instrument, passing 800 to 3000 litres a second.—Emile **Saillard**: The estimation of saccharose in beet molasses. Inversion method with double neutral polarisation. The method proposed eliminates errors due to the action of alkaline salts upon saccharose and on invert sugar, and also errors caused by the products of the action of alkaline salts upon active nitrogen compounds present in the beet molasses.—N. **Arabu**: Studies on the Tertiary formation of the basin of the Sea of Marmora. The Vindobonian stage of Troade.—J. de **Rey-Pailhade**: The existence of philothion in the crystalline lens of the eyes of animals. Philothion is a special albumen, characterised by the existence in its molecule of labile hydrogen capable of combining with free sulphur at a temperature of 40° C., with production of sulphuretted hydrogen.—M. **Tiffeneau**: The destination of chloralose in the organism and its relations with glycuronic compounds. In the dog, chloralose is eliminated in part unchanged, and partly in the form of a new acid, chloralose-glycuronic acid. Chloralose does not give rise to chloral and glucose in the organism, and its physiological effects are not due to the chloral it contains.

NEW SOUTH WALES.

Linnean Society, November 25, 1914.—Mr. W. S. Dun, president, in the chair.—A. M. **Lea**: Descriptions of new species of Australian Coleoptera. Part x. Three genera and forty-eight species (families Lucanidæ, Malacodermidæ, Curculionidæ, and Chrysomelidæ) are described as new.—C. **Hedley**: Studies on Australian Mollusca. Part xii. This paper continues the subject of previous communications, and embraces notes gathered abroad in the British and other museums. The Australian species formerly grouped under Voluta are enumerated, revised, and arranged in modern genera. A partial revision of Thais and Zafra is attempted, and various critical species of Arcularia, Montfortia, Tallorbis, and Acmæa are discussed.—L. A. **Cotton**: The diamond-deposits of Copeton, New South Wales. A description of the variations in the Tertiary stream-deposits is given, together with the relations of these to the distribution of the diamonds. The investigation has made clear the relations of the various parts of the Tertiary leads, and, incidentally, has suggested an interesting physiographical feature. It is pointed out that it is highly probable that the Gwydir and Macintyre Rivers of Tertiary times originally formed one stream uniting a little to the west of Inverell. An important discovery was made by Mr. A. R. Pike, in 1904, which has a significant bearing on the origin of the diamond. This was the finding of a diamond in a matrix of dolerite. Later investigation has indicated that it is probable that most, if not all, the diamonds in the field have been derived from this type of rock.—Dr. R. **Greig-Smith**: Contributions to a knowledge of soil-fertility. No. xii.—The action of toluene upon the soil-protozoa. The action of toluene upon the protozoa of the soil depends upon the moisture-content. When less than one-tenth of the water-holding capacity of the soil is present, certain members of the Ciliates, Amœbæ and Flagellates may not be destroyed when amounts up to 20 per cent. of toluene are added to the soil. If more than one-tenth of the water-holding capacity is present, the Ciliates are destroyed by 1 per cent. or 2 per cent. of toluene, while the action upon the Amœbæ and Flagellates is irregular. Conditions which destroy the sulphur-oxidising bacteria, also destroy the Ciliates.—Rev. W. W. **Watts**: Some notes on the ferns of North Queensland. These notes are the result of a trip through the Cairns district, as far south as Bartle Frere and the Russell River, and as far west as the Tully Falls.—Archdeacon F. E. **Haviland**: The pollination of *Goodenia cycloptera*, R. Br. *G. cycloptera*, R. Br., is a decumbent species, in this State, generally restricted to the western plains. The process of pollination, as the result of three years' observation, is described.—A. F. Basset **Hull**: A collection of fossil Polyplacophora from N.W. Tasmania, with descriptions of three new species. In addition to valves of *Lorica duniana*, Hull, and *Chiton fossinus*, Ashby and Torr, the collection studied comprised the remains of three strongly marked species of Loricella, hitherto undescribed. The fossils are from the well-known beds between Wynyard and Table Cape.

A TREATISE ON USEFUL MINERALS AND ROCKS.

The Deposits of the Useful Minerals and Rocks, their Origin, Form, and Content. By Prof. Dr. F. Beyschlag, Prof. J. H. L. Vogt, Prof. D. P. Krusch. Translated by S. J. Truscott. Vol. i. Pp. xxviii+514. (London: Macmillan and Co., Ltd., 1914.) Price 18*s.* net.

THIS book is the English version of the first volume of a comprehensive treatise on useful minerals and rocks by three authors who are collectively well qualified to deal with the subject, both from the scientific and the economic points of view. The work, when complete, will consist of three volumes, two of which, dealing with ore-deposits, have already appeared in German. Its main object is to explain and illustrate by descriptions of individual occurrences the general principles governing the nature and mode of occurrence of the deposits. The authors emphasise the fact, now generally recognised, that a knowledge of the causes which have resulted in the formation and deformation of these deposits is of value to all persons who are engaged in exploiting the mineral resources of the world. Their point of view is thoroughly scientific, and the classification which they adopt is, therefore, primarily based on genetic principles.

Ore deposits are divided into two great groups, to which the terms syngenetic and epigenetic are applied; those of the former originate at the same time as the country rock, those of the latter have been brought into the positions which they now occupy after the country rock had been produced. The syngenetic group includes magmatic segregations and sedimentary deposits. The epigenetic group includes contact-deposits, cavity fillings (including lodes) metasomatic deposits, and impregnations.

Having sketched in broad outline their scheme of classification, the authors deal with the causes which have determined the forms of the different deposits, describing in this connection the general principles of folding, faulting, over-thrusting, and the like. Then follow chapters on the minerals found in ore-deposits, on the various modes of formation of these minerals, on the relative distribution of the elements, with special reference to the metals, and on the origin of ore-deposits. The main causes to which the genesis of ore-deposits is attributed are crystallisation from molten magmas, pneumatolysis, contact-metamorphism, metasomatosis, precipitation from solution, and the mechanical concentration of pre-existing minerals. In dealing with the origin of ore-deposits by crystallisation or precipitation from solution, they practically discard the old, and at one time popular, theory of "lateral secretion," and accept the view that, if we leave out of account the effects of surface action on ore-deposits already formed, the solutions came from below and can in most cases be connected either directly or indirectly with igneous action.

Having dealt with general principles and given a historical sketch of the classifications adopted by different writers from the time of Werner to the present day, the authors proceed to consider the different types of deposit under four heads: (1) magmatic segregations, (2) contact deposits, (3) lodes, irregular cavity fillings, and metasomatic deposits, and (4) ore-beds. About half of the volume under review and the whole of the second volume, which has not yet appeared in English, is devoted to the description of typical occurrences. The first two of the above groups are dealt with in this book together with tin-lodes and quicksilver deposits which belong to the third group. As an illustration of the method of treatment adopted in this portion of the work we may very briefly summarise the account given of the nickel-pyrrhotite group of sulphide ores. These deposits form a widely-distributed and well-marked group. The most important characteristic common to them all is that they occur within, or at the margins of, masses of norite or gabbro. Thus of fifty occurrences in Norway by far the greater number occur in unaltered norite. The most important minerals are nickeliferous pyrrhotite, pyrite, and chalcopyrite. The pyrrhotite usually contains about 2·5 per cent. of nickel with some cobalt. Sometimes the proportion rises to 8 or even 12 per cent., but in such cases the presence of pentlandite, (FeNi)S, can be easily recognised and, owing to recent researches on metallographic lines, it may be regarded as certain that the abnormal percentages of nickel present in certain cases are due to admixed pentlandite; whether, in addition, a smaller nickel and cobalt content enters into the composition of pyrrhotite still remains an open question.

As regards the morphology of the deposits, the authors point out that transitions occur from normal gabbro or norite containing less than 1 per cent. of sulphides to rocks containing 10 or even 30 per cent. Such varieties are termed pyrrhotite-norite, and from these to masses of practically clean sulphides transitions may also be found. From these and many other facts, the authors conclude that the nickel-pyrrhotite deposits are the result of segregation from a basic magma. Having thus dealt with generalities, they proceed

Z

to describe individual occurrences, beginning with the most important of all, that of Sudbury, in the northern portion of Ontario. Their description of the Sudbury mining field is illustrated by a geological map of the area and by a plan and section of one of the important mines. A brief history of mining in the district is given, and the account concludes with a table showing the total production of the field and the average content of nickel and copper in the ore smelted at Sudbury. Then follow briefer descriptions of similar deposits in Norway, Sweden, and other countries.

A special feature of the work is the abundance and excellence of the illustrations. Each section is preceded by a bibliography, and the value of the book as a work of reference is thus greatly increased. Mr. Truscott has done his work so well that in reading the book one is apt to forget that it is a translation.

THE SIDEREAL PROBLEM.

Stellar Movements and the Structure of the Universe. (Macmillan's Science Monographs.) By Prof. A. S. Eddington. Pp. xii+266. (London: Macmillan and Co., Ltd., 1914.) Price 6*s*. net.

THE history of astronomy is in some ways exceptional among the sciences. It is the most laborious of all, and from this fact arises a certain apparent discontinuity. For years the work goes on, and outwardly there is no very conspicuous result beyond the piling up of records the true value of which must often be far from obvious at the time. Naturally, this part of the burden falls largely on the professional astronomer, though we do not forget men like Groombridge, inspired by a faith not always easy to analyse. Sometimes a line of work of evident value, like the attempt to measure the radial velocities of the stars, is prosecuted for years without any positive result before a new way of advance is opened by realising the correct principles of an appropriate instrumental design. Then the stream flows with astonishing rapidity, as the reader of Dr. Campbell's recent work on "Stellar Motions" may see. Even in the absence of a decisive factor of this kind there come times when different lines of inquiry are seen to converge, and with their confluence new points of view and fresh possibilities which affect the course of the science are suddenly opened out.

Such a time seems to have arrived about the beginning of the twentieth century. A large number of proper motions were known with increasing accuracy, the distances of a few stars had been fairly determined. Photometric studies were well advanced, and some progress had been made in the problem, apparently so simple but in reality so difficult, of counting the stars. Some of the cruder notions to be observed in Struve's "Etudes d'Astronomie Stellaire" had been generally discarded. But the prospect of a synthetic treatment of the sidereal problem seemed remote indeed. Prof. Eddington's review of the progress made in the last few years, to which he has himself made notable contributions, is exceedingly welcome. Here the results are stated in the clearest possible way, and the problems which have been solved or which lie before us in the future are defined in precise terms. It is a valuable work which will enable those who have not followed the progress made step by step to realise what has been accomplished, and from which those who have some familiarity with the matters discussed will derive much advantage by seeing the subject treated as a whole.

The scope of the book is in one respect rather severely limited. It is in no sense an historical account of the subject. The references to any investigations made in the course of the last century are merely incidental and exceedingly brief. For this the author himself expresses regret in the preface. To have traced the historic order by which the present situation has been brought about would have been beside the purpose of the work, and might have expanded it unduly. But a clear preliminary statement of what had already been accomplished by the year 1900 in elucidating the structure and tendencies of the stellar universe would have been very valuable. It would have made it possible to do a little more justice to the work of astronomers like Kapteyn, Seeliger and Kobold, and it would have furnished some standard of comparison by which to appreciate the present position.

Of the twelve chapters into which the book is divided the first two describe succinctly the data of observation which constitute the resources for attacking the problem and a general outline of the universe as the author conceives it. A singularly interesting chapter on the nearest stars follows, in which a most skilful use is made of the small sample of information open to discussion. The known examples of that simplest type of stellar motion in which the stars are recognised as possessing a common, uniform movement are next described. This conception originated with Mädler and Proctor, and, reinforced by a knowledge of radial velocities, bids fair to give detailed information, as opposed to merely statistical results, of the most illuminating kind. There is no reason to think that what has been done in this direction is more than a beginning.

After a chapter on the solar motion a full

account of the two-stream theory, based mainly on Prof. Eddington's own researches, is given. The mathematical foundation of this theory and of Schwarzschild's ellipsoidal hypothesis is placed in a separate chapter, an excellent arrangement from the point of view of the general reader. The unmathematical reader must also pass over much of the statistical investigations in chapter x., though to the mathematician the application of the theory of integral equations to statistics will be particularly interesting. Except in these two sections the general reader should have no great difficulty in following the main line of the argument. Other chapters deal with those remarkable phenomena which are associated with the spectral classification of the stars, and which constitute the most significant discoveries in recent astronomy; the difficult problem of counting the stars in the sky according to magnitude, based largely on recent work at Greenwich, but paying perhaps an exaggerated respect to a well-known memoir of Kapteyn; and finally, the attempts which have been made to explain the stellar system in dynamical terms, attempts which seem rather premature in view of our still imperfect knowledge of the kinematical relations.

In conformity with the editorial scheme of the series to which it belongs, the book conveys throughout a strongly personal view, from which at some points the reader may be tempted to differ. But it is on the whole an eminently sane view, and this means much when in the nature of the case provisional judgments alone are possible. Ideas are in a state of flux, and gratitude is due to Prof. Eddington for fixing the phase of the moment in a permanent, accessible form. H. C. P.

THE ENAMELLING INDUSTRY.

The Raw Materials for the Enamel Industry and their Chemical Technology. By Dr. J. Grunwald. Translated by Dr. H. H. Hodgson. Pp. viii + 225. (London: C. Griffin and Co., Ltd., 1914.) Price 8*s*. 6*d*. net.

THE preparation of enamels for the purposes of ornament dates from a very remote period; we find them in use in ancient Egypt and Babylon, although in the earliest known specimens they were used as inlays in the metal objects they adorned, and not melted on them until somewhat later times It is not, however, until the beginning of the nineteenth century that the coating with enamels of iron hollow wares, saucepans, and the like for domestic use was practised, a process that many years afterwards was applied to the enamelling of iron in sheets and plates. The materials dealt with by the author are those employed in the manufacture of enamels for these purposes on a commercial scale.

The economic importance of the industry on the Continent is evident, if we consider that it gives employment in Germany to 25,000, and in Austria-Hungary to 19,000, persons; and a large part of the output finds a market in England.

The appearance of a translation of Dr. Grunwald's book is opportune at the present time, when methods are being discussed for the satisfactory organisation of our industries and the equipment of works, with the object of producing articles which hitherto have largely or entirely been made in other countries.

Its perusal brings forcibly to our notice the part which science has played, and is playing, in the management and control of the processes of the enamelling industry, and that complete success can only be attained by the co-operation of science and practical skill. Much scientific investigation, however, is still needed before certain hindrances to the success of many of the operations of the enameller can be successfully grappled with.

The object of the book is to supply those engaged in enamelling works with an account of the composition, properties, and limitations of use of the various materials employed and of their practical application on a large scale. An exact knowledge of these, it is scarcely necessary to point out, is absolutely essential in order to overcome the difficulties which often arise in works' procedure.

Much of the information contained in the book, it may be said, can be found in works on mineralogy and applied chemistry, but it is so scattered that, for purposes of reference, it is practically inaccessible to the busy worker.

The chief materials dealt with are the felspars, quartz, fluorspar, borax, cryolite, the alkalies, and the various agents for colouring and for giving opacity. The composition and properties of each are given at some length, and the nature of the impurities liable to be present and their effects on the character of the enamels are clearly set forth.

A point of practical importance is emphasised as regards the felspars that, as a rule, it is inadvisable to replace felspar silica by quartz or clay, even although the equivalent proportions are observed. In this connection it is well known that in enamels, as in many other substances, identity in chemical composition is often accompanied by considerable divergence in physical properties.

The author has evidently had considerable practical experience in enamelling, and the remarks appended to the description of each of the materials on their *rôle* and application in works'

procedure, and the chapter on the composition of enamels, are specially valuable.

The accounts given, however, of the preparation of the materials are in a few cases of doubtful value, and in the case of the metallurgy of tin even inexact. It is, too, not obvious what useful purpose can be served by the introduction of the graphic formulæ of the felspars.

These are, however, minor defects. The book is a good one, and the appearance of a translation into English has rendered the industry in this country a valuable service. It should be in the hands of everyone connected with enamelling works. W. G.

NEW BOOKS ON CHEMISTRY.

(1) *Van Nostrand's Chemical Annual*, 1913. Edited by Prof. J. C. Olsen. Pp. xiv+669. (London: Constable and Co., Ltd., 1914.) Price 12*s*. 6*d*. net.

(2) *A Text-book of Chemistry*. By W. A. Noyes. Pp. xv+602. (London: G. Bell and Sons, Ltd., n.d.) Price 8*s*. 6*d*. net.

(3) *The Electrical Conductivity and Ionisation Constants of Organic Compounds*. By Dr. H. Scudder. Pp. 568. (London: Constable and Co., Ltd., 1914.) Price 12*s*. 6*d*. net.

(1) "VAN NOSTRAND'S Chemical Annual for 1913" is arranged on much the same lines as the well-known German "Chemiker Kalendar" of Biedermann. It contains a great number of tables of constants and a vast amount of other information useful to chemists. It is, in short, the kind of reference book which no practical chemist can afford to be without; for the amount of time it must save will soon repay him for its rather high price.

Seeing that the bulk of each annual issue is a mere copy of a former one, it seems as if something could be devised whereby the small amount of new matter and corrections might be published separately without the expense of repurchasing the whole volume. The present issue is embellished with an excellent portrait and a short obituary notice of Prof. Henri Moissan.

(2) A text-book written for beginners is always difficult to appraise at its true value unless one has some notion of the character and extent of the oral and practical teaching which necessarily accompany it. As it stands there is little to find fault with in this volume, either in regard to the arrangement of subjects, the descriptive portion, or the facts, yet unless there is a great deal of amplification we have grave doubts if it could be recommended unreservedly as a satisfactory first text-book. The matter is condensed into short paragraphs dealing with a great variety of topics. We find, for example, in the first hundred pages or thereabouts, in addition to much experimental information, accounts of the ionic theory, equilibrium, reversible reactions, catalysis, valence, the phase rule, the atomic theory, the van 't Hoff-Le Chatelier law, molecular volumes, etc. Even the "quantum theory" is introduced later in a paragraph of fifteen lines, and we have no hesitation in saying that, in so far as it attempts to convey any information, it is so much wasted space.

The book is, in short, a *multum in parvo*, no doubt excellent as a summary of many and divers facts and theories.

We would ask again, as we have frequently done in reviewing other elementary text-books, whether any object is served by introducing at the beginning definitions and generalisations of the nature of which the student has as yet only vague ideas? Is anything substantial to be gained by stating (p. 5) that matter is anything which has mass, or that matter is anything which requires energy to set it in motion, when, on the next page, energy is defined as anything which may set matter in motion?

A great difference is often observed in the attitude of students towards physics and chemistry, and the reason probably is that in the one he is taught to reason logically, because he is made to think logically; in the other he is confronted with phenomena about the nature of which he is rarely encouraged to express his opinion, because he is provided, often unconsciously, with the explanation. The paragraph on elements and compounds (p. 9) affords an illustration. "If the red oxide of mercury is heated in a small tube, metallic mercury will distil, whilst a glowing splinter held at the mouth of the tube will burst into flame. The heat causes the decomposition of the oxide of mercury into mercury and a gas which is called oxygen."

It is a gratuitous assertion that the phenomenon is one of decomposition; why not say with the old phlogistonists that the red powder has combined with something in the air to form the metal and left the oxygen? Until the loss of weight is recognised this explanation is equally logical; but then, of course, if we begin by calling the substance oxide of mercury we merely end by proving what we have tacitly assumed at the outset.

(3) Dr. Scudder's book is a complete bibliography of the ionisation constants of all the organic compounds which have appeared from 1889 to 1910 inclusive, with corrections down to 1913. That the work involved in compiling these tables must have been enormous may be estimated from the author's statement that 78 journals and

5000 separate memoirs have been examined page by page. The substances are arranged in alphabetical order, and are also indexed according to formulæ. The references are indicated by numbers which correspond to the index of authors given at the end of the volume.

The book is well printed on good paper, and is solidly bound in cloth. It is the only complete work on the subject, and will be a valuable addition to English standard books of reference.

J. B. C.

OUR BOOKSHELF.

Boilers, Economisers, and Superheaters: Their Heating Power and Efficiency. By Prof. R. H. Smith. Pp. viii + 128. (London: Crosby Lockwood and Son, 1915.) Price 7*s*. 6*d*. net.

The author's purpose in this book is to provide material whereby the designer of steam boilers may take account of the transmission of heat by radiation from the incandescent fuel and the incandescent parts of the flame in as full and scientific a manner as the data at present available makes possible. It is assumed that combustion is completed within, or close to the surface, of the mass of coal, and that the heat so produced is divided between heating the solid coal and heating the generated gases. This assumption enables the furnace gas temperature to be calculated for various ratios of air actually admitted to the furnace to the air required by chemical theory, and for various heating values of the fuel. The result indicates that the temperature depends almost solely upon the air ratio, and to a minute degree only upon the heating value of the coal. The heat given up by the gases passing along the flues is then dealt with and similar calculations are given for economisers; applications to superheaters form the subject of a separate chapter. The laws of heat transmission in boilers are too complex for ready use in engineering drawing offices, and the author has reduced these laws to the form of diagrams. It is unfortunate that these diagrams, while showing the way in which the quantities involved vary, are reproduced to a scale too small to be read accurately; the reader interested in boiler design is invited to purchase copies of the original large-scale diagrams. There is a great deal of interesting and useful matter in the book, but it is not presented in a very readable form, and the practical designer is likely to consult the diagrams much more frequently than he will refer to the text.

Through the Grand Canyon from Wyoming to Mexico. By E. L. Kolb. Pp. xix + 344. (New York: The Macmillan Co; London: Macmillan and Co., Ltd., 1914.) Price 8*s*. 6*d*. net.

This is a graphic but unassuming account of one of the very few successful descents through the country of the Grand Canyon by boat from end to end. For European readers it should have contained a map, to ensure the appreciation of the vast distances involved and the remoteness from civilisation of the plateau-heights on either hand. Anyone who has travelled along gorges, such as the Bosnian canyon of the Vrbas, will realise the effect of a sudden contact with the outer world, where some trail descends by a gentler part of the valley-side, finds a passage across the river, and climbs again to the upper air. Such episodes, leading to the visiting of ranches where pioneers and outlaws still lead unhampered lives, broke the long series of hazards which the fearless author and his brother set before themselves. No two of the cataracts are alike, and the tale is so well told that the reader feels himself limited by rock-walls 4000 ft. in height; he sees the huge fallen blocks that seem to bar the passage, the spray rising from some swift descent ahead, the fierceness of which cannot yet be adequately gauged; he feels the whirl of the water round him in the rapids, where the boat twists like a porpoise in green waves; and at the end, among the sand-bars and marshes close to Needles, after a hundred-and-one days of travel, he takes leave of his guides with a genuine and affectionate regret.

The brothers Kolb are professional photographers, as the fine illustrations in this book so amply testify. The famous journey of J. W. Powell in 1869 is, of course, fully acknowledged, and references are given to Stanton, Galloway, Stone, and to the nameless trappers or prospectors who are known to us only by shattered boats or bleaching skeletons in the gorge. The geological study of the district has aptly influenced Mr. Kolb's descriptions, and seldom has a great adventure, carried out with skilled endurance, been told so simply and with so fine an absence of self-regard. Grenville A. J. Cole.

Pumping by Compressed Air. By E. M. Ivens. Pp. vi + 244. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 12*s*. 6*d*. net.

In compiling this book the author has had the advantage of being able to draw on considerable practical experience derived from installing and testing air lifts operating under a wide range of conditions. Very good and clear descriptions are given of various types of displacement pumps, return air systems, air lifts, and pumping systems generally. Of particular interest are the sections dealing with the air lift. In this system a long vertical pipe is led down the well, and has an open mouth near the bottom and under the water-level, so that normally the water stands at a considerable height inside the pipe. Compressed air is led down the well by a separate pipe, and is discharged through suitably shaped orifices into the first-mentioned pipe at a point well below normal water-level. The ascending bubbles of air cause an upward flow of water, which is finally discharged into a tank at or above ground-level. The theories of Harris and of Lorenz regarding the action in air lifts will be found in the book, together with much matter of practical interest. The practical treatment is good, and forms a

useful addition to a subject the literature of which is not extensive.

In dealing with the more theoretical matters concerning the laws of expansion and compression of gases the author is not so fortunate, and there are a number of loose and careless statements. Thus on p. 160 we find Boyle's law stated as follows: At constant temperature the volume of gas is proportional to the absolute pressure. The author is not unaware of the fact that the volume is inversely proportional to the absolute pressure, but this and other similar careless statements of facts mar an otherwise good and useful volume, and call for a thorough revision for the second edition.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Electrical Notation.

SIR JOSEPH LARMOR'S letter in NATURE of January 21 (p. 561) reminds me that I have long wished to protest against the misuse of alphabetical symbols to designate the names of units. The word *ohm*, for instance, ought not to be abbreviated to ω; and the apparently authoritative suggestion now made that other names shall be written in the same sort of unreadable and worrying shorthand is essentially, though not superficially, illiterate as well as utterly unmathematical.

The *naming* of units has been conspicuously useful; the consumption of much-needed and already overworked symbols as substitutes for names is a wasteful practice which should be resisted among physicists, and be only tolerated in microscopy for purely biological use.

OLIVER LODGE.

University of Birmingham, January 23.

Mendelism in the Seventeenth Century.

THE Mendelian revival of breeding has brought to light many interesting facts concerning the inheritance of coat-colour in rabbits. From the work of Hurst, Castle, Punnett, and others, it is now known that when the wild "grey" or "agouti" rabbit is mated with white, black, or "blue" specimens, the offspring produced all display the colour of their wild parent. Although this is doubtless well known at the present day, it is, I believe, not generally known that these facts had been ascertained by rabbit-fanciers in Holland in the seventeenth century, and were put on record by the illustrious Leeuwenhoek in 1683.

In a letter from Leeuwenhoek to the Royal Society, addressed to Sir Christopher Wren, and dated July 26, 1683, the following remarkable passage occurs:—

"Multi nostratium civium alunt cuniculos, cum ad voluptatem, tum ob lucrum: suntque hi cuniculi plerumque magni atque albi, auribus praelongis donati, quod pulchritudinis loco ducunt. Ut vero hi cuniculi in lucem edant pullos grisei sive cinerei coloris, qualis est sylvestrium, utque pro his possint verno tempore vendi, foemellae albae marem griseum ac sylvestrem ex tumulis arenarum petitum, ubi omnes grisei coloris sunt, sociant: atque tales masculos intense griseos committunt non tantum cum albis, sed & versicoloribus, nigris, caeruleis foemellis: Ex quibus tamen quicquid procreatur, colorem patris refert; ut nunquam etiam observatus sit ullus ex tali jugatione productus cuniculus, qui fuerit capillo albo, aut alio quam griseo. Praeterea tales nunquam attingunt magnitudinem matris, neque aures acquirunt praelongas, neque pro matris natura plane cicurantur ac mansuefiunt, sed retinent semper aliquid ferocioris ferinaeque naturae ac indolis."

The letter will be found in the so-called "Opera Omnia" of Leeuwenhoek (Lugd. Batav., 4 vols., 1722). Owing to the confusing arrangement and pagination in this work—which consists of a number of separate sections, published at different dates, each with its own pagination—it is not easy to give an exact reference to a particular passage. In the copy of the "Opera Omnia" which I have consulted, the letter occurs on p. 49 (first pagination) of vol i. ("Anatomia et Contemplationes"), under the title, "De generatione Ranarum," etc. The passage in question begins at the foot of the following p. 53.

I may add that the letter is not to be found in Samuel Hoole's English edition of Leeuwenhoek's "Select Works" (London, 2 vols., 1798, 1807). This translator expurgated all Leeuwenhoek's letters dealing with spermatozoa. He calls them "Disquisitions of a peculiar kind, which to many Readers might be offensive."

Feeling some doubt as to the colour or marking which "*versicolor*" is intended to denote, I compared the Latin letter with an English version which was published under the title, "*An Abstract of a Letter from* Mr. Anthony Leeuwenhoeck *of* Delft *about Generation by an* Animalcule *of the Male Seed*, etc.," in the *Philosophical Transactions* of the Royal Society, vol. xiii. (xii.), p. 347, 1683. Both Latin and English versions are translations from the Dutch: for Leeuwenhoek could write no language but his own. In the English version, which is somewhat differently worded from the Latin, the words "*versicoloribus, nigris, caeruleis*" are rendered "Blew, Black, and Pyed." "*Versicolor*" evidently denotes some kind of piebald marking; though it probably does not mean—as one might perhaps conclude—the modern "Dutch" pattern. This, Prof. Punnett tells me, is of comparatively recent introduction, and has superseded an earlier or "original Dutch" marking which "has less white and has practically dropped out of the fancy."

It is clear from Leeuwenhoek's words that the Dutch rabbit-fanciers had, as early as 1683, discovered that the offspring produced by mating wild "grey" buck rabbits with tame long-eared white, black, blue, or piebald does, are always exclusively grey in colour; and that they are sufficiently like the wild rabbit in other respects also for them to be marketable as such.

Leeuwenhoek's statement that the hybrids produced by crossing piebald with wild rabbits are invariably "grey" in colour—without any white—seems open to question. Recent experiments have not yet solved the problems of the inheritance of pied patterns in rabbits. Prof. Punnett, who has been studying the matter for some years, tells me that when wild rabbits are crossed with modern Dutch, "the F_1 animals may be, though rarely, completely self-coloured. Generally they have a little white. The amount of this varies, but never approaches the amount found in the Dutch."

The statement that the progeny of long-eared tame doe-rabbits and wild males never possess such long ears as their mothers, appears to have been confirmed by Castle. "He crossed the long-eared lop rabbit with ordinary short-eared individuals. F_1 had ears of intermediate length" (Bateson, "Mendel's Principles of Heredity," 1909, p. 251). I do not know of any confirmation or contradiction of Leeuwenhoek's final

assertion that the offspring of wild males and tame females tend to manifest the wild temper of their fathers.

It seems remarkable that nobody—so far as I am aware—has hitherto directed attention to the passage which I have quoted above. It occurs incidentally in a letter which described such novelties as the spermatozoa and red blood-corpuscles of the frog, and the ciliate Protozoa parasitic in the frog's intestine. But it is perhaps even more remarkable that neither Leeuwenhoek at the time, nor anybody else for some two hundred years subsequently, perceived the importance of such observations as the rabbit-fanciers of Holland had made. Leeuwenhoek was, of course, an "animalculist": and he cites the case of the rabbits to confute "*non nemo Doctorum*"—evidently an "ovist"—and to "bring a sufficient proof of the fruits coming from the *Male seed*, and the *females* only contributing to the nourishment and growth of it."

Leeuwenhoek's remarks evidently do not constitute the earliest known reference to rabbit breeding. For Darwin ("Animals and Plants," chapter iv.) gives earlier references to Gervaise Markham (1631), and Aldrovandi (1637), which show that several kinds of rabbit were already kept and bred at the beginning of the seventeenth century. Nevertheless, the passage which I have quoted above is, perhaps, the earliest exact account—based upon experiment—of the inheritance of any character in any animal or plant; and as such I think it is worthy of record.

I am indebted to my friend, Prof. R. C. Punnett, F.R.S., for information on certain matters mentioned in this letter; and I would refer the reader interested in the subject to his important paper, "Inheritance of Coat-Colour in Rabbits," published in the *Journal of Genetics*, vol. ii., No. 3, 1913, for further facts.

CLIFFORD DOBELL.

Imperial College of Science, South Kensington, London, S.W., January 15.

Books for Belgian Students.

WE are gradually building up a little Belgian University here for students who, for one reason or another, cannot go to the front, and for professors who are past the age of serving. Altogether we have between one hundred and two hundred students, and some fifteen to twenty professors.

Last term we were able to establish effective teaching in four faculties, and this term we have increased the number to six. In the faculty of medicine we are in need of copies of some standard text-book on human anatomy—preferably Gray's.

This University has already found several thousand pounds to support our guests, and will have to find several thousands more to keep things going until next June. Consequently we have to husband our resources very carefully, and cannot afford to purchase such expensive text-books as Gray's "Human Anatomy."

It may be that your readers have copies of this work lying unused on their shelves. If this is so, I should be grateful if they would send them to me for the use of these students. At present ten or a dozen copies would suffice.

A. E. SHIPLEY.

Christ's College Lodge, Cambridge, January 25.

An Unexplained Laboratory Explosion.

I SHALL be glad if any of your readers can give me an explanation of the following occurrence.

Owing to the fact that we are somewhat out of the way here, and, in consequence, fresh bleaching powder is difficult to obtain, I have found it necessary, when demonstrating the formation of chloroform, to find some method other than the usual treatment of alcohol with bleaching powder.

With this object, a few days ago I prepared a mixture of 60 grams of slaked lime with 400 c.c. of cold water and 40 c.c. of alcohol. The mixture was placed in a 2000 c.c. flask, through the cork of which a long tube conducted chlorine to the bottom of the liquid. Through the cork also went another short tube connected to a condenser.

Chlorine had been passing into the liquid fairly quickly for about twenty minutes, and the contents of the flask had warmed up to perhaps 50° C., when a slight smell of chlorine became evident at the end of the condenser, together with a small amount of white fumes; but inside the big flask, except for the slight rise of temperature, there was no evidence of chemical action. Suddenly, with no warning whatever, the whole apparatus blew up; I might almost say detonated, as there was not a piece bigger than a sixpence left, either of the flask, the condenser, or the small flask put to catch the distillate when it should arrive.

Owing perhaps to the violence of the explosion, I got off with a few scratches on my face. My clothes were cut by pieces of glass, however, and the fragments were scattered for at least six yards all round. There was no odour, either of chloroform or anything else, apparent; only that of the chlorine from the generating flask, which, curiously enough, had escaped injury. The whole delivery tube was intact, and also the exit tube from the big flask, the neck of which, with the cork, was left sticking in the clamp, so that I was able to be sure that the trouble was not due to a blocking up of the exit.

Demonstration of Strain-hardening of Steel.

THE accompanying photograph (Fig. 1) represents the side of a steel bar. The bar was first marked by a punch in the way shown, and the punch marks were afterwards completely filed out. The side was then polished and the bar pulled in a testing machine beyond the elastic limit of the material. The polished surface was gradually destroyed everywhere except just under the punch marks, where the overstrained

FIG. 1.

material retained its polish and the marks again became evident. In the strained bar the marks remain distinctly raised above the rest of the surface. A similar experiment was made with a shorter bar that was afterwards subjected to compression along its length. Again the punch marks became clearly visible, but this time they remained as polished depressions instead of raised surfaces.

BY-PATHS IN NATURAL HISTORY.

(1) THE aim of Mr. Dugmore's copiously-illustrated book is not only to portray the beaver as a living piece of Nature's marvellous work, but also to explain how the harmless little creature can justify its existence before man, and how it has established its claims to consideration at the hands of civilised humanity and to that legal protection from the State which has been so grudgingly accorded to it. It may at once be said that in every particular, except that for which the bookbinder is responsible, the volume is a success.

The author begins by describing in the fullest detail the working habits of the beaver; its doings as a woodcutter, an architect, and a roadmaker, and most of all as a skilled constructor of dams, canals, and other works for the control of waterways. Here the author has a good deal to say about the unknowable psychological influences that lie behind all these wonderful operations—the selection and preparation of trees for felling, the clearing of the road beforehand, and the nice carpenter's calculations afterwards, the hydrographic survey work, the neat appreciation of the essentials of hydrostatics, the management o floating bodies, the utilisation of currents anc backflows, etc. Is it all instinct, or is some of i fore-knowledge, and conscious anticipation o results? "Where is the way where ligh dwelleth?" It is unprofitable to discuss insolubl problems, but while it is reasonable to believe tha the animal, however subject to innate impulses must also make inferences in the same way a man does, it is extravagant to suppose that i has a perfect understanding of its doings—that i formulates its experiences and reflects upon thei practical application.

Another chapter deals with the life-history of th animal—its birth and growth, its family and socia relations, and the ordinary vicissitudes of its existence.

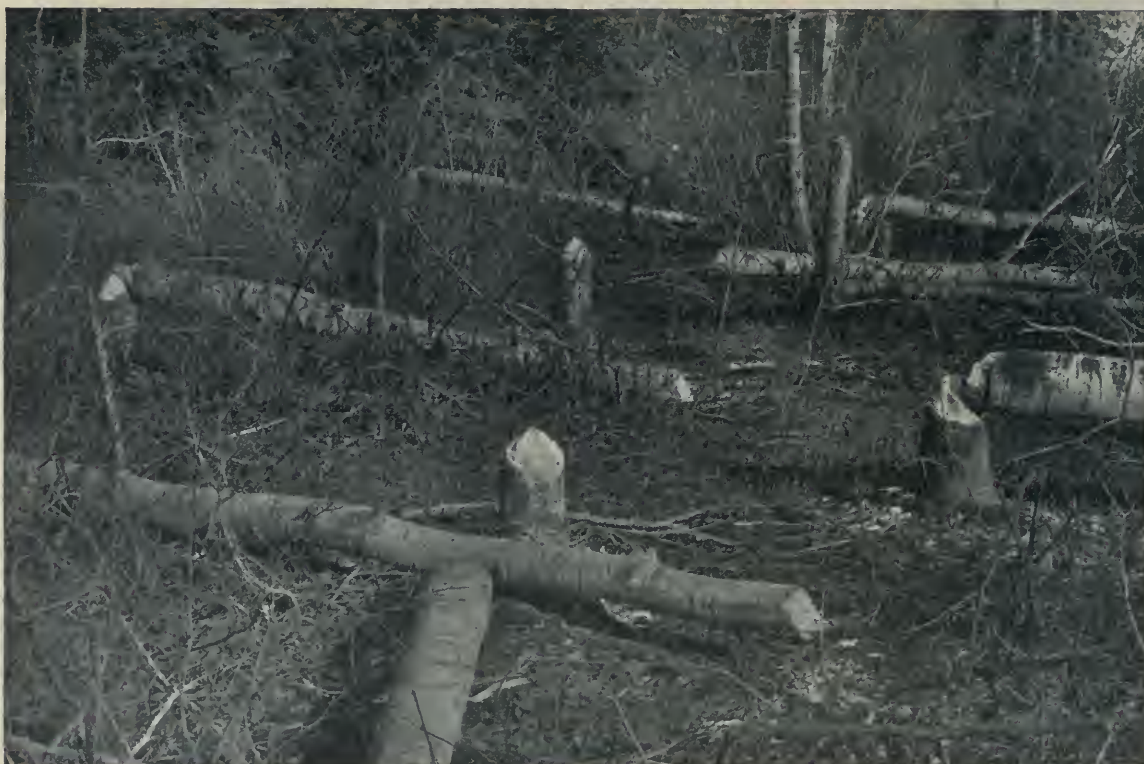

Photo.] [*A. R. Dugmore.*

Part of a poplar grove which was completely cut down by a small colony of beaver. It will be seen that the trunks are entirely stripped of their branches, which were carried away to the storage pile. From "The Romance of the Beaver." (Heinemann.)

A third section treats of the beaver as an agen in modifying the face of the earth, in particula by converting insignificant streams into chains o ponds and lakes. Such reservoirs, so long as th beavers are there to attend to the dams, bring i their train many benefits and conveniences, direc and indirect; and after the animals have disap peared may become rich alluvial flats, the best c tillage for man. On these and other good grounc the author ardently advocates the protection c the beaver by statute, notwithstanding the fa that it does a certain amount of damage to timb —mainly, however, of inferior kinds. His gener remarks upon the protection of wild animals a

particularly opportune at a time when, in the name of the beneficent goddess Hygeia, people who ignore the marvellous interdependence of all the specific parts of the organic world, are proposing to exterminate blindly large elements of the mammalian fauna of great tracts of country in Africa.

(2) To entitle these promiscuous sketches "bird biographies" seems at first sight rather to take bird-bolts for cannon-bullets, until one considers the illustrations, and attempts to realise the time and labour, and the prodigious patience, to say nothing of the numerous kinds of technical aptitude, that they represent. These illustrations are the feature of the book, and they do equal credit to the skill and the taste of the author and his assistant; all the familiar British birds are here, from the ousel cock so black of hue to the wren with little quill, as well as many that are not so familiar, as the buzzard, the raven, the grey goose, the grebe, and the dipper. The admirable series that portrays the seven ages (more or less) of the buzzard are quite perfect.

In their literary and other aspects the sketches are simple, careful, and unlaboured, and are replete in observation and information at first hand.

(3) Of this little volume about half is concerned with animals, and the rest with "other matters" relating to India—stories woven round familiar Indian types, sketches of social and ethnological and philological interest, brief flights to the borderland of politics and economics, etc.

A charming little essay on the coconut-tree may be selected as illustrating to perfection not only the author's happy knack of finding tongues in trees and good in everything, but also the quickness and diversity of his fancy and his easy grace of expression. Here, starting from a familiar commodity of the sweet-shop, he suggests an Oriental sea-shore with its background of palms swaying in the salt-laden breeze, and, like the old traveller Ludovico di Varthema, tells in a few significant words how *Cocos nucifera* is still the tree of life to the village communities that dwell beneath its kindly shade, bringing from the wonderful earth unfailing gifts of food, oil, wine, fuel, timber, and fibre for spinning, besides building-material and domestic utensils almost ready-made. In an age of mechanical crafts, so confident of its "progress" as to forget that a polity not surely rooted in agriculture is at its best an interesting pathological specimen and at its worst an unholy chaos, it is a joy indeed to find a popular writer who can reveal so clearly the paraphernalia of a modest civilisation issuing so readily from one benign tree. After the same fashion the author hangs upon the betel-nut-palm and other common natural objects piquant discourses, full of sage hints and quaint diversions, on social and ceremonial attitudes characteristic of the East. On the other hand the essay on Indian poverty goes, but with the same humane touch, into the etiology of certain prevalent diseases of the body

Kingfisher outside her nesting hole. From "Bird Biographies and other Bird Sketches."

politic, and criticises with severity but without rancour the arrogance of the complacent zealots who aspire to cure them.

The essays on animals are full of humorous suggestions. The best are those which recount the author's own observations and reflections upon living creatures, although those in which by an ingenious blend of adroit jest and teleological version of fact the author—ably supported by the

artist—brings out chiefly the comical aspects of animal life may, perhaps, be more appreciated by the general reader.

A chapter on cures for snake-bite is intended to illustrate the play of vernacular superstition rather than to explain the rational basis of European methods of treatment, but since the history of acquired immunity to snake-poison and of the attendant discovery of antivenine is outlined, it is a pity, perhaps, that the names of Sewall and Calmette were not mentioned among the great original *dramatis personae*.

THE NEW ISSUE OF THE BRITISH PHARMACOPŒIA.

THE publication of a new issue of the British Pharmacopœia is an event of considerable importance to the medical as well as to the pharmaceutical world. It reflects, so far as is compatible with official recognition, the changes that have taken place in the opinion of physicians as to what drugs and preparations are of sufficient importance to be included in it, and the opinion of pharmacists as to how such drugs are to be defined and such preparations of them to be made. Though the Medical Act of 1858 requires that the General Medical Council shall cause the British Pharmacopœia to be published, it is well known that the labour of revision, in so far as it relates to the monographs and appendices in the work, has been carried out, practically in its entirety, by the Committee of Reference in Pharmacy to which somewhat scanty acknowledgment is made in the preface. That to pharmacists alone this most responsible part of the revision can safely be entrusted has long been officially recognised in most countries in which a pharmacopœia is published, and the opinion has been freely expressed that the time has now arrived when British pharmacists should occupy a more satisfactory position in the revision of future issues of the British Pharmacopœia.

Such of the articles and preparations of the Indian and Colonial Addendum of 1900 as were deserving of retention have now been embodied in the text, but it is observable that a large proportion has been dropped; of those retained the following alone are used to some extent in this country: couch grass, arnica flowers, black catechu, cotton-root bark, grindelia, ghatti gum, rhizome and resin of Indian podophyllum, and black haw bark.

The additions to the Pharmacopœia are not numerous, there being only forty-three. The most important of these are acetone, acetylsalicylic acid, picric acid, adrenalin, barbitone (diethylbarbituric acid, also known as veronal), benzamine lactate (beta-eucaine lactate), calcium lactate, cantharidin, chloral formamide, cresol, diamorphine hydrochloride (diacetylmorphine hydrochloride), ethyl chloride, guaiacol, guaiacol carbonate, hexamine (hexamethylenetetramine), ipomoea root (the so-called Mexican scammony root from which scammony resin may now be obtained), solution of adrenalin hydrochloride, solution of formaldehyde, solution of formaldehyde with soap, methyl salicylate, methylsulphonal, phenolphthalein, resorcin, acid sodium phosphate, strontium bromide, and theobromine and sodium salicylate (diuretin). The number of new synthetic drugs is therefore remarkably small, and affords an indication of the opinion of the medical profession of the permanent value of the host of such remedies that have been introduced during recent years.

The omissions, 166, are far more numerous, the following being the most important of the drugs discarded: arnica rhizome, bismuth oxide, gamboge, cantharis (now replaced by cantharidin), coca leaves (now replaced by cocaine and its hydrochloride), saffron, galbanum, jaborandi leaves (now replaced by pilocarpine nitrate), hops, mezereon bark, calabar beans (now replaced by physostigmine sulphate), elder flowers, sarsaparilla, scammony and mustard. As a general rule the preparations of discarded drugs have also been omitted; of other preparations reference may be made to the class of concentrated liquors, all of which have been deleted.

Alterations in strength are not numerous, nor are they, with a few exceptions, important; many of them have been necessitated by the endeavour to comply with the recommendations of the Brussels International Conference, an endeavour which has for practical purposes been effectively accomplished. The greatest change has been in tincture of strophanthus, which is now four times as strong as it used to be, and the most far-reaching that of tincture of opium, which has been increased in strength by one-third.

Perhaps the most conspicuous change in the Pharmacopœia is the omission (except from the doses) of all imperial weights and measures. The dual system of the issue of 1898, which was a constant source of trouble, has therefore been abolished, and the formulæ are in general now arranged to produce 100 or 1000 parts by weight or volume. The percentage composition is thus evident at a glance, and considering the present extensive use of metric weights and measures no inconvenience should arise from the change. The use of the term "millilitre" instead of "cubic centimetre," appears strange at first, but it must be admitted that the millilitre, though not in general use, is the more strictly correct designation. "Mil," "decimil," and "centimil," convenient contractions that have been recognised by the Board of Trade, are used in stating the doses. A "drop" is no longer a vague and variable quantity; in accordance with the International Agreement the external diameter of the dropping tube is to be exactly 3 millimetres, 20 such drops of water at 15° being equivalent to 1 millilitre.

Volumetric solutions are now designated as N/1, N/10, etc., in agreement with common usage. The directions for preparing these solutions have been omitted from the appendices, the statement only of the strength corresponding to the designation being made. No fewer than twenty-five volumetric solutions are employed in

the present Pharmacopœia as compared with eight in the last. Temperatures are expressed in degrees centigrade, and the atomic weights adopted are those agreed upon for 1914 by the International Committee.

When the monographs are scrutinised it is seen that scarcely any have escaped alteration of some kind, and that most have been notably improved. The verbosity of the last Pharmacopœia has been replaced by a terseness that is sometimes almost harsh. Whenever possible the monograph contains in the first few lines a definite statement of the minimum permissible percentage of pure substance, alkaloid, etc., and a means is given by which this may be ascertained. Particular attention is devoted to the proportion of those dangerous impurities, lead and arsenic, that may not be exceeded. No fewer that fifty-six such lead and ninety-one arsenic limits have thus been introduced; the methods for determining them are given in the appendices, and are those originally introduced by Mr. C. A. Hill and now in general use in pharmaceutical laboratories.

The monographs for the volatile oils, fixed oils, fats, etc., have also undergone thorough revision. In most of them the limits of specific gravity, optical rotation, and refractive index are stated; determinations of acid value, saponification value, iodine value, ester content, and alcohol content are frequently given, in addition to which the assay for a particular constituent, such as cineol, cinnamic aldehyde, etc., is also introduced where desirable.

The monographs of crude drugs and galenical preparations have undergone a similar thorough revision. In the former the most conspicuous change has been the extension of the microscopical characters; these are fully described whenever the information is important for the identification of the drug, and in many cases the microscopical characters of the powder are also given. The principle of standardisation has been extended, and the assay processes of the last Pharmacopœia have been revised in the light of recent investigations.

Allusion has been already made to some of the additions and alterations in the appendices. The articles and reagents used in chemical testing are, with few exceptions, defined as those "of the British Pharmacopœia" or "of commerce, pure." Appendix xvii. consists of a list of abbreviated Latin names introduced as the result of a communication from the chairman of the United States Pharmacopœial Convention; this is a distinctly novel feature. No suggestion is made that either pharmacists or physicians should employ these abbreviations, and it remains to be seen whether the introduction will have any practical value.

Looking at the Pharmacopœia as a whole, it is evident that the general principle on which the revision has been carried out has been that of substituting practical for theoretical or academical standards. Many of the methods adopted have already been subjected to prolonged trial in pharmaceutical laboratories, and the limits fixed are those which have been found to be practically attainable. The reports that have from time to time been issued show that most of the suggestions and data for these improvements have emanated from the Committee of Reference in Pharmacy, and to this body full credit should be given for the revision it has accomplished successfully.

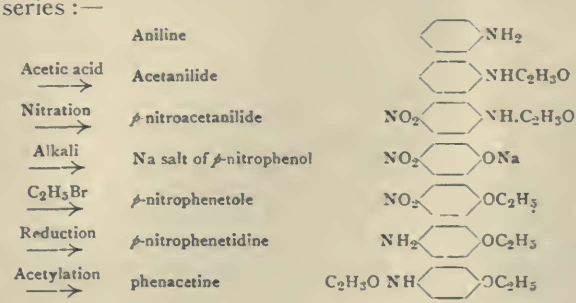
SYNTHETIC DRUGS IN GREAT BRITAIN.

At the commencement of the war, the sudden cessation of all supplies of synthetic drugs from German sources rendered it probable that the stocks in hand in this country would not be sufficient to meet the demand until such time as the English manufacturers could adapt themselves to the altered conditions. Early in September, therefore, the Admiralty asked the Imperial College of Science and Technology to prepare for them 30 lb. of phenacetine, 50 lb. of hexamethylenetetramine, and $1\frac{1}{2}$ lb. of β-eucaine. For the past five months the staff and research students of the Organic Department of the college have been engaged in carrying out this request, with the result that the required quantities have now been forwarded to the Naval Hospitals at Haslar, Chatham, and Plymouth.

With the exception of salvarsan, which is being made by Messrs. Borroughs and Wellcome, and aspirin, which is now being made by Messrs. Boots, Ltd., no synthetic drugs have been manufactured previously in this country. As regards drugs from natural sources, however, it is probable that English firms have always produced very much more than the German firms.

PHENACETINE is a product of the Baeyer firm at Elberfeld and has never been made before in this country. It is probable that all the phenacetine in commerce emanates from this firm, although it is understood that the immediate needs of this country are now being met by the importation of considerable quantities of this drug from the United States of America.

After numerous experiments, the method found most suitable to the conditions prevailing in a scientific laboratory was that shown by the series:—

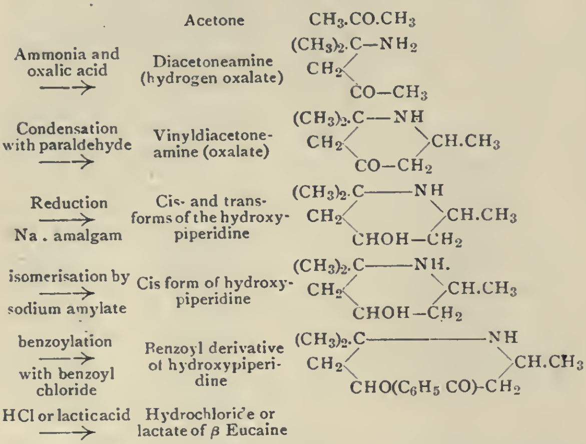


The various operations were so arranged that ultimately $1\frac{1}{2}$ lb. of pure phenacetine were prepared daily, the by-products being recovered and used again.

HEXAMETHYLENETETRAMINE.—The preparation

of this drug is a comparatively simple matter, involving the treatment of a solution of formaldehyde with ammonia. It is understood that the compound is now being prepared in considerable quantities in this country.

β-EUCAINE, which is an important local anæsthetic, has not been prepared in England hitherto, and there is apparently very great difficulty in obtaining any of it for medicinal use. The preparation of the drug is a long and tedious process, and many initial difficulties had to be overcome before the correct conditions were found. Ultimately the following general scheme was worked out, and found to give satisfactory results:—



It should be added that the cost of the materials used in these preparations was defrayed by the Imperial College, and that the services of the workers were given gratis. J. F. THORPE.

NOTES.

AT the anniversary meeting of the Royal Astronomical Society, to be held on February 12, the question of the admission of women will again be brought forward; and it will be proposed that the council take all necessary steps to render their election possible. Whatever arguments may, from selfish motives, be used against the admission of women to membership of professional corporations, no logical reason can be found for excluding women from societies which exist purely for the advancement of scientific knowledge. In astronomy women have shown aptitude for observation and exceptional powers of description. So long ago as 1828 the Royal Astronomical Society awarded its gold medal to Caroline Herschel for the help she had given her brother (her work as an original discoverer was overlooked at that time); and the society has already two lady honorary members, namely, Lady Huggins, elected in 1903, and Miss A. J. Cannon, of Harvard College Observatory, elected last year. Other well-known names of women who have done notable work for astronomy are Mrs. Somerville, Mrs. Roberts (Mdme. Klumpke), Miss Agnes M. Clerke, Mrs. Maunder, and Mdme. E. Chandon (Paris Observatory). Women have for some time attended meetings of the Royal Astronomical Society by invitation of the council; and the society should now take the further step of converting the favour to a right. Among the scientific societies in which this equality of sexes exists already are the Royal Anthropological Institute, British Astronomical Association, Institute of Chemistry, Entomological Society, Geologists' Association, Linnean Society, London Mathematical Society, Royal Meteorological Society, Royal Microscopical Society, Physical Society, Röntgen Society, Royal Geographical Society, Royal Society of Arts, Royal Statistical Society, and the Zoological Society. The Royal Astronomical Society will thus be in good company if it decides that the time has come for the removal of the barriers by which women have been denied the privilege of being proposed for fellowship on equal terms with men.

DR. J. A. MURRAY has been appointed acting director of the Imperial Cancer Research Fund.

LORD FISHER OF KILVERSTONE and Vice-Admiral Sir Edmond J. W. Slade have been elected honorary members of the Institution of Petroleum Technologists.

IT is with much regret that we have to announce the death on Saturday, January 23, after a brief illness, of Mr. F. W. Rudler, for many years curator of the Museum of Practical Geology at Jermyn Street.

IT is announced in the issue of *Science* for January 15 that the Rockefeller Institute for Medical Research will receive 40,000*l.* under the will of the late Mr. Henry Rutherford, for cancer research work.

PROF. ARTHUR KEITH has been granted leave of absence for six weeks by the Royal College of Surgeons for the purpose of delivering a course of five lectures on anthropology at the Western Research University, Cleveland, Ohio.

THE anniversary of the birth of Sir Francis Galton, Tuesday, February 16, will be celebrated as usual by a dinner and lecture. This year Prof. J. Arthur Thomson has undertaken to deliver an address dealing with some aspects of war and eugenics.

THE annual meetings of the Institution of Naval Architects will be held on Wednesday, March 24, and the following day, in the hall of the Royal Society of Arts, John Street, Adelphi, W.C. The Marquis of Bristol, R.N., president, will occupy the chair.

WE learn with regret through a message received from the council of the Imperial Society of Naturalists, Moscow, of the death, at sixty-eight years of age, of Dr. Nicolas Oumoff, president of the society, and professor of physics in the Imperial University of Moscow.

THE gold medal of the Royal Astronomical Society has been awarded by the council to Prof. A. Fowler for his spectroscopic investigations of sun-spots, stars, and comets, and for his successful interpretation of cosmic phenomena by means of experiments in the laboratory. The presentation of the medal will be made at the annual general meeting of the society on February 12.

Dr. Tokutaro Ito, of Tokyo, has written to Lady Hooker to inform her that her distinguished husband—the late Sir Joseph Dalton Hooker—"has been recently selected by the contemporaries in Japan, as one of the twenty-nine heroes of the world that modern time has produced." We wrote to Dr. Ito a few weeks ago to ask for a copy of the complete list of men thus selected, and hope to be able to give the names before long.

The Second Indian Science Congress, organised by the Asiatic Society of Bengal, was held at the Presidency College, Madras, on January 14–16, under the presidency of Surgeon-General W. B. Bannerman. The sections of the Congress, and their chairmen, were as follows:—Agriculture and applied science, Dr. H. H. Mann; physics, Mr. C. V. Raman; chemistry, Prof. P. C. Ray; zoology, Dr. N. Annandale; botany, Dr. C. A. Barber; ethnography, Mr. H. V. Nanjundayya; geology, Dr. W. F. Smeeth.

The Institute of Industry and Commerce informs us that a committee representing chemical manufacturers and scientific societies has been decided upon and that a meeting of all concerned has been convened and will meet this week, at the offices of the institute, Exhibition Buildings, Aldwych Site, Strand, W.C., to consider the present situation. Chemical manufacturers who are interested can obtain permission to attend the meeting by making application to the secretary at the above address.

The rumoured death on the field of battle of Robert Douvillé is confirmed by a note in the *Revue critique de Paléozoologie* just received. The young *chef des travaux* at the Ecole des Mines had published a series of valuable studies on ammonites, of particular interest from his attempt to explain their phenomena of descent with modification on the principles of advanced biological theory. His colleagues in this country will feel much sympathy with his distinguished father, Prof. Henri Douvillé, and will lament a great loss to the science of palæontology.

At the annual general meeting of the Royal Meteorological Society, held on January 20, the council, in its report, referred to the various investigations and work carried on by the society, including the researches in the upper atmosphere, the collection and discussion of phonological observations, the arrangements for the preparation of a climatological atlas of the British Isles, and the delivery of popular lectures on meteorology. Capt. H. G. Lyons was elected president, and Mr. F. Campbell Bayard and Commander W. F. Caborne secretaries, for the ensuing year. The new members of council are:—Mr. J. S. Dines, Mr. A. P. Jenkin, and Sir J. W. Moore.

A meeting of the General Organising Committee for the International Botanical Congress, which had been arranged to be held in London next May, took place at the Linnean Society's rooms on Thursday last, January 21. A report was given of the work of preparation which had already been carried out by the executive committee, and the members were asked to consider the present position. The two following resolutions were carried:—(1) That the congress be not held in 1915; (2) that the present executive committee continue to act so long as necessary. The committee was strongly of opinion that a meeting of the congress in London should not be abandoned, and the suggestion was made that it might take place at the next quinquennium, in 1920. But it was agreed that nothing definite could be settled at the present time, and the following resolution was passed:—"That the executive committee be authorised to convoke a meeting of the general committee at some future date to consider the date of the congress." It was also decided that in the meantime the general committee be called together once a year.

From a letter received by Messrs. L. and H. Hagenbeck, of Hamburg, from Dr. Bultikofer, director of the Rotterdam Zoological Garden, and published in *Science* of January 15, we learn the following news relating to the Antwerp Zoological Garden:—All the bears in the garden were shot prior to the bombardment. The large feline carnivora were put into strong transportation cages and removed to the rear of the garden, also prior to the bombardment, while the small felinæ were transferred to cages in the cellars of the Festival Building. A few days before the surrender of the city, when the heavy cannonading started fires in all parts of the city, which could no longer be put out in consequence of lack of water, the large carnivora were likewise shot by resolution of the board of directors, but contrary to the director's advice. None of the other animals were killed, with the exception of a few venomous snakes. During the bombardment only one shell dropped into the garden, striking the ground in the open space for the turtles, where it fortunately did no material damage.

The new building on Tower Hill of the Institute of Marine Engineers is illustrated in *Engineering* for January 22, and was inaugurated by the president of the year, Sir Archibald Denny, on Wednesday last week. The president urged that the institute should take up as a study how information might best be gathered and transmitted to the designers, and emphasised that such information should be as accurate as possible in order to be of service. So convinced is Sir Archibald of the value of short memoirs on sea experience that he has put at the disposal of the council a sum of money, the interest on which will enable it to distribute prizes for the best memoirs each year. The membership of the institute is now nearly 1500, and the new building includes a spacious lecture-room, library, reading-room, various social rooms, and the usual offices. The institute has done good work in the past in the way of bringing marine engineers together for the interchanging of experiences, and on the lines suggested by Sir Archibald Denny should be capable of extending its usefulness greatly.

In July, 1912, a Russian expedition, under Lieut. G. Brussilov, left Petrograd for the Arctic. It was intended to winter in the Katanga or some other Siberian river, and then to complete the north-east passage (which, it is curious to recall, was yet to be

accomplished by a Russian expedition), carrying out geographical and ethnological research. Another expedition, under Rusanov, started for these seas in the same year, and anxiety has been felt about both, in the absence of any news save rumours of a wreck at the mouth of the River Pechora. Captain Sverdrup was therefore dispatched in command of a relief expedition on the *Eclipse*, and it was reported last September that he himself was in difficulties, the ship being ashore near the mouth of the Ob. He was fortunately encountered by another vessel, and the *Eclipse* was towed off and proceeded. It is now announced, in messages from Petrograd, that she is in winter quarters in lat. 74° 45′ N., long. 92° E. On existing maps this position falls well inland in the Taimyr Peninsula, so that it may perhaps be assumed that she has found a berth in a bay on this coast. It does not appear that the search has yet succeeded.

SOME interesting particulars of the life of Dr. J. Muir, the widely known naturalist, whose death was announced in NATURE of December 31, are given in the *Scientific American*. John Muir was born in Dunbar, Scotland, April 21, 1838, and went to the United States when 11 years old with his parents, who settled in the wilderness of Wisconsin, where later he studied in the University of Wisconsin. His love of nature induced him to take up a wandering life, during which he covered much of the territory of the South-west and West, constantly increasing his knowledge of natural history, as well as allied sciences. About 1876 he joined the United States Coast and Geodetic Survey to enable him to extend the field of observations, and covered great sections of Alaska. The great Muir Glacier bears his name. He was one of the party that went in search of De Long and the lost *Jeanette* expedition, and also of the Corwin expedition, during which he had an opportunity to study the Glacier formation of the Bering Sea, and the coast of Siberia, and later went to Switzerland and Norway for purposes of comparison. Besides being a naturalist he was an able geologist, explorer, artist, and philosopher, and in his younger years showed that he was a clever inventor. He was widely known as the "Guardian of the Yosemite" and the "Naturalist of the Sierras" from his intense interest in those regions, and he did much for the preservation of the national forests and parks.

MR. T. F. BURTON has succeeded Mr. Watson Smith as editor of the Journal of the Society of Chemical Industry, and the first issue of the journal under his editorship is before us. No other journal can have so great an influence upon the chemical industry of the United Kingdom as that issued fortnightly by the Society of Chemical Industry; and at the present time, when a new editor is commencing his responsibilities, it is appropriate to point out that chemists will never again have so favourable an opportunity of asserting their influence on industry and gaining a greater hold in this country than during the next twelve months. The technical abstracts in the journal are very valuable, but perhaps the more purely scientific notes might be left to the Chemical Society. The space saved could be devoted to more general and commercial chemical topics, and so justify the journal as the organ of an industrial organisation. Though the papers communicated by members are not usually of a high standard, owing to some extent to the enforced secrecy about chemical processes, the current issue contains a contribution of striking merit by Mr. E. V. Evans, describing the solution of the all-important problem of the removal of carbon bisulphide from coal gas. More might be done, as indeed was attempted a few years ago, to publish summaries on the development or present position of certain selected branches of chemical industry. The opportunity to-day is a great one; it rests largely with the society whether the industrial chemists of the kingdom are to organise collectively to seize it, or whether action is to be left to the more progressive individual firms.

AT the end of last year Mrs. James Buckland sent us a letter which apparently had been issued to other periodicals at the same time, referring to the feather trade. In the course of this appeal to women to begin the new year with a resolve to abstain from the use of feathers in their millinery, the remark was made:—"The bulk of the plumage which comes into the London market—smuggled out of India and our Colonies for the most part—goes in a raw state to Germany, whence it is returned to this country made into hat decorations." As similar assertions relating to the importation of birds' plumage from India to Germany are often made, we have gone to the trouble of instituting inquiries with the view of obtaining accurate information upon this subject. We have been unable to find any particulars either in the official trade returns of Germany or of India as to the trade between these countries in birds' feathers. An examination of the German returns also shows that the imports of feathers into that country from the other British possessions are quite insignificant. The bulk of plumage of all descriptions, including ostrich feathers, comes into the London market, and the dyeing and mounting of these are done chiefly here and in France. This is the case with all high-class goods, but cheap articles of fancy feathers, wings, and mounts, have been bought here in the rough, sent to Germany, and then returned to us. There seems to be little justification for the statement that the bulk of the plumage in its raw state goes to Germany and is returned made into hat decorations, although some of it, exported from here, does find its way back again. Perhaps Mrs. Buckland, or someone else interested in the preservation of beautiful birds will furnish us with the definite information upon which the charge is based that the plumage trade is largely dependent upon the supply of birds' feathers to Germany from India and our Colonies. Unless such evidence is forthcoming we are of the opinion that by the publication of statements which do not admit of complete justification by fact, advocates of better protection of birds let their zeal outrun their discretion.

MR. A. SMITH, curator of the City and County Museum at Lincoln, has issued at the price of one

penny a useful catalogue of the collection of implements of the Stone age. From Lincolnshire only one Palæolithic implement, now in the British Museum, is recorded, but the local museum possesses a good collection of Neolithic implements discovered in the county. Most of these are the gift of the Rev. Canon A. Rowe, augmented by a series recently presented by the authorities of the British Museum.

THE December issue of the *National Geographic Magazine* is devoted to the Nearer East. The most important contribution is that by Frederick and Margaret Simpich, under the title "Where Adam and Eve Lived," in which the scenery, city, and rural life of Bagdad and its neighbourhood are described and illustrated by a collection of admirable photographs. Mr. Simpich, in a second article, describes an adventurous trip to the little-known Nedjeb, "the Shia Mecca," where the fanaticism of the people is readily excited against Christian visitors. The writer had a narrow escape from attack when he attempted to examine the Abbas Mosque, the inner glories of which no Christian has ever seen.

THE report of the Bristol Museum and Art Gallery for 1914 is a record of steady progress, but the death of Lady Smith, of Ashton Court, deprived it of one of its most generous benefactors. During the year the director accompanied the British Association to Australia and procured a good collection of corals and marine invertebrata from the Great Barrier Reef. The great Watkins collection of Gloucestershire insects, including some 13,000 specimens, has been remounted and classified, and the other collections have been widely extended. The museum is largely used by students, and the authorities have made an important new departure by deciding that research work upon the museum collections or in the field shall in future be a definite part of the duties of the museum assistants.

WE have to acknowledge the receipt of the *Aarsberetning* of the Norske Meteorologiske Institut for the financial year ending June 30, 1914. The records of 507 stations are included, some of which, however, contain much fuller statistics than others.

IN No. 4 of vol. ii. of the *Children's Museum News* reference is made to a special case of the influence of the museum on the mind and pursuits of a boy, and thus of his whole future career. Although his family were all engaged in business occupations, he became deeply interested in wireless telegraphy, and now, after a special course of instruction, hopes to graduate in electrical engineering. "What the Children's Museum has done for this boy is typical of what it is constantly doing in a greater or less degree for other children." The number of visitors in October last was 4729—an increase of 1033 over the corresponding month of the preceding year—and in November 4864.

THE Board of Agriculture and Fisheries has issued a compendium of regulations for the show of thoroughbred stallions, suitable as sires for half-bred horses, to be held at the Royal Agricultural Hall, Islington, on March 2 and 3. The show is in connection with the Hunters' Improvement and National Light Horse Breeding Society. A cup for the champion stallion, to which a King's premium has been awarded, to be selected from those recommended for super-premiums, has been graciously offered by H.M. the King. It will be tenable for one year only; but a gold medal will also be awarded by the Board to the owner of the winning stallion. Fifty King's premiums, averaging a little more than 300*l.* each, are offered to owners who arrange for thoroughbred stallions to travel in prescribed districts. In addition, super-premiums, not exceeding a dozen in number, of the value of 100*l.*, will be given for stallions of exceptional merit.

THE Earl of Cromer presided at the monthly general meeting of the Zoological Society, held on January 20, when the Council reported that 52 additions were made to the menagerie in December, of which 27 were presented, 18 received on deposit, and 3 in exchange, and 4 born in the Gardens. Among the more notable of these are a dwarf mongoose (*Helogale undulata*) from the Tana district of British East Africa, deposited; a golden-eared honey-eater (*Ptilotis chrysotis*) from Papua, presented by Mr. A. Ezra, and a pair of red-crowned fruit-pigeons (*Alectroenas pulcherrima*) from the Seychelles, received in exchange; the first and second of these being the first representatives of their kind received at the Gardens. The number of visitors to the Gardens in December was 17,279, a decrease of 12,541 as compared with the corresponding month of 1913. The total number of visitors in 1914 was 1,055,208, or 102,766 fewer than in the previous year; the total gate-money amounted to 24,666*l.*, or 3557*l.* less than in 1913. The total number of additions to the list of Fellows was 305, or 59 fewer than in 1913, and 7 below the annual average for the last decade. Auditors were appointed to go through the Society's accounts for the past year on February 24 next.

AN important economic application of ecology is suggested by Prof. F. W. Oliver and Dr. E. J. Salisbury in a study of vegetation and mobile ground, as illustrated by the shrubby sea-blite (*Suaeda fruticosa*), reprinted from the *Journal of Ecology*, vol. i., No. 4. The authors give the results of their detailed and continuous observations on the distribution and manner of growth of this plant on the shingle beach at Blakeney Point, Norfolk, showing that where conditions permit its establishment on the lee edge of a beach it will, as the beach slowly travels over it, respond by continually growing to the surface, hence the plant disposes itself in longitudinal belts on the beach corresponding in establishment to periods of dormancy of the beach. By its great capacity for rejuvenescence and power of arresting the travel of shingle, and thus raising the height of a beach, Suæda would appear to be pre-eminently adapted for planting on shingle spits and similar formations with the object of arresting landward travel. The authors point out that as knowledge accrues of the detailed mechanism of accretion due to the establishment of plants on blown sand, tidal flats and shingle beaches, it will become

possible to exert some degree of control over the form and distribution of the resulting topographical features, and they look forward to the time when, as an outcome of detailed vegetation studies of the kind here presented, the art of moulding the plastic coast line will develop into a recognised craft.

THE rainfall of 1914 is dealt with in *Symons's Meteorological Magazine* for January, and rather more fully in the *Times* of January 19, by Dr. H. R. Mill, Director of the British Rainfall Association. The results are given in anticipation of the more copious discussion which will appear some months hence. Of 5500 records some 3500 have been already received, and a representative selection of the stations has been used. The months of February, March, November, and December were wet, and of these February was the wettest in Ireland, and December in Great Britain. The rainfall of December is said to have been exceptional in all parts of the Kingdom, and especially so in the South of England. From April to October the rainfall was in general well below the average, and it is surmised that the dryness of this period was about as abnormal as was the great rainfall of December. In England and Wales the rainfall for the year was 106 per cent. of the average, in Scotland 102 per cent., in Ireland 106 per cent., and for the whole of the British Islands 105 per cent. The records of 57 years at Camden Square and 41 years at Slough show that no other December has yielded so large a rainfall, and it is suggested that it was not only the wettest December, but probably the wettest month on record for the southern counties. At Camden Square the rainfall for December was 25 per cent. of the annual fall for 1914. The map giving the December rains for the Thames Valley shows extensive areas with the measurement of 10 inches, whilst in the neighbourhood of Hindhead the rainfall for the month was 12 inches.

THE recent increase of the number of 10-candle-power pentane lamps sent to the Bureau of Standards to be tested, has led to a detailed examination of the conditions under which such lamps should be operated in America to give the most accurate results. A memoir on the subject by Messrs. E. C. Crittenden and A. H. Taylor appears in part 3 of vol. x. of the Bulletin of the bureau. It deals with the preparation and testing of the pentane, the ventilation of the photometer room, and the preparation and operation of the lamp, and shows how the candle-power of the lamp is affected by the pressure, temperature, and humidity of the air of the photometer room. In general the directions for use of the lamp are in agreement with those issued by the Metropolitan gas referees of London, but in some of the details the two differ owing partly to the greater humidity of the American atmosphere.

UNDER the auspices of the University of Tokio the hot and mineral springs of Japan are being tested for radio-activity, and reports by Messrs. S. Ono and H. Ikewti, on the springs of four districts appear in the Proceedings of the Tokio Mathematico-Physical Society for November, 1914. The measurements were made by the bubbling method, and give for the hot springs in the south of the province Higo values between 1·4 and $0{\cdot}3 \times 10^{-12}$ curie of radium emanation per c.c. of water, for the cold springs of the province Etigo the figures are 0·3 to 0·1 at Matunoyama, and 17·3 to 14·8 at Murasugi, and for those in the north-east of Sinano 0·16 to zero. In comparing these figures with 2×10^{-12} gram of radium which forms the average content of a gram of rock, it is to be noted that the curie is the amount of emanation in equilibrium with a gram of radium, and at normal temperature and pressure occupies 0·60 cubic millimetre.

AN important paper was read by Mr. E. Kilburn Scott before the Society of Chemical Industry on January 4 on a new electric furnace for the production of nitrates from the atmosphere. The author emphasised the immense importance, in view of the war, of manufacturing nitrates from the air by electric power, and described a new three-phase furnace which, it was claimed, has substantial advantages over the existing single-phase furnaces now in use on the Continent. Briefly, the new type of furnace consists of three electrodes, spaced 120° apart, consisting of ½-in. steel rods, bent at about 30° from the vertical. The top of the furnace, through which air is circulated, is a boiler with vertical copper tubes for the gases to pass through. The advantage of this system is that with a given periodicity of supply thrice as many arcs are formed in a given time as would be the case with single-phase. The three phases give a combined flame of conical shape which is hotter than if the same energy were expended in three separate furnaces, because the latter have only a single flat flame and the losses by radiation are much greater. The efficiency per unit cost of plant is much increased by the arrangement described, and the heat energy can be largely recovered by using the steam produced in the boiler to generate electricity, the combination thus working regeneratively. Owing to the increased temperature the yield of oxides of nitrogen, too, is largely raised under the new system of working. Since the Notodden factory was started the percentage concentration of nitric oxide has been doubled merely by making small modifications in furnace construction and in the rate of supply of air, but it is still under 20 per cent. The fact that it is so much lower than the value theoretically possible indicates that great improvements are still possible in the working details of the process.

ATTENTION was directed by French surgeons some time ago to the unusually high proportion of the French wounded suffering from tetanus, gangrene, and other forms of blood poisoning. In the *Comptes rendus* of the Paris Academy of Sciences for January 11 is a paper by M. Victor Henri which throws some light on the cause of this. From the results of the examination of a number of unexploded German shells, M. G. Urbain has been able to prove the presence of phosphorus. Common shell of 77 calibre and shrapnel shell mostly contain a large quantity of a violet-brown powder, smelling strongly of white phosphorus, and 97 per cent. of which consists of

various kinds of phosphorus, the red variety predominating. In the common shell the phosphorus is contained in a cylindrical box, diameter 25 millimetres and height 60 millimetres, placed in a cavity behind the explosive. In the shrapnel shell, the bullets are placed in a cylindrical white metal box 65 millimetres diameter, and the space between the bullets is filled with the same violet-brown powder. The whole is rammed tight, so that the bullets, which are roughened, retain a certain quantity of the phosphorus. As a result, pieces of German shells and shrapnel bullets carry more or less phosphorus into a wound. This fact should be specially brought to the notice of surgeons, since phosphorus can produce a mortification of the tissues even with a shrapnel bullet, and micro-organisms, especially the anaerobic organisms, which produce tetanus and gas gangrene, find a favourable medium for their development and the wound may become grave. It is therefore advised that wounds produced by shrapnel and fragments of shell should be deeply incised and cleaned with the greatest care.

MESSRS. LONGMANS, GREEN AND CO. announce that from February 1 the complete list of publications of the Manchester University Press will be published by them throughout the world.

OUR ASTRONOMICAL COLUMN.

ANNUAL REPORT OF THE U.S. NAVAL OBSERVATORY.—The report, for the year 1914, of the superintendent of the U.S. Naval Observatory, is presented as Appendix No. 2 in the Annual Report of the Chief of the Bureau of Navigation, 1914. While the report itself only covers twenty pages, the contents are very concentrated, and cover a very large field of activity. The superintendent refers briefly to the distribution of time, the issue of the American Ephemeris and Nautical Almanac, the observations of sun, moon, planets, satellites, comets etc. Each of these subjects is more fully described in the subsequent paragraphs under the various sub-headings. Regarding the longitude determination between Washington and Paris by wireless signals, it is stated that the reduction of the observations is well advanced, and this will constitute the first direct determination between the Naval Observatory and Europe. Ten American observatories took advantage of the opportunity of using these signals and made the necessary observations to determine their longitudes.

THE APPLEY BRIDGE AEROLITE.—A description of the Appley Bridge meteorite (see NATURE, November 5, 1914, and January 7) sent to the Royal Astronomical Society by Messrs. W. C. Jenkins (Godlee Observatory) and E. C. Rhead, appears in the Monthly Notices of the Society for December, 1914. Of the recorded falls in Great Britain that of Wold Cottage is the only one of greater weight than the present one. Ultimate analysis showed silica, magnesia, iron, and alumina were the principal constituents; small quantities of sulphur, nickel, and phosphorus were found. Chlorine, sodium, potassium, calcium, strontium, and antimony were detected and lead was suspected. It is stated that a careful—chemical—search for titanium gave negative results. The question arises, was chromium specially looked for?

ANNUAIRE DU BUREAU DES LONGITUDES, 1915.—We have received a copy of this very useful publication, issued by the Bureau des Longitudes, Paris. The table of contents is, of course, parallel with that of the volume for 1913, that is to say, in addition to minor changes in the first section, the second section is made up of geographical and statistical tables, etc., in place of the chemical and physical data given last year. There is a noteworthy addition in the shape of a description of the constellations from the pen of M. G. Bigourdan, containing a list giving details of more than 400 of the brighter stars in 88 constellations. The usefulness of the list might have been increased by the addition of a column containing type of spectrum. A valuable essay (162 pages) by the same able author on the methods of testing mirrors and objectives forms the final section.

THE THEORY OF A SUNSPOT SWARM OF METEORS.—Prof. R. A. Sampson (Monthly Notices, Royal Astronomical Society, December, 1914) discusses some points in the theory that sunspots are produced by a bombardment of the sun by meteors of the Leonid swarm detached by encounter with Saturn. Two objections are advanced: first, that the conditions required by the hypothesis would require an improbable mass for the Leonids, and, secondly, that the orbit of the Leonids does not allow the required encounter of the swarm with Saturn. What is probably the more interesting outcome of Prof. Sampson's investigation is the deduction of a new date for the capture of the Leonids. It is shown that there are three dates, all more recent than Leverrier's (A.D. 126), in which the critical conditions for capture obtained; one of these, A.D. 885, comes a little before the earliest recorded shower (A.D. 902), and accordingly is considered the more probable date.

THE RESTORATION OF AN ICHTHYOSAUR.

SOME three-quarters of a century ago the late Sir Richard Owen directed attention to the very frequent occurrence in the flattened skeletons of ichthyosaurs from the Lias of Whitby and Lyme Regis of a sudden flexure in the vertebræ of the tail at a distance from the tip of about one-fourth the total length. This flexure, he argued, must have been due to the presence of a terminal tail-fin, placed vertically, like that of a fish, although not fish-like in structure. The truth of this has been made apparent, not only by the impression of the soft parts in some of the ichthyosaurs from the Lias of Holzmaden, but likewise by the skeletons of their successors disinterred by the Messrs. Leeds from the Oxford Clay near Peterborough, all the latter exhibiting a structural modification at the point in question. Of these wonderful Oxfordian skeletons a reconstructed example, of which we are enabled to give a figure, has recently been set up in the fossil reptile gallery in the Natural History branch of the British Museum, and is believed to be the first entire articulated specimen placed on exhibition. It belongs to the big-eyed, broad-paddled, and practically edentulous group constituting the genus Ophthalmosaurus, of which it represents the species known as *O. icenicus*. As mounted, it measures a little more than 13 ft. in total length, and carries about fifty pairs of ribs, of which the first half-dozen or so are crowded together in order to enable them to underlie the scapulæ.

The work of fitting together and mounting the *disjecta membra* of this skeleton was one which called into play all the skill of the articulators of the geological department, to whom great credit is due for the accomplishment of such a difficult task.

A point of special interest in connection with these

toothless ichthyosaurs is the nature of their food, which was almost certainly different from that of their strongly toothed Liassic precursors, which appear to have been less well adapted for a pelagic life. It is not that the heavily armoured ganoid fishes of earlier formations had died out, as witness the presence of Lepidotus in the Oxfordian; and it may be that the ichthyosaurs of that epoch fed on belemnites instead of fish. If this be so, the Cretaceous toothless pterodactyles may likewise have made an analogous change in their diet, as compared with that of their well-toothed ancestors, only in their case it may have been merely from hard-scaled to soft-scaled fishes.

Skeleton of *Ophthalmosaurus icenicus* from the Oxford Clay exhibited in the Geological Department of the British Museum (Nat. Hist.). Reproduced from the *Museums Journal.*

DEVELOPMENT OF THE CULMS OF GRASSES.

An important paper by Mr. R. S. Hole, forming Forest Bulletin No. 25 of the Indian Forest Research Institute, deals with the development of the culms of grasses. The author points out that the generalisation, based upon the study of grasses and cereals of temperate climates, that the culms are annual does not hold good in the case of various economically important species which are dominant in the savannah lands of Indian forests; hence the discovery of a method by means of which the age of the culms of any particular species can be readily determined is a matter of practical importance bearing directly on such questions as the selection of the best rotation to adopt in the case of grasses worked for paper pulp or the liability of certain species to fire damage at particular seasons. The observations recorded in this paper are of general interest, as the plant chosen for investigation was wheat, and the following are the chief results obtained.

Grass culms show in general two periods of growth—a preparatory period characterised by short internodes carrying scales or under-sized leaves, and a subsequent period of vigorous growth characterised by long internodes carrying well-developed leaves. In the average primary culm (1) the same number of leaf-bearing internodes is produced in these two stages, but the period of preparatory growth is approximately three-fourths of that of vigorous growth; (2) the average number of long internodes produced is approximately equal to the number of months in the period of vigorous growth, and this number is practically the same whether calculated from the primary culms alone, from the axillary culms alone, or from a mixture of these as found in the final crop. In the older axillary culms (1) both growth periods, but more especially the preparatory period, are shorter than those of the primary culms, and there is little difference between the two classes of culms as regards the date of ripening grain; (2) the number of leaf-bearing short internodes is approximately half the number of the long internodes, and the preparatory period of growth is approximately half the vigorous growth period. The author thus obtains for both annual and perennial grasses the generalisation that the average number of leaf-bearing long internodes produced in a culm—that is, excluding the apical segment terminating in the inflorescence—is approximately equal to the number of months comprising the period of vigorous growth.

F. C.

PARIS ACADEMY OF SCIENCES.

The Bonaparte Fund.

THE committee appointed to deal with the allocation of the Bonaparte Fund for the year 1914, has made the following proposals, which have been unanimously adopted by the academy:—

(1) 2000 francs to Pierre Breteau, to enable him to pursue his researches on the use of palladium in analysis and in organic chemistry.

(2) 2000 francs to M. Chatton, to give him the means of continuing his researches on the parasitic Peridinians.

(3) 3000 francs to Fr. Croze, to enable him to continue his work on the Zeeman phenomenon in band and line spectra, the amount to be applied to the purchase of a large concave grating and a 16-cm. objective.

(4) 6000 francs to Dr. Hemsalech, for the purchase of a resonance transformer and a battery of condensers for use in his spectroscopic researches.

(5) 2000 francs to P. Laïs, director of the Vatican Observatory, to assist in the publication of the photographic map of the sky.

(6) 2000 francs to M. Pellegrin, to facilitate the pursuit of his researches and the continuation of his publications concerning African fishes.

(7) 2000 francs to Dr. Trousset, to aid him in his studies relating to the theory of the minor planets.

(8) 2000 francs to M. Vigouroux, to assist him in continuing his researches on silicon and its different varieties. These researches, in which it is necessary to make use of hydrofluoric acid, necessitate the use of expensive receivers.

(9) 3000 francs to M. Alluaud, for continuing the publication, undertaken with Dr. R. Jeannel, of the scientific results of three expeditions in eastern and Central Africa.

(10) 9000 francs to be divided equally between MM. Pitard, de Gironcourt, and Lecointre, all members of the scientific expedition to Morocco organised by the Société de Géographie.

(11) 2000 francs to Prof. Vasseur, to assist him in his geological excavations in a fossil-bearing stratum at Lot-et-Garonne.

(12) 3500 francs to Dr. Mauguin, for the continuation of his researches on liquid crystals and the remarkable orientation phenomena presented by these singular bodies when placed in a magnetic field. The grant will be applied to the construction of a powerful electromagnet.

(13) 2000 francs to Dr. Anthony to meet the cost of his researches on the determinism of the morphological characters and the action of primary factors on the course of evolution.

(14) 4000 francs to Prof. Andoyer, a first instalment towards the cost of the calculation of a new table of fifteen figure logarithms.

(15) 4000 francs to M. Bénard, to enable him to continue his researches in experimental hydrodynamics on a large scale.

(16) 2000 francs to Dr. Chauvenet, to enable him to continue his researches on zirconium and its complex combinations.

(17) 2000 francs to Prof. François Franck, for the chronographic study of the development of the embryo, with special examination of the rhythmic function of the heart.

(18) 2000 francs to Prof. Sauvageau, for the pursuit of his studies on the marine algæ.

PROBLEMS OF PRODUCTION IN AGRICULTURE.[1]

THE fact that this address is to be delivered in the capital city of a State in which semi-tropical, and even tropical, conditions prevail, suggests some consideration of the future of countries in which vegetative development, and therefore the production of food, can attain such a level as is possible here.

At the outset let me remind you of two prime facts in the natural history of man. In the first place all civilisation is based upon food supply; no other industry is creative, and the wealth of a community might almost be measured by the amount of time that remains at its disposal after it has secured, either from its own land, or by exchange, the food it needs to live upon. Secondly, we must look forward at no very distant date, as the life of nations goes, to the exhaustion of those capital stores of energy in the world—coal and oil—on which the current industrial system is based. How long the stores may last is a matter of dispute, but 500 years is a liberal estimate, and we can be pretty sure, in a world in which prophecy is notoriously unsafe, that nothing remains to be discovered which can take the place of those savings from the energy of bygone epochs that are represented by coal and oil. With the passing of industrialism the importance of agriculture will grow, and while the world as a whole will still be able to support the same number of people as are fed by agriculturists of to-day, great readjustments of the population will have to be effected, according to the productive powers of the land in each country. Should population continue to increase, and the spread of organised and stable government ensures that it will grow, there must come a demand for the better utilisation of the land and for a higher production of food than at present prevails; indeed, even in the last few years symptoms of this increasing demand for food have been in evidence. Let us see what the land can be made to do at the present time in the way of supporting population, and for that we must turn to the East, where long experience of the art of intensive agriculture goes hand in hand with an optimum climate and a population of maximum density. Rural Japan is reported to carry a population of 1922 to the square mile, entirely supported by agriculture, but maintaining in addition its quota of officials and industrials. Even this number is exceeded in China, where a farm of two and a half acres will support a family of eight to ten people, and where, in some special cases, as on the island of Chungming, the population living wholly on the land may rise nearly to 4000 per square mile. Compared with these figures the density of population on Western land is trifling. The United States is said to maintain no more than 61 per square mile of its cultivated land, England something above 90, Ireland about 120, and Belgium, perhaps the most intensely cultivated of European countries, not more than 200 per square mile of cultivation. Now, these enormous densities of rural population are accompanied by a very low standard of living; the people, if strong and healthy, exist on the very margin of sustenance. To take a cash standard, an experienced rural labourer in China cannot command more than 6*d*. a day, on which he will support a family. But for this small pay of 6*d*. a full day's work will be obtained; indeed, such a day's work as the white man would find it almost impossible to give under the climatic conditions prevailing.

[1] Part II. of the presidential address delivered before Section M (Agriculture) of the British Association at Brisbane, by the president of the section, A. D. Hall, F.R.S. Part I. appeared in NATURE of October 8, 1914.

Such a state of continuous toil seems to be the necessary outcome of an individualistic system of farming in countries with no great industrial outlets, where the pressure of an increasing population results in continued subdivision of the land. Of its kind Chinese agriculture is magnificent, so far as one can judge from the accounts; the land is made to do an extraordinary duty, bearing two or three full crops a year; waste is non-existent, and long experience has taught the farmers to anticipate in practice some of the most recent discoveries of science in the way of conserving and recuperating the fertility of the soil. Though no statistics are available, the land seems to have been raised to its highest level of productivity per acre, just as it has attained its maximum population-carrying capacity.

Now the Australian, like other farmers in new countries, is often reproached for the low yields per acre that he obtains—10 to 15 bushels of wheat per acre, as against 32 in England, and rather more in Holland and Belgium. Unfavourable as is this comparison of Australia with Europe, still greater appears the superiority of China and Japan, though it cannot be reduced to statistics. But the Australian quite rightly replies by setting up another standard of comparison; not the production per acre, but the production per man is his criterion, and on this basis the Australian farmer takes a very high position indeed. Against the productivity of the land when labour is unlimited he opposes the ideal of the productivity of the man when aided by machines and unlimited land.

Organised large-scale farming supports far more people than the labourers actually employed on the land; it buys machines and raw materials like fertilisers, it pays rent and makes profits, all of which go to the support of other people, who are at bottom fed and maintained by the production from the land. I have calculated that the most highly cultivated farm with which I am acquainted in Britain, a farm selling merely meat, potatoes, and corn, would actually support people at the rate of more than 1000 per square mile, if they were to live at such a low subsistence level as that of the Oriental small farmers. The standard of living that in fact prevails is, of course, very different, but, nevertheless, when all the exchanges of commodities and services against food are completed, that square mile of highly organised farm land is the ultimate support of a population comparable with that resident on Eastern land even though the number of people actually tilling the soil is small enough.

But even if the number of people maintained by a given area under Western conditions is far greater than would appear from those employed in cultivating the soil, there must come a time when the pressure of an increasing population will necessitate a much higher agricultural efficiency in the way of production of food per acre. Now, if we attempt to meet this pressure by subdivision of the land, attracted by the specious appearance of a large population supported on the soil, the operation of competition will force them down to such a low standard of living as we find in China and Japan. A large number of men on the land does not necessarily make for more food for the community, because in practice we find that the standard of cultivation and production per acre of the small holder is actually below that of the larger farmer in the same class of business. For example, one thousand acres might be cultivated by twenty men, so as to produce as much food as if it were divided up and made to carry 200 men on five acres apiece; the community, considered as a whole, is richer in the former case by the labour of 180 men, labour that can be devoted to the production of other articles which the small holders would have to go without. Clearly, if twenty men can grow a maximum of food on the thousand acres, it is mere waste to employ 200 men about it, though, at first blush, in the latter case, the land seems to be carrying ten times more men. The only question is whether the intensive cultivation, which is more or less forced upon the two hundred holders of five acres, can be obtained when the area is cultivated, as a whole, by only twenty men. There is no lack of evidence that it can, but the means by which such large-scale farming can in the end beat mere grinding human labour, is by utilising to the full all the resources of science, machinery, and organisation. In fact, when the world becomes fully populated, the application of science to agriculture is the only method by which the community can be saved from falling into the Oriental condition of a community of labourers working incessantly for a bare subsistence.

Now, we may ask ourselves what remains for science to do towards the improvement of agriculture. Practically everything. Agriculture is half as old as man; centuries of experience, of trial and error, of slowly accumulated observations, are bound up in the routine of the commonest cultivation of the soil; the science applied to agriculture is at the outside little more than a century old, and so far has only partially succeeded in explaining and justifying existing practices. It is still in the reign of first approximations to the truth; these specious first approximations which so regularly break down when applied to the real thing on a large scale, where the second or even the third terms really dominate the issue. The farmer is fond of reproaching the scientific men with the discrepancy between theory and practice; there should be none if the theory is complete, but in such complex matters as the growth of plant and animal we are yet very far from being able to bring into account all the factors concerned. A shipbuilder, for instance, having built to a certain speed and measured off his distance on the map, may reckon on making his port on a certain day; he finds himself wrong, because of the existence of a current which takes a knot or more off his speed. His theory was not wrong, only incomplete. Fuller knowledge may map the currents and their velocity, but even the new calculation may be put out by some unexpected weather factor. Now the growth of a plant is determined by an infinitely more numerous and less measurable series of factors than the speed of a ship, small wonder then that the calculations based upon them are apt to be so erroneous.

Imperfect as is our knowledge, yet we have progressed far enough to see in what directions fruitful work may be done, and may plan our campaign of research. In connection with the soil, for example, the big problem is probably the prevention of the waste that goes on at an increasing rate as the soil becomes more enriched by the accumulation of organic matter. Many soil bacteria, as we know, deal with the compounds of nitrogen in the soil so as to set free nitrogen gas from them, all of which actions are sheer waste of the most valuable constituent of the soil, and to such an extent does this change take place that we cannot, as a rule, expect to recover in the crop more than one-half of the nitrogen contained in farmyard manure applied to the soil. Where the soil is rich, and a high level of production is being arrived at, the percentage of waste may be even greater; for example, on the Rothamsted wheat plot, which has received 14 tons of dung every year, only about one-quarter of the nitrogen applied in the manure has been recovered in the crop, and less than a quarter remains stored in the soil. When a hundred pounds of nitrate of soda per acre is applied, nearly the whole of the nitrogen it contains will be recovered

in the increased crop; with an application of 200 lb. there may be a waste of 25 per cent. of the nitrogen, with still greater losses as the application is increased. The loss is not due to mere washing out of soluble materials, because it is greatest when the nitrogen is applied in organic manures. Under existing conditions, high productivity in the soil is associated with a high rate of waste, and nowhere is this more marked than when cultivation is carried on under tropical conditions, so that one of the chief difficulties of tropical and semi-tropical agriculture is to maintain the stock of humus and nitrogen in the soil. An illustration of the waste that so often goes on in the soil is furnished in the practice of the cultivators under glass in England. For the growth of cucumbers and tomatoes they are in the habit of making up a very rich medium, half soil and half dung, but after a very few crops they are no longer able to use this mixture profitably, but must throw it away and renew their beds, though the rejected soil is still extremely rich in the elements of plant food. The recent investigations at Rothamsted have shown that the fertility of this "sick" soil can be restored by merely heating it for an hour or two to a temperature approaching that of boiling water, the cost of which operation is considerably less than that of renewing the soil. In this case the uselessness of the sick soil appears not to be due to the destruction of the nitrogen compounds, but to their retention in a condition unavailable for the plant. The nitrogen compounds have to be broken down to ammonia or nitrates before they can feed the plant; this process is effected by certain groups of bacteria, the numbers of which are limited in the sick soil by the excessive development of another group of soil organisms—protozoa, amœbæ, etc., that feed upon the bacteria.

We are only just beginning to take stock of all the changes in the soil materials that are effected by living organisms, some necessary, some competitors with the plant, some wasteful; the ultimate problem is to bring these processes under control in the field as well as in the laboratory. The antiseptic treatment of the land at large, after the fashion we can now clean up soils in pots, may seem an impossible dream, but not more impossible than the production of a heavily yielding weedless field of wheat would have seemed to primitive man. Already much may be done to set up a better micro-flora and -fauna in the soil by improving its physical conditions. The good effects of such processes as liming and drainage are largely due to the encouragement that is thereby afforded to the valuable organisms. Soil inoculation with such necessary bacteria as those which fix nitrogen when living in the nodules on the roots of leguminous plants has been widely attempted, but with very little practical success. The failures have generally been due to the fact that soils from which the nodule organism is absent are without it because of some chemical or physical defect; it is not sufficient merely to seed it with the organism, the soil itself must first of all be brought into a state to maintain its existence. The best of grass seeds would be wasted unless the land on which they are sown is first made clean and fertile. The amelioration of soils on their physical side, by bringing clay and silt to the sands, sand and coarse particles of various kinds to the clays, will eventually be taken up on a great scale, now that engineering has made it possible to move earth wholesale by cheaper means than by primitive spade and cart. I have seen a cold clay carrying miserable pasture converted into good market garden land by nothing more than the application of a thick layer of town refuse and ashes; only organisation is needed to make such processes economic, even when the immediate, and not the ultimate, return is reckoned.

From the point of view of manures we shall have to look forward to an ultimate scarcity of nitrogenous fertilisers; the exhaustion of sodium nitrate is only a question of time, the present sources of sulphate of ammonia will disappear with the coal, and the water power which is now giving us nitrate of lime and cyanamide will then be too precious to be used in making fertilisers. Even if the new process for the synthesis of ammonia proved as economical as is expected, we ought still to depend upon the natural processes of nitrogen fixation, and make the farm self-supporting as regards nitrogen at a high level of production. The clover crop in the rotation usually followed in England will, under present conditions, gather in enough nitrogen for the growth of about twenty-four bushels of wheat to the acre, an equal quantity of barley, and twelve tons of turnips. How can we similarly maintain production at a level of 40 bushels of wheat, with other crops in proportion, yet without any nitrogenous fertiliser from outside?

A more immediate problem of the same kind is before the investigator; all around our great cities exist great market gardening industries, which have been built up by means of the cheap supplies of stable manure that were to be obtained therefrom. The market gardener close to London and as far afield as Bedfordshire, rendered thin sands and gravels fertile by using 40 tons or more of London dung every year, but the advent of the motor-car has curtailed, and will eventually put an end to, that supply, in which case how is the market gardening to be carried on? Nitrogen compounds and the other bare elements of plant food can be bought, but humus is also necessary to get these thin soils to yield a proper growth; what needs to be worked out is the cheapest and most effective way of utilising leguminous green crops and the other nitrogen-fixing organisms of the soil to maintain the fertility of such land, keeping in view the fact that it cannot be thrown out of productive cultivation for any length of time. What is needed is not a field experiment merely, but a discussion of a whole system of cultivation on the economic as well as on the scientific side. This suggests the general consideration that economic research in agriculture is still in its infancy. How often do we find close at hand two farmers, both good practical men, with entirely divergent views on the rotation to follow or the management of their stock, one swearing by early maturity and a forcing diet, the other by cheap if slow production. The advantage of one system over the other is not a mere matter of opinion and personal idiosyncrasy, it is possible to reduce it to terms of pounds, shillings, and pence. The prime necessity is the application to farming of a system of costs book-keeping, such as prevails in a well-organised business. It is possible to obtain such figures from a farm; the method is as yet perhaps too complicated for the ordinary farmer to follow, but as an instrument of investigation in the hands of a teacher at one of the agricultural colleges it may be made to yield results of great value both to the individual farmer and to all those who have to take more general views of agriculture.

Returning to the purely scientific aspects of research, the whole of existence is based upon the fundamental process by which the green leaf utilises the energy of the light falling upon it to split up the carbon dioxide of the atmosphere and transform it into those fundamental carbon compounds—sugars, starches, etc., which build up the substance of the plant. The animal creates nothing; it is only a transformer, and rather a wasteful one at that, of the compounds initially built up by the plant. Now, though the leaf is thus the prime creative force, it is yet a comparatively ineffective machine for dealing with the energy

contained in the light, for it does not succeed in storing up in the shape of plant materials it produces as much as 1 per cent. of the energy that falls upon it as light, and in bright, tropical light the percentage utilised is even less. A steam engine, given a certain amount of energy in the shape of coal, turns out again about one-seventh of it in the shape of useful work; a gas or oil engine is an even more effective transformer. Can the duty of the leaf be increased so that it shall effect a greater production of dry matter for the amount of light energy it receives? We know very little as yet about even the sequence of chemical changes in the leaf beyond the fact that we begin with carbon dioxide and water and end with oxygen and some sort of sugar, we are beginning to acquire knowledge as to the extent the rate of change is affected by the supply of light, carbon dioxide, and water, and by the temperature. But we have now many examples in chemistry of reactions being speeded up or rendered more complete by means of some adjustment of the external conditions, so it is perhaps not too much to expect that this fundamental process of carbon assimilation may also be tuned up until the leaf becomes of greater efficiency than at present in producing tissue from the materials and energy supplied to it.

Probably the most immediate successes are before the plant-breeder, now that the application of the Mendelian theory has provided a method which renders both speedy and certain the processes of crossing and selection whereby the practical men of the past, working almost at haphazard, have already effected such enormous improvements in our cultivated plants. Among cereals, the qualities in demand, qualities which we know to be obtainable, are resistance to disease, stiffness of straw, and a large migration factor. We want to get rid of the plant-doctor, as it were; spraying and other prevention or curative treatments are both costly and of limited efficacy; the desirable method is to keep the plant free of disease by means of a naturally resistant constitution, and by establishing healthy conditions of soil and nutrition. As to stiffness of straw, the incapacity to stand up is probably the chief cause which limits the yield of corn crops in Britain wherever the farming is high. When a man keeps much stock, and buys cake either for his bullocks, or to feed to his sheep on the turnips, the land becomes so rich that the first corn crop will only stand up under exceptionally favourable weather conditions, and the farmer, so far from buying more fertiliser, cannot take full advantage of what is already in the soil. The land is often rich enough to yield 60 bushels of wheat to the acre, but it is exceptional that a crop of such weight will stand up so that it can be harvested by a self-binder. Mr. Beaven, in this section, has already dealt with migration; clearly it is a matter of great importance to the plant-breeder. Though the details have only been worked out for barley, the different varieties of any cultivated plant, wheat, for example, are very much alike as regards their gross productive power—*i.e.* the whole material grown weighs much the same in a dried condition. Even different crops produce much the same amount of dry matter when grown under the same conditions, this gross productive power being in all cases the similar product of the environment—*i.e.* the result arising from the supply of food, water, light, temperature, etc. But granted that the different crops possess this same gross productive power, then their comparative usefulness depends upon the greater or less completeness with which they transform the crude material into products that may be used as food for man. In the cereals, for example, we want as much as possible of the original stuff manufactured by the leaf to be migrated later in the plant's life into the seed; of the total weight of the crop we want the largest possible proportion to be high-grade grain and not low-grade straw. Mr. Beaven has shown that the various varieties of barley do differ constantly in their proportion of grain to straw, and as, without doubt, the same differences hold for other crops, this is a matter which must be watched by the plant-breeder.

Cereals are not, however, the only materials upon which the plant-breeder has to work; indeed, they are already among the most advanced of our domesticated plants, and the other farm crops require great improvement before they reach the level of wheat and oats. Sugar beet affords a most interesting case; by selection the percentage of sugar contained in the root has been raised by one-half. The total amount of material grown per acre remains, however, much where it was, because of the difficulty, the impossibility, in fact, as yet, of testing the yielding capacity of a seedling root whereas its sugar contents can be measured with ease. The same difficulty is seen among our other root crops; such improvement as has been effected in the mangold, turnip, etc., has chiefly been in the shapeliness and habit of growth of the root, these alone being the characters that are apparent to the selector dealing with a group of seedlings. To some extent these may be correlated with total yield, but how little may be judged from the fact that the long red mangold, one of the very oldest varieties, is still the largest producer of dry matter and sugar per acre. The comparative yield of cereal varieties may be tested by the growth of a few hundred plants under rigorous conditions; some similar method will have to be worked out for root and fodder crops, before the plant-breeder can make much headway with them. Granted such a method, the plant-breeder has a fine, unexplored field before him in the leguminous and cruciferous fodder crops, and again in the fibre plants. Commercial flax, for example, is an entirely heterogeneous mixture of varieties, which never appears to have been subjected to the most ordinary selection. The fodder crops are matters of immediate importance; because the more intensive cultivation of the western side of Great Britain, where the high rainfall renders the growth of cereals a somewhat speculative industry, subject to loss at harvest and difficulties in the spring preparations for sowing, depends upon the elaboration of a system of farming based upon rapidly growing fodder crops. At present these districts produce milk, meat, and store stock, mainly from grass land that gets but little aid from the cultivator. The gross productive power of such land is small, and under the plough can be enormously raised, but arable farming has hitherto been avoided, except at times of abnormal prices, because of the risks attending harvesting. With improved fodder crops in place of grain a more profitable system of husbandry would replace the crops. Again, a new country like Australia will have to evolve its own fodder crops to suit the climate, and its own soil regenerating plants.

Despite the fact that a given area of land will produce something like ten times as much human food of a vegetable nature as of meat and milk, if mere power of supporting life is considered, we may assume that the human race will not for a long time, if ever, turn to vegetarianism. Absolute pressure of population, supposing the maximum has to be supported that the land can be made to carry, would put an end to the preliminary conversion of vegetable into animal food, but it is probable that the dominant races will insist on remaining flesh-eaters even if that necessitates the limitation of their own numbers. However, the scientific man has at present little to say to this sociological question; his business is to

make the animal a more efficient converter of coarse vegetable fodder into high-grade food. That there is plenty of room for development in this direction may be inferred from the facts that Prof. Wood has directed attention to in the paper he has recently submitted to this section. What the grazier calls a good doer will lay on as fat and flesh 20 per cent. of the energy it receives in its food, as against 7 per cent. stored by a bad doer; here is an enormous margin for improvement if the average cattle are only brought up to the level of efficiency of the best. No one has yet worked out the most economic rate of feeding for different classes of live stock, the type of ration that will produce the largest amount of meat from a given weight of food, independent of the rate at which the increase takes place.

Granted the dependence upon research of the agriculture of the future if it is to meet the requirements of an increased population and a more advanced state of society, how can the required investigations best be organised? We may take it for granted that in some form or other the State must find the funds; in this connection at any rate there are no prizes for the private worker such as would make agricultural research a tempting, even a possible, commercial speculation. There is a very limited field for patents or royalties; the breeder of a new crop variety can only exploit it with success if he has some big commercial organisation behind him, and even then a very few seasons place it in everyone's hands. The solutions to most of the great outstanding problems which I have outlined above could not be sold at a price, however much they might improve the output of every farmer. Indeed, there is this character about the advances which science may make in agriculture, and it explains the lack of interest in research exhibited by many hard-headed farmers, that the benefit comes to the community rather than to the individual. Farmer is competing with farmer, and if production is raised all round the price is apt to drop correspondingly, so that shrewd men who are doing very well as things are, are very content with their limited vision, provided the general ignorance remains unenlightened. However, we need not argue this point; every civilised country has accepted the necessity of maintaining agricultural research; even Great Britain, the last home of go-as-you-please, has fallen into line within the last year or two.

Assuming that the State pays, shall the immediate organisation and control of the work remain with the State direct, or be placed in the hands of semi-official bodies like the universities? The character of the work required must settle this question. We may as well make up our minds at the outset that agricultural research is a very complex affair, which is going to arrive at commercial results very slowly. It deals with the fundamental problems of life itself; its problems mostly lie in the border country where two or more sciences meet, the debatable land which the man of pure science distrusts and affects to despise because there his clean and simple academic methods do not apply. Hence we have to attract to research in agricultural matters minds of the very best quality, men of imagination and determination, and give them scope and freedom to make the best of themselves. Now it has been recently claimed that the nation can only attract men of the necessary quality to research by instituting some system of prizes that shall be commensurate with the rewards that lie before the successful lawyer or business man, who has embarked upon some competitive commercial career. I entirely dissent from this view; the quality of a man's work is not to be measured by the results it happens to attain, for results are often matters of luck, but least of all is to be measured by the amount of public attention the results arouse. It is in the nature of some kind of discoveries to excite the popular imagination, but these discoveries do not necessarily involve more credit to the discoverer than many others the burial-place of which in this or that volume of Transactions is known only to a select few. Once make publicity the criterion, and the scientific man is at the mercy of the boom and the advertisement; a good newspaper manner is more valuable than high thinking. Moreover, I would for the man of science say with Malvolio: "I think nobler of the soul." Give him a living wage and proper opportunities and he will give his best work without the added inducement of a chance of making his fortune. The real point is the living wage, and this does not mean the starveling price at which a man can be bought just after taking his degree. At present the career of research has some of the aspects of a blind-alley employment, the young man enters on it with enthusiasm, only to find ten years later that he has no market value in any other occupation and that he is expected to continue on an artisan's wage.

We have then to ensure the scientific man continuous employment; in such special subjects as agricultural science presents, we cannot trust to pick him for a particular job, and let him go when it is finished; there must be some reasonable sort of a career in investigation. The State cannot simply pay for results; men will not qualify for such precarious chances of employment. The great results come as incalculably as the great poetry, their value is similarly untranslatable into the cash standard, and though no provision of posts can ensure a supply of the finest flowers of the mind, routine science has this advantage over routine poetry, that it has some value and is even necessary to bring to fruition the advances of the pioneers. And when the great mind does happen to be born, he can only be turned to account if an organisation exists within which he can find opportunities for work. Now such an organisation seems to be provided by the universities rather than by the State. The type of man who makes an investigator is apt to be markedly individual; he can work better under the looser system of control that prevails in a university than under the official hierarchy of a Government department. The methods of research are anarchical, and ought to be continuously destructive of accepted opinions; when a Government department takes an official point of view, it is apt to insist on its being respected, and not criticised by its officers on the strength. It has happened within recent years that a scientific man in Government employment has had to choose between his salary and his conscience, and though university laboratories are not always temples of free thought, their atmosphere is distinctly more open than that of a Government office. The type of man most fitted for research is more attracted by a university than a department; he wants his value to be measured by the quality of his scientific work, rather than by his official adaptability. But the greatest objection to making research a function of Government is that it is of necessity subjected to an annual detailed justification of its expenditure to a non-expert legislative body. When one reads the cross-examination of this or that investigator by the Committee of Public Accounts of certain States which maintain departments of agricultural research, one realises the hopelessness of expecting the slow, far-reaching scientific work that ultimately counts, from men who are subject to such an annual criticism. The almost complete sterility of certain State organisations for research on a great scale can be absolutely set down to the call that prevails for an annual report of results which seem to pay their way; only a talent for advertisement comes to the front under such a

régime. Of course, a State must maintain laboratories which undertake a certain amount of investigation in connection with its duties in the control of disease, etc., but, though it may be difficult to draw a defining line between research that arises out of administration and research in pursuit of knowledge, the distinction is easy to make in practice. For example, the State needs a veterinary laboratory for the purpose of checking the conclusions upon which the administrative regulations regarding this or that disease are based, and of testing serums, vaccines, and the like, but it would prove false economy in the end to entrust to this official institution the sole responsibility for investigations into animal diseases.

Another advantage that arises from entrusting agricultural research to the universities is that thereby one obtains the advice, and often the active co-operation of men in the departments of pure science. I have already indicated how complex are the questions that agriculture raises; the man who is working out soil problems may find one day that he is brought to a standstill by some physical or even mathematical difficulty he is not competent to deal with, on another occasion he may wish to consult a geologist, or again a zoologist. No soil laboratory pure and simple can afford to have men of all these qualifications upon its strength, but if it is attached to a university, its men are naturally in constant contact with other specialists from whom they may informally obtain the assistance they need. A special purpose laboratory must suffer if it is isolated from the general current of science, and this is particularly true of agriculture with its many contacts, and the natural inclination to locate its institutions in the country. Some link must be maintained between the research institution and the practical farmer, not so much for the sake of the latter, because he is rarely in a position to utilise directly, or even to understand, the work of the investigation, but in order to keep the work real and non-academic. Even from the purely scientific point of view the most fruitful lines of research are those suggested by practical life; many effects that prove to be of fundamental importance to theory, only become apparent in the large-scale workings of the commercial undertaking. The contact with farming that the research-worker needs should be provided by his association with the university department that is teaching agriculture and advising the farmers of its district; thus is established the connection that on one hand brings the farmer's problems to the investigators, and on the other translates the investigators' results into practical advice. As I see it, the ideal organisation of research in agriculture is to associate a more or less specialised institution for the investigation of a particular class of problem with a university possessing an agricultural department, which is also charged with extension work by way of lectures and advice within its own sphere of influence. How specialised the institution may become must depend upon the numbers of universities available, but there is a real economy in specialisation, in inducing each institution to throw its whole strength into one line of work, for universities, like men, cannot afford to be Jacks of all trades.

Many of my hearers may think I am sketching out a very ambitious and extensive programme about which the only certainty is the creation of a considerable number of salaried posts for men of science, but when I think of the futilities upon which so much public money is spent in every country, I am almost ashamed to justify the expenditure by pointing out that an increase of 10 per cent. in any one of the staple crops of a country, such an increase as is well within the powers of the scientific man to effect in no great length of time, would pay over and over again for the organisation I have indicated. Even if the research went on for the sake of knowledge alone, every nation is able to allow itself a certain amount of intellectual luxury. Moreover, to return to my original text, it is only by the aid of agricultural science that the world is ultimately going to be allowed to enjoy any luxuries at all; as the fundamentally agricultural basis of society again becomes apparent, the one thing that will save it from sinking down into a collection of families each wringing a bare subsistence from a tiny plot of ground will be the application of the fullest knowledge to the utilisation of the land.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—In consequence of the abnormal conditions created by the war, the election to the Poynting chair of physics has been postponed, and Dr. G. A. Shakespear has been appointed acting professor of physics.

EDINBURGH.—Dr. G. L. Gulland has been appointed to the chair of medicine, vacant through the resignation of Prof. Wyllie.

LONDON.—It is announced that Sir Henry Miers, F.R.S., has resigned the principalship of the University in order to accept the appointment of Vice-Chancellor of Manchester University. The resignation has been accepted by the Senate with great regret. Sir Henry Miers was appointed principal in 1908, in succession to Sir Arthur Rücker, F.R.S. He was formerly Waynflete professor of mineralogy at Oxford.

OXFORD.—On January 26 Convocation gratefully accepted a sum of 450*l*. offered to the University by friends of the late Prof. Gotch, with the view of perpetuating the memory of the late Waynflete professor, and of encouraging the study of physiology within the University. The income of the fund will be applied, first, to the establishment of a Gotch memorial prize to be awarded annually, after examination, to a student in the physiological laboratory; and, secondly, to the creation and maintenance of a Gotch memorial library in the same laboratory. A portrait of Prof. Gotch is now hung on the walls of the department which was the scene of his fruitful labours.

In the same Convocation leave of absence was given to Prof. G. C. Bourne, Linacre professor of comparative anatomy, who is engaged in military service. Mr. E. S. Goodrich is acting meanwhile as the professor's deputy.

The books bequeathed to the University by the late Prof. Ingram Bywater, are stated by Sir William Osler, F.R.S., regius professor of medicine, to be of high value and interest.

THE Secretary of State for India has appointed Mr. L. G. Owen to be professor of mathematics at the Government College, Rangoon. He has also appointed Mr. W. Fyfe to the post of Instructor in Manual Training for the Madras Presidency.

AMONG the bequests included in the will of the late Dr. I. Burney Yeo, emeritus professor of medicine at King's College, London, are 3000*l*. to the Royal Medical Benevolent College, Epsom, and 5000*l*. to King's College (London) Hospital Medical School for a "Burney Yeo Fund" to be used for furthering the success of the school.

THE London County Council has arranged for a free course of lectures to be given at the Horniman

Museum, Forest Hill, S.E., at 3.30 p.m. on Saturday afternoons, commencing on January 30, upon the following subjects:—Lightning and the thunderbolt in folk-lore, Mr. E. Lovett; From the ancient herbalist to the modern botanist, Dr. E. Marion Delf; The history and associations of the art of spinning by hand, Mr. W. Dale; The history of writing, Mr. A. R. Wright; Children's toys: their origin and folk-lore, Mr. E. Lovett. Particulars of further lectures will be announced later.

AT the end of last month the Merchant Venturers' Technical College, Bristol, published a preliminary list of present and former members of the College who are at present serving with the Army or Navy, and who have volunteered for service; 362 names were included, but since the list was printed additional names have been received daily, and the total now amounts to 416. Among those whose names appear in the list, there are 26 naval officers and 36 officers holding commissions in the Army. Perhaps the best known name amongst the former students who appear in the list is that of Squadron Commander E. F. Briggs, who received his engineering training in the College, commanded the aerial raid on the Zeppelin factory at Friedrichshafen, and was wounded and captured there in November last.

WE have received a copy of the first issue of a new American educational periodical entitled *School and Society*. It is to be a weekly magazine, and will follow the general lines that are familiar to us in this country in our contemporary *Science*. The paper will be conducted by the editor of *Science*, Prof. J. McKeen Cattell, professor of psychology in Columbia University, and is intended chiefly for teachers in the lower and higher schools of the United States. Among the contributors to the first issue are Dr. Eliot, president emeritus of Harvard University, and Prof. G. Stanley Hall. We commend the new publication to students of education as likely to provide authoritative information about educational effort in the United States in an interesting and attractive form. The magazine is published by the Science Press of New York City, and each number costs 10 cents.

A BEQUEST of 600,000*l*. to Oberlin College by Dr. C. M. Hall, the distinguished electrochemist and manufacturer of aluminium, is announced in the issue of *Science* for January 15. The bequest is in the form of 400,000*l*. endowment to be used for any purpose, 100,000*l*. to be used to build an auditorium, 20,000*l*. for the auditorium's maintenance, and 40,000*l*. to be spent for improvements to the grounds. The college receives in addition all property in Oberlin owned by Dr. Hall, and a valuable art collection. From the same source we learn that by the will of Miss Grace H. Dodge, for many years known for her educational and philanthropic activities in New York City, contains bequests of 280,000*l*. for educational and charitable purposes, as well as a number of deferred bequests of the same character. The sum of 100,000*l*. is bequeathed to Teachers College, Columbia University, in the founding and conduct of which she took an active part. The college will receive two deferred bequests, one of which may be large.

THE fifth report of the Royal Commission on the Civil Service (Cd. 7748) is concerned with the Diplomatic Service (including the Foreign Office) and the Consular Service. Among the recommendations of the Commissioners made in connection with the Diplomatic Corps and the Foreign Office, are the following:—The existing property qualification for admission to the Diplomatic Corps (*i.e.* the possession of a private income of at least 400*l*. a year) should be abolished. The Board of Selection, which interviews applicants for the diplomatic establishment of the Foreign Office and for the Diplomatic Corps, and upon the reports of which nominations to sit at the examination are granted by the Secretary of State, should be reconstructed on a broader basis, and should include a non-official member. The existing requirement that applicants for the diplomatic establishment of the Foreign Office and for the Diplomatic Corps should first obtain the permission of the Secretary of State to appear before the Board of Selection should be removed. All applications should be laid directly before the Board of Selection. The entrance examination for the Foreign Service (*i.e.* the diplomatic establishment of the Foreign Office and the Diplomatic Corps) should be the combined examination for the administrative grades of the General Civil Service (Class I.) A small Departmental Committee should be appointed with a view of providing for the better training of junior members of the Diplomatic Corps, the reduction of its numbers, the devolution of routine work, and the improvement of office methods abroad. In connection with the Consular Service, it is recommended that recruitment should be by open competition in all branches of the Consular Service. The principle should be adopted of taking young men at an age corresponding to a definite stage in the educational system of the country, and then training them for their work. On passing out of training, probationers should be appointed to the grade of Consular Assistant, and placed under the charge of a selected Consul at an important station to learn practical work.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 21.—Sir William Crookes, president, in the chair.—Dr. C. **Chree**: Atmospheric electricity potential gradient at Kew Observatory, 1898–1912. A previous paper discussed results obtained from the Kelvin water-dropping electrograph at Kew Observatory for the period 1898–1904. The present paper discusses the data from the fifteen years 1898–1912. Particular attention is given to the character of the diurnal variation, as to how it varies throughout the year, and as to the nature of the differences apparent between different years. The predominance of the 12-hour term over the 24-hour term in the diurnal variation, which is especially conspicuous in summer, is found to vary greatly from year to year. The 12-hour term shows less fluctuations either in amplitude or phase than the 24-hour term.—Prof. A. E. H. **Love**: The transmission of electric waves over the surface of the earth.—An analytical solution of the general equations of electrodynamics is obtained for the case of waves generated by a vibrating doublet in presence of a conducting sphere, and is adapted to obtain the known solution for perfect conduction, and the correction for moderate resistance, such as that of sea-water. The known solution is expressed by the sum of a series involving zonal harmonics, and the correction by a similar series. Different results have been obtained by different writers who have investigated the numerical value of the former sum. In the paper a new method of summing the series is explained, and worked out in detail for the wave-length 5 km. In the case of perfect conduction the result confirms that found by H. M. Macdonald (Proc. Roy. Soc., Ser. A, vol xc., 1914, p. 50). The effect of resistance is found to be a slight increase of the strength of the signals at considerable distances, counteracting to some small extent the enfeebling effect of the curvature of the surface.—L. **Silberstein**: Electromagnetic waves in a

perfectly conducting tube. The problem of waves in conducting tubes, which has already been treated by various authors, is here taken up with the purpose of developing some of its solutions which offer noteworthy peculiarities with respect to the velocity of the corresponding waves. The waves investigated are axially symmetrical and of permanent type. Their velocity of transfer along the tube is a comparatively simple function of the period of vibration and of the "order" of waves, and it exceeds, for each of these waves, the velocity of light in free space. The peculiarities of distribution of the lines of force are illustrated by two examples with annexed drawings. The paper closes with remarks concerning superpositions of waves of the specified kind, more especially of electromagnetic pulses.—H. B. **Keene**: An electrically-heated full radiator. The essential conditions in a determination of the constant of the Stefan-Boltzmann law of radiation are, either that both "emitter" and "receiver" are full radiators, or that the amount by which they fall short of full radiators is known—an amount difficult to determine with certainty. Hitherto, a measurement of this constant has not been made under full radiation conditions. This paper describes an electrically-heated "constant temperature enclosure" which has been constructed for temperatures in the neighbourhood of 1100° C. It consists of a hollow cylinder of alumina, about 8 in. in diameter, closed with conical end pieces of the same material. Three separate windings of platinum strip provide a means of adjusting the temperature distribution within the enclosure, which can be made uniform to within two or three degrees. At the apex of one of the cones is a circular aperture which emits radiation closely approximating to full radiation. It is intended to use this radiator in conjunction with a full receiver, described in an earlier paper, in order to determine the value of the radiation constant under "black-body" conditions.

Geological Society, January 6.—Dr. A. Smith Woodward, president, in the chair.—C. I. **Gardiner**: The Silurian inlier of Usk (Monmouthshire). The Usk inlier lies a few miles north of Newport (Mon.). Between the coalfields of South Wales and the Forest of Dean the Old Red Sandstone is bent into an anticline, the axis of which runs very nearly north and south. This has been denuded away to the west of Usk, and Silurian beds have been exposed, the rocks seen being of Ludlow and Wenlock age. In the southern part of the inlier the Silurian rocks are arranged in two anticlinal folds, the axes of which run nearly north and south and dip southwards. These folds are separated by a fault. The Old Red Sandstone is believed to rest unconformably on the Ludlow Beds along much of the margin of the Coed-y-paen anticline, and beneath the Ludlow beds, which are about 1300 ft. thick, come 35 to 40 ft. of a Wenlock Limestone, which covers Wenlock Shales: of these latter some 850 ft. are seen. At their base the Ludlow Beds seem to pass conformably down into the Wenlock Beds, and the Wenlock Limestone is probably not at the summit of the Wenlock Shales. The Wenlock Limestone occurs either in irregular layers separated by sandy shales, or in massive beds largely made up of crinoid fragments.—S. R. **Haselhurst**: some observations on cone-in-cone structure and their relation to its origin. In a brief review our state of knowledge is summarised, and the deductions of other investigators are analysed. The author critically examines the accepted hypothesis that cone-in-cone structure is something essentially due to crystallisation. He describes the results of some high-pressure mimetic experiments. These experiments were designed to produce this structure, and reveal what the author believes to be many new points on the origin of concretions and cone-in-cone in particular. The experiments are new, inasmuch as the media used, namely: brittle, semi-plastic, and plastic, are enclosed in tunics of varied design, and then subjected either to a high uniform hydrostatic pressure or to a direct thrust. The author concludes from the evidence:—(1) That cone-in-cone is not due to crystallisation, but is a mechanically produced structure due to great and localised pressure; (2) that it is closely allied to the phenomenon known as pressure solution; (3) that cone-in-cone structure is closely associated with other rock-structures which are mutually indicative the one of the other, and also of their mode of origin.

EDINBURGH.

Royal Society, December 21, 1914.—Sir Thomas Fraser, vice-president, in the chair.—Sir Thomas **Fraser**: The poisoned arrows of the Abors and Mishmis of north-east India, and the composition and action of their poisons. A large collection of arrows, bows, and quivers had been received from time to time from medical and military officers of the Indian Army, and it was soon apparent that different poisons were used in different groups. In one group, chiefly used by the Mishmis, the action of the poison suggested aconite as the active agent. In another group, used by the Abors, the arrows yielded, on extraction with ether, an oil with the physical characters of the oil of *Croton tiglium*. This oil could not produce death in warm-blooded animals, but was lethal to frogs. The poison on the aconite arrows varied greatly in power. If the whole of the poison of one arrow were absorbed, a most improbable possibility, the most active arrows carried enough to kill three men. —J. Herbert **Paul**: Regeneration of the legs of Decapods from the preformed breaking planes. When a lobster, hermit crab, or shore crab loses a limb, a small limb bud forms as the first stage in the process of regeneration. When the animal moults, this bud rapidly expands to the size of the true complete limb, becomes covered with a hard calcified layer like the rest of the integument, and gains full functional power in a few days. The paper contained a detailed account of the manner in which the various stages of regeneration were effected. When the old limb is lost the valvular action of the diaphragm at the breaking plane prevents hæmorrhage; and in the regenerative process a new diaphragm is the first structure laid down.—Prof. Alex. **Smith** and R. H. **Lombard**: The degrees of dissociation in the saturated vapours of the ammonium haloids. The paper was concerned with the densities and degrees of dissociation of the chloride, bromide, and iodide of ammonium. In the chloride the degree of dissociation was nearly constant within the range of temperatures from 280° to 330°; in the bromide it reached a maximum about 320°, and diminished steadily up to 388°; and in the iodide it was practically zero. There was evidence in the last case of association above 340°. The results for the bromide showed that, about 320°, the heat of dissociation was positive. This seemed to be the first observation of a positive heat of dissociation in the gaseous state.

PARIS.

Academy of Sciences, January 11.—M. Ed. Perrier in the chair.—L. **Lecornu**: The deformation of cylindrical tubes.—André **Blondel**: Calculation of the range of optical projectors both on land and sea. A formula is deduced in which certain constants can only be determined experimentally, and suggestions are made as to the best means of determining these constants. — Edouard **Heckel**: *Solanum Caldasii*

Kunth (*S. guaraniticum,* Hassler) from the systematic point of view. *S. Caldasii* and *S. etuberosum* have been regarded by Berthault as identical species. The author points out their differences, and states that the only point they have in common is the fact that they both occur in Chili.—F. **Bompiani**: The geometry of Laplace's equation.—J. **Cabannes**: The diffusion of light by air. A beam of light from a quartz mercury lamp was examined at right angles to the path of the beam, and measurements made both optically and photographically of the intensity of the diffused light. No diffusion occurs when the beam is in a vacuum, and Lord Rayleigh's diffusion formula was quantitatively confirmed.—L. **Gay**: The expansibility product.—Œchsner de **Coninck**: The molecular weight of the oxybenzoic acids. The method is based on the determination of the calcium in the calcium oxybenzoates, these being obtainable in a state of high purity.—J. **Repelin**: The prolongation towards the east of the Senonian synclinal of the Plan d'Aups, Saint-Baume.—Jean **Chautaud**: The origin of the petroliferous mounds of Texas and Louisiana. Contribution to the study of the origin of petroleum. The hypotheses put forward to account for the formation of these mounds are not in accord with the geological structure of the region. These hypotheses are criticised in detail, and it is shown that the mounds have an origin which is independent of orogenic or eruptive actions. The processes of formation suggested by the author are sedimentation in an intermittent lagoon, followed by a hydrocarbon decomposition of the organic *débris,* the transformation of the anhydrite into gypsum, with resulting compression and the migration of the petroleum under the influence of the pressure exerted on the mother rocks.—N. **Arabu**: Studies on the Tertiary formations of the basin of the Sea of Marmora. The Vindobonian in Thrace.—A. **Boutaric**: The polarisation and absorptive power of the atmosphere. Observations carried on during three years confirm the views of K. Angström that the absorptive power of the atmosphere should depend on the diffusion and quantity of the absorptive gas present, mainly water vapour. The main factor is shown to be the diffusion. From observations of calorific intensity, polarisation, and hygrometric state carried out at a given station for some years, it is possible to predict the calorific intensity at different times on a given day from measurements of the polarisation and hygrometric state, or even from a simple polarimetric observation alone.—A. **Goris** and Ch. **Vischniac**: Tormentol, a principle extracted from *Potentilla tormentilla*. The substance is crystalline, contains no nitrogen, and has the composition $C_{33}H_{50}O_{10}$. Its constitution has not been completely worked out, but it is an ether-alcohol.—F. **Bordas**: A new arrangement for the disinfection of clothing. A description of an apparatus, easily put together, capable of disinfecting with steam at a temperature of 105° to 108° the clothes of five hundred men per hour.—Victor **Henri**: The possibility of phosphorus being carried into wounds produced by the projectiles of the German artillery (see p. 598).—W. R. **Thompson**: An intracuticular parasite of *Hamemalis virginiana*.

January 18.—M. Ed. Perrier in the chair.—Maurice **Hamy**: The exact determination of the collimation of non-reversible meridian telescopes. It is shown that the usual method of adjustment with two collimators may be affected by a systematic error and the substitution of two plane parallel mirrors is suggested, their diameter being at least equal to that of the objective of the instrument. Such mirrors can now be made with high precision, and a method of adjusting them to exact parallelism is given.—M. **Guichard**: Surfaces such that the centres of the spheres osculating the lines of curvature of a series, shall be a paraboloid of revolution.—F. **Gonessiat**: Results of the observations of two occultations of the Pleiades by the Moon. Details of observations made at Algiers on September 20 and December 11, 1914.—B. **Jekhowsky**: Observations of Delevan's comet, 1913*f*, made at the Observatory of Paris, with the equatorial in the western tower of 30·5 cm. aperture. Positions are given for December 18, 24, 26, 28, and 29, both of the comet and the comparison stars. On December 29 the comet appeared as a rounded nebulosity 40 seconds diameter with a nearly stellar nucleus of 6·5 magnitude.—G. A. **Miller**: Sylow's theorem.—Foveau de **Courmelles**: Determination of the position of projectiles in the human body by radioscopy. Two methods based on the use of a fluorescent screen are described.—J. **Bougault** and Mlle. R. **Hemmerlé**: The tautomerism of phenylpyruvic acid. In a previous communication J. Bougault suggested that phenylpyruvic acid might exist in two tautomeric forms, enolic and ketonic. Further proofs of this isomerism are now given, based on the differences in reactivity of the acid and its alkali salts towards acetic acid, potassium permanganate, and semicarbazide. The free acid has the enolic form, $C_6H_5.CH:C(OH).CO_2H_1$, the neutral salts being ketonic, $C_6H_5.CH_2.CO.CO_2M$. The conditions for passing from the one form to the other have been studied.—Ch. J. **Gravier**: A phenomenon of multiplication by longitudinal scission in a Madrepore, *Schizocyathus fissilis*.—Alfred **Angot**: Value of the magnetic elements at the Val-Joyeux Observatory to January 1, 1915.—Alfred **Angot**: The earthquake of January 13, 1915. From the records of the seismograph at Parc Saint-Maur; the position of the epicentre was easily fixed at about 1300 kilometres S.E., that is, in Italy. The displacement was much less than that caused by the earthquake in Russian Turkestan on January 3, 1911.—J. **Danysz**: The treatment of wounds by solutions of nitrate of silver of strengths 1 in 200,000 to 1 in 500,000. A demonstration of the advantages of using certain antiseptic substances, especially silver nitrate, in very dilute solution.

THE WEB OF LIFE.

Tierbau und Tierleben in ihrem Zusammenhang betrachtet. By Prof. Dr. F. Hesse and Prof. Dr. F. Doflein. Band ii. Das Tier als Glied des Naturganzen. By Franz Doflein. Pp. xv + 960 + plates. (Leipzig and Berlin: B. G. Teubner, 1914.) Price 20 marks.

ONE of the fundamental ideas of biology, which found many illustrations in the work of Darwin, is that of the inter-relatedness of organisms in the web of life. Just as there is a correlation of organs in the body, so there is a correlation of organisms in the economy of nature. No creature lives or dies to itself; the orbit of one life influences many others; everywhere we find linkages and wheels within wheels. An organism is compared by Prof. Doflein to a modern house, connected by various pipes and wires with other houses in the city and with the outer world, but the image is crude and too static. It is only in man's personal affairs that we find anything like the manifold, intricate, and subtle inter-relations that are to be seen in vigorous animals leading a full life. It is, indeed, altogether a matter of action and reaction between organism and environment, but with what complexity and nuance! Now things are in the saddle coercing the organism, and again the living creature exercises its prerogative and becomes master of its fate.

Prof. Doflein, Weismann's successor at Freiburg, has been studying this aspect of animal biology for more than ten years, and has given us his results in a work which must be placed in the front rank among ecological or bionomic studies. The book is nothing short of a great achievement. It has gathered interesting material from many fields; it includes much that is personal; it has worked out a clear classification of the manifold inter-relations; it is written in a vivid style; and if we said all we think about the abundance, freshness, and beauty of the illustrations, we should not be believed. We do not know of any British, American, or French book of natural history that even approaches it—a fact doubtless implying a smaller purchasing public. Prof. Doflein is well known for his work on the Protozoa and as a naturalist-traveller, and it is remarkable that he should have found time during the last ten years to write this large volume, a fit companion to its predecessor, by Prof. Hesse of Bonn, which treated of the organism as an individual.

In dealing with the comprehensive subject of the inter-relations of animals in the web of life, Prof. Doflein has evidently had in his mind throughout two allied, but distinct, general conceptions. The first is that of the organism as a bundle of adaptations to normal circumstances—what he calls "organisatorische Anpassungen"; the second is that of the organism as a self-assertive plastic agent, which can adjust itself to environmental vicissitudes—what he calls "regulatorische Anpassungen." The first is the hereditary racial equipment of wrought-out adaptations (as far as these concern give-and-take with animate and inanimate surroundings); the second is the individual capacity for adjustment, for modification, for thrusting as well as parrying. In both cases the adaptiveness may be structural, or functional, or psychical. Thus a ptarmigan from the mountains has a stronger heart than a willow-grouse from the plains—a structural adaptation. A bird or mammal continuously and normally regulates its production of heat according to its loss—a functional adaptation. Ants have an instinctive behaviour in relation to their queens—a psychical adaptation. But when a mammal transported to a cold country puts on a thicker coat, or when a bird adjusts the nature of its food-canal to altered diet, or when ants taken from Algiers to Switzerland entirely alter the door of the nest (in relation to new enemies), we have to deal with structural, functional, and psychical adjustments which are not more than individual reactions. This distinction between racial adaptation and individual adjustment is prominent in the book, but the author does not use it stiffly. He is clear, for instance, that the individual trades with his talents.

Beginning with the animate environment, Prof. Doflein deals with nutritive relations (including symbiosis, commensalism, parasitism, etc.); relations to enemies (including protective resemblance, mimicry, autotomy, etc.); sex-relations; migrations; care of offspring; social relations (including gregariousness, co-operation, and the communities of ants, bees, and termites). After 750 pages on these attractive themes, he passes to the inanimate environment, and deals with cosmic periodicities, the medium, the substratum, pressures, chemical influences, the quantity and quality of the food, temperature, climate, and light. This part of the book is like Semper's well-known work, "The Natural Conditions of Existence as they affect Animal Life" (1881), brought up to date. The volume ends with a discussion of the theoretical significance of adaptive structures and habits. What is new is the synthetic treatment of the whole question of inter-relatedness, which is, of course, fundamental in any biology

worthy of the name, and the wealth of fresh material that the author has collected from far and near. Among the interesting plates, we may refer to those illustrating symbiosis, protective coloration, wild geese, the courtship of capercaillie and blackcock, cave animals, and phosphorescence.

As we pass from this valuable treasury of bionomics, many reflections rise. We recognise the impossibility of understanding details of structure apart from details of environment—a commonplace, of course, but illumined by some of the subtle instances that Doflein gives. We appreciate the light that the manifold inter-relatedness of organisms throws on the value of even small variations. The selective process has to be envisaged in relation to the web of life. We realise afresh the importance of the organism's active agency. It is modified by its environment and it is adapted to its environment; but there is more, it actually adapts the environment to itself. And, finally, we are filled once more with wonderment at the vision of life slowly creeping upwards through unthinkable ages, asserting itself insurgently amid a callous physical nature. All that the author of this fine work has told us confirms the impression of a deep tendency to inter-linking and systematisation—the Darwinian *systema naturae*—which is more than a mere image of what obtains increasingly, in spite of all rendings of the web, in the progress of mankind.

J. ARTHUR THOMSON.

ASSAYING AT THE ROYAL SCHOOL OF MINES.

Assaying in Theory and Practice. By E. A. Wraight. Pp. xi+323. (London: Edward Arnold, 1914.) Price 10*s*. 6*d*. net.

THIS book will be welcomed by all assayers who appreciate the value of the teaching at the Royal School of Mines, and is of special interest to old students of the School, for the reason that it gives an account of the methods of assaying which have been taught there during the last few years. Almost all the notes issued to the students in the laboratory are contained in the book, and, in addition, besides other matter, the author gives some general remarks which will be of use to mine assayers and prospectors. Mr. Wraight is well equipped for the task of reminding his former students of what he has taught them. He was for some years the senior demonstrator in the assay laboratory of the Royal School of Mines, and in that capacity has been able to command the attention and affectionate respect of all who have come under his guidance. His work has only recently passed into other hands.

Mr. Wraight has made no attempt to write a complete book on assaying. The number of methods given is comparatively small and the gaps are considerable. For example, no mention is made of the volumetric methods of assay of silver bullion, or of the dry method for antimony, or of any method at all for platinum. The author observes that he has some thoughts of preparing a second volume containing analyses of ores, slags, etc., and of iron and steel. It may be hoped that he will include in it much besides these important sections.

As might be expected by those who know the author's work, there are few mistakes to be found in the book, and none of much importance. The method of determining silver in gold bullion given on p. 153 is an untrustworthy one, which is becoming obsolete. The method of parting with cadmium is not given. On p. 182 it is stated that graphite is not attacked by basic oxides. On p. 297, in the estimation of protective alkali in cyanide solutions, a decinormal solution of nitric acid is recommended instead of the usual oxalic acid or the fairly satisfactory sulphuric acid. The book certainly deserves a place on the shelf of works assayers. As a concise and clear statement of well-tried methods, it could scarcely be improved.

T. K. R.

JAPANESE MATHEMATICS.

A History of Japanese Mathematics. By D. E. Smith and Yoshio Mikami. Pp. vii+288. (Chicago and London: The Open Court Publishing Co., 1914.) Price 12*s*. net.

NOW that Europeans are becoming acquainted with the history of mathematics in Japan, it is possible for them to form a kind of general opinion about the work of Japanese mathematicians. Unless future research bring to light works of a calibre superior to those now known, we must acquiesce in the conclusions stated in the terminal pages of the present work. Briefly, they are that Japan has not originated any great and far-reaching theory, such as the infinitesimal calculus, or function-theory, or group-theory; while on the other hand, native methods of great ingenuity, applied to particular problems, did lead to equivalents for such things as Horner's method in solving equations, the general rule for computing a determinant, and a large number of ways of calculating π, some including the use of infinite series.

Another thing in which the older Japanese mathematicians excel is in dealing with a set of

simultaneous equations; they are not baffled by the occurrence of huge coefficients in the course of elimination, and contrive to solve equations of incredibly high degrees. Finally, the elegant designs of familiar things, such as toys, fans, etc., suggested equally elegant problems of a quite distinctive kind, such as the Gion Temple problem, an account of which is given, pp. 197–8. The first solution involved an equation of degree 1024, which was successively reduced (we are told) to 46 and 10—the last by Ajima, who seems, so far as we can judge, to have been the greatest mathematician of his nation up to the present time.

The fourteen chapters of this book are all interesting, but we can only point out a few of the topics. There is an excellent account of the way of using sticks and abaci for calculation, and of the early system of notation; this is followed by showing how the same implements were used to solve equations, after the manner of Horner. Coming now to the third period (1600–1675 or so) we have circle-rectification of an Archimedean type, magic squares and circles, and something like a theory of quadrature. Seki Kōwa is the leading figure of the time, and chapter vi. is entirely devoted to him, and gives abundant evidence of his talent and ingenuity. The authors, however, class him rather with C. Wolf or Barrow than with Newton or Leibnitz. Chapter vii. deals with Seki's contemporaries and the probable importation of some western mathematics through contact with the Dutch.

Chapter viii. is on the *yenri*, or "circle principle." Practically, this means the formulæ connected mainly with cyclometry, some of which are essentially infinite series such as we have in analytical trigonometry (*cf.* for instance, pp. 152–3). Matsunaga worked out π to 50 figures in the eighteenth century.

Of the remaining chapters the most notable is that on Ajima Chokuyen (1739–1798). Among his achievements may be mentioned his (analytical) solution of Malfatti's problem, and his anticipation of Steiner by discovering poristic rings of circles touching each other and two given fixed circles. He also dealt with repeating decimals, diophantine problems, and quadrature; in the last he comes nearer than any of his predecessors to the idea of a definite integral as the limit of a sum. He may possibly have been influenced by European work.

A special feature of the book is the large number of illustrations. Those which are diagrams for problems are always elegant and often remarkably beautiful (*e.g.* pp. 96, 185, 186, 198, 240, 245); others are very instructive, like those of the abaci, pp. 30–31.

We cannot help asking ourselves: What is likely to be the trend of Japanese mathematics for the next generation or so? Japanese students are now made acquainted with the vast structure of European mathematics, and it is too massive and too much based upon the fundamental nature of things for them to ignore. If they are to add to it, they must become acquainted with it, unless they go on making pretty little things that the master-builders will put into their proper place. But it would be a great pity if, in striving to contribute to the substantial parts of the building, the Japanese were to bury their special talents, innate sense of asymmetrical beauty, and exceptional endurance and power of taking pains. Such things as on one hand celestial mechanics, and on the other diophantine analysis, seem admirably suited to their genius; if there be a planet of the solar system beyond Neptune, or if there be a proof of Fermat's last theorem, a Japanese is as likely to discover it as anyone. G. B. M.

PRACTICAL EDUCATION.

(1) *A Handbook of Vocational Education.* By Dr. J. S. Taylor. Pp. xvi+225. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 4*s.* 6*d.* net.

(2) *A Class-Book of Commercial Knowledge.* By E. J. Balley. Pp. iii+125. (London: G. Bell and Sons, Ltd., 1914.) Price 1*s.* 6*d.*

(1) THE aim of Dr. Taylor's book is to give "a systematic survey of the general field of vocational education, embodying both the historical and logical aspects of the subject." But the author has not done full justice either to the subject or to himself by the short summary he has produced. With the introduction, pleading for equal opportunities for all, for education for citizenship, for a due recognition of the bearing of the industrial revolution on the teaching of trades, English opinion will be in full sympathy. So, too, with later chapters insisting on the need for guidance in the choice of an occupation, and on the part that trade schools should play in making good the loss of the thorough, all-round training afforded by the old apprenticeship system at its best. But the historical account of industrial education in Europe, given in chapter ii., is far too sketchy to be of real value.

Germany, and in Germany the admirable continuation school system of Munich, designed and built up by Dr. Kerschensteiner, holds pride of place, and the constructive side of Dr. Taylor's book may be said to be based on Dr. Kerschensteiner's principles. In his whole-hearted devotion to this master, who has exhibited in rare

combination the talents of administrator as well as teacher, he forgets how much of Dr. Kerschensteiner's success is due to conscription. It is a conscript army that has rendered possible conscript continuation schools, and the iron discipline of the whole system of higher education in Germany. The essential condition of reform in continuation school work in Great Britain and in the United States is to secure there, as has been done in most German States, that young persons who have left the elementary school and gone to work shall continue their education in day, not night, classes. But the hope will be nursed on both sides of the Atlantic that this end will be achieved by some milder political measure than conscription.

As regards the training of vocational teachers, few will refuse assent to Dr. Taylor's contention that "a teacher of trades must be expert in two arts—the art of teaching and the art of some craft." Theorising on the subject, educationists tend to give excessive prominence to its pedagogic aspect. In practice they are forced to act like business-men, and to accept a working compromise.

The bibliography is quite inadequate. Perhaps the most notable omission is that of Dr. Stanley Hall's great work on "Adolescence." Even an American book should acknowledge the world's debt to that distinguished American philosopher.

(2) Few words are needed to commend Mr. Balley's "Class-book of Commercial Knowledge." It is an excellent little book, and should be of the utmost value in secondary schools where some introduction to commercial studies is at last being recognised as desirable. The form of the book is good, for it is planned like an up-to-date text-book on other secondary-school subjects, the examples are modern and business-like, the specimens of business documents bound up with the text are a pleasure to handle, and may even stir the imagination of a future captain of industry. The author has succeeded in his object, viz., to show that the subject of commerce is both educative and interesting. Bookkeeping proper has been wisely left alone, as a separate subject. In a new edition more might well be said in section iii., dealing with office work, on modern methods of card-indexing and filing.

OUR BOOKSHELF.

Świat I Czlowiek. By A. Heflich and S. Michalski. Vol. iv. Pp. 355. Second Edition. (Warsaw: Published by the Editors, 1913.) Price 2 roubles.

Unique in its kind and of broad educational value is a Polish publication organised in Warsaw some years ago and edited from the beginning by Messrs. Al. Heflich and St. Michalski. The whole work, the aim of which is to help the self-educator in all the principal branches of scientific knowledge and scientific method, consists of three series: (i) "A Guide for Autodidacts," (ii) "Man and the Universe" (the universe in the light of the theory of evolution), and (iii) "The History of Thought." The recently-published second edition of vol. iv. of the second series contains a very interesting exposition of social evolution among animals and men, and of moral evolution, by Dr. L. Krzywicki, a thorough chapter on evolution of psychical life, by Dr. M. Borowski; further, an exposition of evolution in art, by Dr. W. Tatarkiewicz; and, finally, an inquiry by Dr. Fl. Znaniecki into the meaning of evolution of man and of the universe.

The present volume closes a large circle of ideas developed in the three first volumes which, after an introductory treatment of the concept of evolution in general, bring the (advanced) private student face to face with the facts and problems of universal and terrestrial evolution, of the evolution of plants, animals and man, of human civilisation, of language and economic life. The "Guide" proper (series I.) consists of several independent volumes covering the needs of the self-educator in the departments of mathematics, natural sciences, philology and history, sociology and law, and philosophy.

It may not be out of place to mention that the whole publication, which, since 1898, has been circulated in many thousands of cheap but beautiful volumes, is entirely supported by the Mianowski-Fund, a national institution of great social utility, and by the disinterested labours of the editors. L. Silberstein.

Crystallography: an Outline of the Geometrical Properties of Crystals. By Prof. T. L. Walker. Pp. xiv+204. (New York: McGraw-Hill Book Co., Inc.; London: Hill Publishing Co., Ltd., 1914.) Price 8s. 4d. net.

The theodolite form of goniometer was invented, and the advantage of determining the position of a face on a crystal by a pair of co-ordinate readings of a single setting was pointed out almost simultaneously by a German, Goldschmidt, and a Russian, Fedorov. The method had, however, been used some years before by an Englishman, Miller, but the posthumous paper in which it was used escaped general notice. It is, however, largely due to the teaching of Goldschmidt and the series of researches carried out by him and his pupils that the convenience of the two-circle measurement of crystals has become widely recognised.

Prof. Walker is imbued with the Goldschmidt spirit, and essays in the volume before us to remove the reproach that no text-book on crystallography written in the English tongue is based on that method. We think that his effort has been crowned with but qualified success. The discussion of the different classes of crystal symmetry and the types of symmetry characterising

each, which occupies the greater part of the book, follows the ordinary, old-fashioned lines, even to the use of the Millerian indices, and the author has wisely refrained from complicating the discussion by devising a brand new set of names for the several classes. The sections on the Goldschmidt method are, on the other hand, scattered throughout the book; it would have been wiser to collect them together and to have expanded them. The argument is incomplete. For instance, the fundamental property of the gnomonic projection, viz., that all zones are represented by straight lines, is very indefinitely stated, and not proved at all. Examples of working out crystals belonging to the six systems should have been included in the several chapters, instead of reprinting more or less fully at the end of the book a few original papers, in which the actual working is subservient to the interest of the particular research. For a full understanding of the Goldschmidt method the student must still refer to the original source.

We are informed that the Hill Publishing Co., Ltd., are the London publishers, but their name is not given on the title-page.

First Book of Physiology and Hygiene. By Gertrude D. Cathcart. Pp. vi+158. (London: Macmillan and Co., Ltd., 1914.) Price 1s. 6d.

IT is apparently the notion in certain educational circles that hygiene can be taught without a preliminary knowledge of the science physiology on which it is founded. If such an idea still lingers anywhere it will be immediately dispelled by a perusal of this attractive little book. The author shows quite clearly that the laws of health are direct deductions from physiological principles. These are explained in clear, simple language, so free as possible from technical terms, and we can highly recommend the book as suitable for readers commencing the study of the subject, or for those who do not wish to take it up from the professional and medical point of view. Where so much is excellent, it seems ungracious to point out a serious mistake, the only one so far as can be ascertained; this is the erroneous statement that the red blood corpuscles are the carriers of carbon dioxide.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Density of Lead from Ceylon Thorite.

LAST May, in conjunction with Mr. H. Hyman, I published the result of an examination of the relative atomic weight of a small specimen of lead, less than one gram, separated from a kilogram of Ceylon thorite, which showed a value rather more than a unit in excess of that found for a specimen of ordinary lead. I have since been engaged in extracting the lead from 33 kilograms of Ceylon thorite, which was first carefully sorted by hand, piece by piece, into various grades. From the finest grade, consisting of 20 kilograms, about 80 grams of lead were obtained, in agreement with the percentage obtained by analysis.

This specimen, and a similar weight of ordinary assay lead, have been carefully purified by identical processes, and finally obtained as metal, by fusing the oxide with cyanide, and repeating the fusion with the metal. The very porous castings so obtained were melted in a mercury pump vacuum in glass tubes with drawn-out jets, and cast into cylindrical graphite moulds in the vacuum, hydrogen to atmospheric pressure being then admitted, and the lead allowed to freeze from the bottom.

It was thought that a determination of the specific gravity would yield results of interest. It is to be expected that the atomic volumes of isotopic elements should be identical, so that, on this view, the densities should be in proportion to the atomic weights. The density of lead distilled in a vacuum was found, by Kahlbaum, Roth, and Siedler, to be 11·3415 ($D^{20°}_{4°}$), and after pressing to 10,000 atmospheres, 11·3470. For the ordinary lead, prepared as above detailed, $D^{20°}_{4°}$ was found to be 11·3465, as the mean of three determinations agreeing within 8 units in the last place, in good accord with that found for distilled lead. On the other hand, the value found for the specimen of thorite lead was 11·376, which is 0·26 per cent. greater, and higher than has been found previously in any trustworthy determination. The atomic weight calculated from the density, taking 207·10 as the figure for ordinary lead, is 207·64. It remains to be seen whether the constants of the lead will be altered by further purification, but one would expect that the effect of any possible impurity would be to decrease, rather than increase the density.

During the purification of the lead, bismuth was specially looked for, but, if any at all was present, its quantity was certainly less than one part in ten millions of the mineral. This seems to dispose of the speculation that bismuth is one of the end products of the thorium disintegration. On the other hand, I was surprised to find a perceptible quantity of iodine in the mineral, and separated between one and two grams, which Mr. J. A. Cranston is now examining. So far as the tests have yet gone, there seems to be a distinct trace, also, of thallium present.

FREDERICK SODDY.

Chemical Department, Aberdeen University, January 30.

The Cause of Streaks upon Lath and Plaster Walls.

IN reply to Mr. Thomas D. Cope's letter in NATURE of January 21, it may be stated that he is correct in supposing that the best explanation of the streaks on the plaster he refers to is that they are due to the hot-air molecules driving the dust particles into contact with the plaster, and the colder the plaster the weaker is the power of the cold-air molecules next it to resist the deposition. This tendency of hot air to deposit its dust on cold surfaces can be seen in a very marked way in any house heated with hot water or steam. Wherever a hot pipe comes through a wall there will always be found a dirty vertical streak on the wall just above the hot pipe, caused by the stream of hot air rising from the pipe depositing its dust on the cold surface.

This action of hot air on cold surfaces accounts for the difference in cleanness of surfaces in rooms heated by open fires, and those warmed by hot air or by the so-called radiators, which do most of their heating by warming the air by contact. In a fire-heated room the furniture is principally heated by radiation, and, being warmer than the air, it repels the

dust; while if heated by hot air, the air heats the furniture, and in so doing deposits its dust on it. These remarks apply to the fine dust, and not to the larger particles which fall on the furniture, and do not adhere to it like the heat-deposited ones. Electric lighting keeps the ceilings much cleaner than gas. Much of this cleanness is due to the much lower temperature of the air rising from the electric bulb than from gas-lighting, but ceilings over electric lights show blackening, especially in smoking-rooms.

The cause of the streaks on plaster referred to by Mr. Cope may, however, be a little more complicated than stated above, because the plaster is porous, and some amount of diffusion will take place between the gases in the room and those at the back of the plaster, and as the laths will reduce the diffusion their action will, to some extent, aid their heat-conserving effect. The principal cause of the streaks would, however, appear to be the heat effect, as it will be generally found that, if the heating and other conditions are the same, the ceilings of the rooms on the top flat of a house are much more lath and beam marked than those underneath, owing to the upper surface of the plaster in the upper rooms being exposed to the cold air under the slates while the ceilings of the lower rooms are kept warmer by the rooms over them.

It is possible the difference in the plaster in the cold room referred to by Mr. Cope may be due not to any action of the water vapour, but to its condensation on the walls ingraining the dust into them.

The reply to Mr. Cope's last question is, yes. A reversal of the phenomenon is quite simple, and has already been referred to. Any surface hotter than the air keeps free of dust; a surface placed in a smoky chimney, if it is hotter than the gases, gets no soot deposited on it. A paper bearing on the above subject, and entitled "The Formation of Small Clear Spaces in Dusty Air," appeared in the Trans. Roy. Soc., Edin., xxxii., part ii.

In my letter in Nature of January 21, the date of a letter there referred to is given as March 16, 1913, which should have been March 6, 1913.

John Aitken.

Ardenlea, Falkirk, January 26.

The cause of these streaks, which are also often to be seen on ceilings, appears to be due to the fact that bodies which are warmer than the atmosphere are surrounded by a "dust-free space," and that dust is battered upon surfaces which are cooler than the atmosphere.

The dust-free space has been described by Tyndall ("Dust and Disease," Royal Inst., 1870), Frankland ("Dust and Disease," Proc. Roy. Soc., vol. xxv., p. 542), Rayleigh (Roy Soc., December 21, 1882; Nature, vol. xxviii., p. 139), Aitken (Roy. Soc. Ed., January 21, 1884) and Lodge and Clark (*Phil. Mag.*, March, 1884, p. 214).

Recently I have discussed the question of the discoloration of walls and ceilings (the *Engineer*, July 3, 1914) in an article on the "Theory of the Radiator."

In the above papers your correspondent will find answers to the questions he puts. R. M. Deeley.

Abbeyfield, Salisbury Avenue, Harpenden, January 22.

Adelard of Bath and the Continuity of Universal Nature.

In the recently published volume of "Roger Bacon Commemoration Essays" (1) Prof. Pierre Duhem's contribution, "Roger Bacon et l'Horreur du Vide," has for its main thesis that Bacon was the first to formulate a theory of universal continuity; an incorrect hypothesis, it is true, but one which Prof. Duhem believes to have served the useful purpose of supplementing "the peripatetic theory of heavy and light" until the discovery of atmospheric pressure. This theory developed in connection with certain problematical phenomena of which this "experiment" is the chief and typical case. If there is suspended in air a vessel of water having a hole in the top and several narrow apertures in the bottom, no water will fall from it so long as the superior aperture is closed. Yet water is heavier than air, and according to the principle of Aristotle's physics should fall to the ground. Writers before Bacon, according to Duhem, explain this anomaly by saying that the fall of the water would produce a vacuum, and that a vacuum cannot exist in nature. But Bacon argues that a vacuum cannot be the reason why the water does not fall, because a vacuum does not exist; he then explains further that although by their particular natures water tends downwards and air upwards, by their nature as parts of the universe they tend to remain in continuity. Duhem holds that Bacon was the first to substitute this positive law of universal continuity for the mere negation that a vacuum cannot exist in nature (2).

Prof. Duhem supports his case by citation of Greek, Byzantine, and Arabian sources, and by use of writings of fourteenth-century physicists available only in manuscripts. But unfortunately for his main contention he has overlooked that remarkable little treatise, "Questiones naturales," which Adelard of Bath, Bacon's countryman, wrote more than a century before Roger penned his "Questiones naturales" (3). In Adelard's fifty-eighth chapter his nephew says—the work takes the form of a dialogue between Adelard and his nephew—"There is still one point about the natures of waters which is unclear to me." He then asks his uncle to explain a water jar, similar to that just described, which they had once seen at the house of an enchantress. Adelard replies in his clear, easy style, so different from the scholastic discussion in Bacon's corresponding passages:—

"If it was magic, the enchantment was worked by violence of nature rather than of waters. For although four elements (4) compose the body of this world of sense, they are so united by natural affection that, as no one of them desires to exist without another, so no place is or can be void of them. Therefore immediately one of them leaves its position another succeeds it without interval, nor can one leave its place unless some other which is especially attached to it can succeed it." Hence it is futile to give the water a chance to get out unless you give the air a chance to get in. Finally, Adelard not only thus anticipates the theory of universal continuity, he describes what actually occurs in the "experiment" more accurately than Bacon or the other physicists cited by Duhem. "Hence it comes about that, if in a vessel which is absolutely tight above an aperture is made below, the liquid flows out only interruptedly and with bubbling. For as much air gets in as liquid goes out, and this air, since it finds the water porous, by its own properties of tenuity and lightness makes its way to the top of the vessel and occupies what seems to be a vacuum" (5).

Lynn Thorndike.

Western Reserve University, Cleveland, Ohio, U.S.A.

(1) Edited by A. G. Little, Oxford, 1914.

(2) Bacon Essays, p. 266. "Le doctrine dont no[us] avons suivi le développement au travers des écrits d[e] Roger Bacon semble bien lui appartenir en propr[e]

A peine, croyons-nous, en avait-il trouvé chez ses prédécesseurs un germe presque infime," etc.

(3) For the dates of Adelard's life and writings see C. H. Haskins in the *English Historical Review*, vol. xxvi., p. 491, and vol. xxviii., p. 515 (July, 1911, and July, 1913).

(4) Adelard elsewhere in the treatise explains that the earth, air, fire, and water which we see and feel are not the elements earth, air, fire, and water, but compounds.

(5) The following is the complete Latin text of the chapter. I have used both the printed edition in the British Museum, where the text is sometimes faulty, and the twelfth-century manuscript in the Eton College Library, which is possibly the autograph. The chapter heading reads, "Quare ex vase pleno inferius aperto aqua non exeat nisi prius superius foramen aperiatur." The text then begins:—

"Adhuc mihi de aquarum naturis quiddam dubitabile restat. Cum enim tempore ut scis iam preterito anum prestigiosam studio incantationis discende addissemus ibique anilibus imbuti sententiis nescio an sentibus aliquot diebus moraremur, eadem in domo vas quoddam mirabilis efficacie ad horas prandiles afferebatur. Quippe cum idem et superius et inferius perforatum multipliciter foret, aqua etiam ad manus abluendas infusa, dum minister aquarius superiora foramina pollice obturabat, nichil aque ab inferioribus emanabat, ablato a superiore pollice statim nobis circumstantibus per inferiora foramina aqua redundabat. Quod ego, ipsum prestigium esse putans, quid mirum, inquam, si anus dominica incantatrix est cum aquarius servulus monstra pretendat. Tu vero more tuo, quoniam incantationibus studiosus eras, minime illi rei vacare dignatus es. Nunc igitur quid de aqua illa sentis aperta; semper erant subteriora foramina et nichil tamen nisi ad aquarii arbitrium fluebat.

(A) Si prestigium id erat, nature potius quam aquarum violentia id incantatum est. Cum enim huius mundi sensilis corpus quatuor elimenta componant, ita ipsa naturali amore conserta sunt ut, cum nullum eorum sine alio existere velit, nullus locus ab eis tum vacuus sit tum esse possit. Unde fit ut, quamcito illorum unum a loco suo cedat, aliud absque intervallo eidem succedat, neque potest a loco cedere, nisi aliud quod substantiali quodam affectat amore possit ei succedere. Clauso igitur introitu succedentis frustra patebit exitus succurrentis, hoc itaque amore hac expectatione in cassum aquae reperies, nisi introitum aeri prestes. Haec enim, ut supradictum est, cum non pura sint, ita coniuncta sunt ut sine se esse non possint vel nolent. Unde fit ut, si in vase superius penitus integro inferius fiat apertio, non nisi cum intervallo quodam et quasi cum murmure liquoris fiat effusio. Tantus enim aer intercedit quantum inde liquoris exit, qui quidam cum ipsam aquam porosam inveniat innativa sibi et tenuitate et levitate penetrando superiorem vasis locum qui vacuus videtur occupat.

LYNN THORNDIKE.

The Economic Status of the Blackcap.

IN NATURE of January 7 Mr. W. E. Collinge (for whose work I have the greatest respect) places the blackcap in his list of injurious birds. As at once a gardener and an observer of birds for about sixty years I wish to protest against this accusation, which, if acted upon by fruit farmers, would soon lead to the extinction of the most charming songster of all the true warblers.

I grant that it eats small fruits, especially raspberries, but I contend that the insects it destroys must, from the economic point of view, fully counterbalance these depredations. This, of course, cannot be proved, because all the insects it devours are not injurious, and the proportion of these will vary in each locality, but considering that the blackcap arrives in this country early in April and does not leave until September, while the season for small fruits lasts practically only from the beginning of July to the middle of August, we have about sixteen weeks when it has to live on insects to six weeks of fruit eating!

Mr. Collinge rightly says that the bird is "not plentiful" (p. 510), but adds that it has considerably increased in numbers during the last eight or nine years (p. 511). To this I must entirely demur—certainly as regards this part of Kent, where much small fruit is grown. It is a bird the clear melodious song of which cannot be overlooked, and as I have been on the look out for it every spring for the last thirty years at least, I am perhaps as competent to form an opinion on this point as Mr. Collinge. I have never more than one pair in my garden, and rarely hear the bird elsewhere. I should say it is not as abundant here now as it was twenty years ago at Colwyn Bay, where I then lived.

ALFRED O. WALKER.

Ulcombe Place, Maidstone, Kent, January 26.

I REGRET quite as much as Mr. Alfred O. Walker to have to condemn the blackcap, but in an investigation of this kind one must always be careful not to allow sentiment or preconceived notions to bias one's opinion.

I have ample evidence that this bird has increased in numbers, at least in the midland counties, during the past six or seven years. I cannot speak for Kent. As to the nature of its food, an examination of the stomach contents of thirty-three adult and four nestling birds showed that the bulk of the food consisted of fruit and peas; there were a few aphids, twenty small lepidopterous larvæ, and the remains of seven beetles. Out-of-door observations made during the past ten years add still further evidence of the injuries these birds will inflict upon wall fruit, currants, strawberries, blackberries, raspberries, peas, etc. During the summer of 1913 I had ample proof in my own garden of the havoc four or five birds can commit on peas.

Mr. F. Smith, of Maidstone, a large fruit-grower and a careful observer, stated in a paper published in 1906:—"A family of blackcaps in a cherry orchard commit grave havoc. They do not eat a quarter of the fruit they pick, and they are also very fond of raspberries and figs. It is the worst summer bird we have in the fruit plantations." This opinion has been confirmed by fruit-growers in all parts of the country.

Where this species is not plentiful or in non-fruit-growing districts, it may be left alone, but in fruit-growing districts it should not be allowed to increase, further, as I stated in 1913, "any attempt at protection will justify fruit-growers in taking vigorous measures for extermination."

WALTER E. COLLINGE.

8 Newhall Street, Birmingham.

Names in Mechanics.

IN the current number of NATURE Sir Oliver Lodge refers to the usefulness of naming units, and many of us remember what a clearing up of ideas resulted in the student's mind from the substitution of the term "radian" for the circumlocution "unit of circular measure." I wish to ascertain any names that have been proposed for units in mechanics, and have attained little or no vogue; as instances "velo" and "celo" may be mentioned, which were proposed as names for the units of velocity and acceleration. I wish also to know how far Prof. Perry's "slug" is in use. Can any reader of NATURE help me?

DAVID MAIR.

NOTES ON STELLAR CLASSIFICATION.

II.

IN the first series of notes[1] I stated how I was trying to find whether a combination of the meteoritic hypothesis and my system of *chemical* classification of stars into two series of ascending and descending temperatures might land us in a method of detecting *physical* differences. The importance of this inquiry depends upon the fact that any system of *chemical* classification along one line must land us in confusion, seeing that equal or nearly equal temperatures, and therefore chemistry—for chemistry is the child of temperature—mark two very different physical states in the life of a star in its progress from nebula to extinction as a cold solid globe.

In order to show the method of attack I give here a diagram showing my classification and that of Harvard (H.3) based upon chemistry. The Harvard symbols given are those of the type stars used in my classification, but the letters B, F, K, etc., are generally used alone.

The difference in physical state assumed on the meteoritic hypothesis is indicated by the wide dotted curve to represent nebulous conditions at the bottom of the ascending arm, and the firm dark line to represent condensed stars at the bottom of the descending one.

I first deal with the evidence of bright lines in certain chemically classified stars as constituting a difference from the normal stars in which bright lines do not occur. The inquiry will show us the stellar species in which these bright lines occur.

In 1876 I suggested that bright lines in stellar spectra might be added to a dark line spectrum by our spectroscopes revealing to us the presence of a gaseous envelope above the most valid absorbing region.[2] I believe Pickering was the first to see such an envelope, and it has been seen since by others.

How such an envelope can strengthen its story when its temperature is increased is shown in a valuable table given in Miss Cannon's catalogue.[3] There we find eighteen stars in which bright Hβ alone is superposed on the absorption line in eight stars. In the others Hγ is added in ten cases. In six stars we get Hδ added to Hβ and Hγ. In one star we get a fourth line, Hϵ, added to the preceding three. As lines are added the intensity of the earlier lines is increased. The extreme case is μ Centauri, where the intensity of the hydrogen lines is ϵ 2, δ 3, γ 6, and β 10. In some cases the bright lines are variable, but the same law holds; the work always begins at the red and decreases towards the violet (Fig. 2).

But this is not all the story. In μ Centauri, where we get the greatest development of the bright hydrogen, there are other lines. All these lines but one are enhanced lines—and of iron!

Among the facts to be borne in mind in considering these questions are those revealed by the recent study of the Madrid photographs of the recent Nova (Geminorum 2), recorded in the last volume of Kensington researches.

The photographs showed a well-marked stage as the Nova cooled down, principally indicated by a bright line near λ 4640 (4639·2); and it was further noted that in previous Novæ the appearance of this line preceded that of the ordinary nebula line near λ 500, and further that it was the brightest line in the whole spectrum where Hβ, Hγ, and λ 4472 were visible.

The 4640 line has been noted in several planetary nebulæ, and among the bright lines of the Wolf-Rayet stars not yet chemically classified.

This line is associated in Novæ and elsewhere with another at λ 4688, not produced by the same substance for the lines vary inversely; it also is frequently seen in the Wolf-Rayet stars.

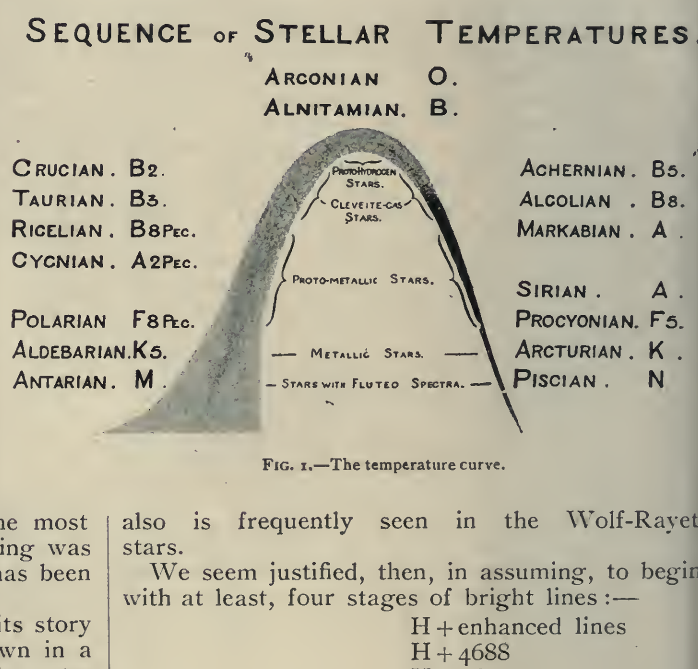

FIG. 1.—The temperature curve.

We seem justified, then, in assuming, to begin with at least, four stages of bright lines:—

H + enhanced lines
H + 4688
H + 4640
lowest temperature H + 500.

and these are common to the stellar envelopes and novæ.

If we include P Cygni, we find another change,

highest temperature H + He + lines of O + N.

Of the substance which produces 4640 we know as yet nothing, but it is possible that 4688 represents carbon, of the existence of which in nebulæ and the Wolf-Rayet stars there is evidence.[4]

On the other hand, in 1905[5] Mr. Baxandall and myself recorded a line at λ 4685·97 in the spectrum of a helium tube, and its occurrence in stars was noted. This would be another origin.

proto-helium. A further inquiry on this subject is necessary, and is under way.

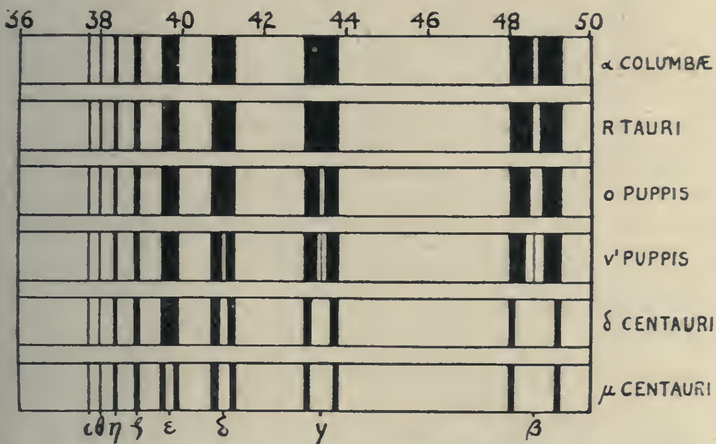

FIG. 2.—Showing how bright hydrogen lines of the stellar envelope make their appearance superposed in the dark absorption lines produced by the subjacent atmosphere or photosphere. This also occurs from the least refrangible side, extending to the blue end as the intensity increases.

It is clear from the above that bright lines have a way of their own, and that the absorption lines and the bright lines have to be studied separately.

It must also be stated that in the majority of non-variable stars with bright lines, the absorption lines have not yet been sufficiently studied to allow of their chemical classification.

I next come to a different origin of bright lines studied in some variable stars. The variability of these is due to a brightening of the continuous spectrum and *the appearance of bright radiations*, at maximum. I have previously (Bull. I.) referred to my hypothesis that these are produced by collisions between meteor swarms.

The simplest case is represented by a swarm B (Fig. 3) revolving round A and colliding at periastron. The light curve of the variability thus produced is represented in the middle part of

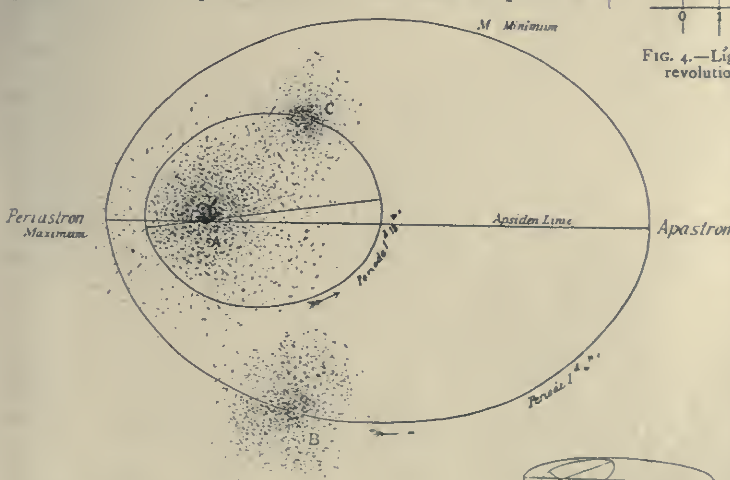

FIG. 3.—Orbits of two meteor swarms B and C round their primary A, colliding at periastron.

Fig. 4, a rapid ascent followed by a slower descent, and the curve is smooth.

The illustrations are taken from Dr. Lockyer's memoir on the variability of η Aquilæ.

In a less simple case, there is a third swarm, C, involved, with a much shorter period than that of B. The combined curve is no longer smooth.

What, then, is the actual physical condition of these two sets of stars with bright lines? In order to answer this question and to test the collision theory in the case of the variables, we must know whether their temperature is rising or falling.

A set of diagrams has been prepared by Mr. N. K. Johnson showing the Harvard and Kensington classifications, the former, except at the bottom, common to the two arms of the temperature curve, which is indicated by two vertical lines and a connecting horizontal line at the top.[6]

To use these we may begin by taking the case of the constant bright line

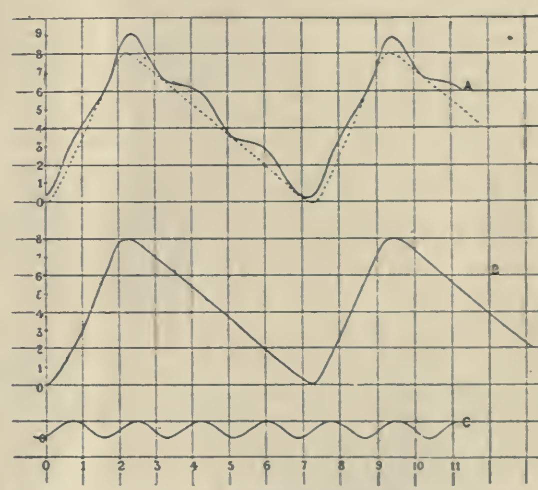

FIG. 4.—Light curves. B, produced by revolution of B; C, produced by revolution of C; A, compound curve produced by both revolutions.

stars, omitting the Wolf-Rayet stars. Of the thirty-eight stars given in the revised Harvard photometry, twelve, indicated by crosses, are included in my classification. All these are near the top of the temperature curve. There is a fair assumption then that the other twenty-six stars may follow suit—that is, that they probably belong to the species which include the twelve; in the absence of a complete classification, therefore, inquiries involving their physical state will be safer in accepting this assumption than in neglecting it.

NORMAN LOCKYER.

[6] The original temperature curve contained gaps below the Cygnian and above the Sirian types for two other possible classes, but these are omitted in the diagrams.

TRINITROTOLUENE IN THE WAR.

IN a recent article in NATURE (December 24, 1914), brief reference was made to the high explosives used as bursting charges for shells, the most important being the much-discussed trinitrotoluene, used largely by the Germans. The following summary of an able contribution on the subject, published in the *St. Thomas's Hospital Gazette* for December, will prove a useful supplement to the previous article in our columns.

Few people realise the exacting conditions which a high explosive for shells must fulfil; these may be summarised as high bursting power, stability in storage, insensitiveness to shock on firing from the gun and on impact of the projectile, where it is desired that penetration shall precede bursting. Yet it must be possible to cause the material which withstands such drastic treatment to detonate when required with frightful violence. It is a case of reconciling the irreconcilable. Further points are safety in handling in the shell factory and the suitability for producing maximum density of loading, say by some such method as melting and pouring into the shell.

The brisance, or bursting power, is shown to depend on the potential energy of the explosive, the velocity of detonation, and the degree of concentration (density of loading).

It will be realised that few substances will fulfil such conditions, and the number will be still further reduced by difficulties and cost of manufacture. The paper discusses the four most important explosives which have been tried for this purpose, namely, picric acid (lyddite), trinitrotoluene (TNT), tetranitromethylaniline (tetryl), and tetranitraniline.

The trinitrotoluene is the symmetrical isomer (1 : 2 : 4 : 6) melting at 80·6. It is manufactured by dissolving *ortho*nitrotoluene in concentrated sulphuric acid, nitrating first to the dinitro and finally to the trinitro stage, the purification being effected by recrystallisation from ethyl alcohol containing a little benzene.

Data are given of comparative trials of TNT and picric acid, both in France and Germany. In velocity of detonation and with the lead block test (increase in size of cavity on firing a charge) the advantage is with lyddite, as the following figures demonstrate:—

	Lyddite	TNT
Velocity of detonation	7745	7140 metres per sec.
Lead block test	228	218 c.c.

TNT caused, however, a greater displacement of earth than lyddite when fired in a bore-hole 1 metre deep.

Except in the last instance, picric acid held a decided advantage throughout, and the question at once arises: Why, then, has trinitrotoluol been adopted by Germany, Russia, Italy, and other countries in preference to the picric acid that is still mainly used by us under the name of lyddite, and by France under the name of melinite? The struggle between the two explosives has been long and of doubtful issue, but it has now probably ended in the victory of trinitrotoluol.

In furnishing the answer to this conundrum the writer continues:—

We have seen it to be inferior in regard to power, velocity of detonation, and density of concentration; its advantages lie in its greater insensitiveness to shock, its freedom from poisonous dust and fumes, the much lower temperature at which it can be poured into shells, and its chemical indifference to substances like lead and iron which are liable to form dangerous picrates. When firing a shell against a ship's armour, at certain limits of the thickness and toughness of the armour-plate and of the velocity of the shell's impact, picric acid would explode when trinitrotoluol would perform its work efficiently, and the latter is therefore better adapted to a high-velocity shell of large calibre.

Since TNT contains too small a percentage of oxygen for complete combustion, attempts to use it incorporated with bodies rich in oxygen, such as potassium chlorate, have been tried. The Belgian high explosive, "macarite," is stated to consist of 30 parts of TNT and 70 parts of lead nitrate. A very high density of loading is thus attained, but the velocity of detonation of macarite is given as only some 4600 metres a second.

In concluding his article, the author says that tetranitraniline or tetryl seem to be the only known substances that may supersede trinitrotoluol.

TYPHOID IN THE FIELD.

THE anti-vivisectionists, by their raging attack on the protective treatment against typhoid fever, have shown us, once more, the dark and ugly side of anti-vivisection. Kind people may try, but may try in vain, to find any excuse for such goings-on. The only possible sort of excuse for them is, that the treatment is not perfect, not faultless; and that, among some hundreds of thousands of men and women who have received it, a few—perhaps one in a thousand—have not done well. One in a thousand is a fair guess, founded on the experience of the 20,000 Valcartier men of the Canadian forces; but Surgeon-General Williams, Director of Medical Services, Australian Imperial Force, says of the protective treatment of 20,000 Australian troops, "Not one single case showed any after-symptom which could be considered worthy of consideration. . . . Not a man had to be taken off duty; drills and exercises proceeded as usual" (*Times,* January 30). Further, we may admit that the overwhelming rush of work, at the beginning of the war, may have caused, here or there, some error of judgment, or some neglect of this or that bit of technique. The strain on the Army Medical Department, the incessant overwork, were well-nigh intolerable; and it is more than likely that some men got the treatment without any precise directions how to take care of themselves after it, or even without much chance of taking care of themselves. If a man, for a couple of days after the treatment, will avoid over-exertion, and alcohol, and exposure to the danger of pneumonia, he may be confident that he will do

well, and will have very little trouble from the treatment.

To admit this much is not to excuse the anti-vivisectionists; indeed, it makes their behaviour look blacker than ever. For example, they discover a case of pneumonia, coming on after the treatment, and forthwith they proclaim it as "septic pneumonia from inoculation." Or they discover a case of a bad arm after ordinary vaccination; this may have been the man's own fault; later he was discharged from the Army for a cause which had nothing to do with his arm. And forthwith they declare that the man's health was so impaired by the protective treatment against typhoid that he had to leave the Army. "Proved to be useless and dangerous"—that is the opinion—if we can call it an opinion—of these people. They are a very small handful of people, in proportion to the general public; but they are trying hard to prevent our men from being protected.

It is probable that some of them are incapable of clear thought on the subject. We may wonder what they will make of the statement just issued from the War Office, and published in Sir Frederick Treves's letter in the *Times* of January 26. Up to date, among our men abroad there have been thirty-five deaths from typhoid. Of these thirty-five men, thirty-four were not protected; it was two years or more since they had received any sort of protective treatment. Among our protected men there has been only one death, and this patient had only had a single dose of the protective treatment, instead of two doses as directed.

What will the anti-vivisectionists say to this? Which way will they look? Will they say that we do not know the proportion of non-protected to protected men throughout the Expeditionary Force? But we do know what strenuous and incessant efforts are made to avoid the sending out of non-protected men. Surely it is a safe guess that the great majority of the Expeditionary Force are protected. Nature leaves these alone; she picks out the non-protected. Two men shall be sleeping in one tent, fighting in one trench; the one shall be taken, and the other left. The anti-vivisectionists know that, lots of them; and we come back to Newman's saying, "Perhaps it is wrong to compare sin with sin, but I declare to you, the more I think of it, the more intimately does this *Prejudice* seem to me to corrupt the soul, even beyond those sins which are commonly called most deadly."

MR. F. W. RUDLER.

As announced with regret last week, Mr. F. W. Rudler died on January 23 at his residence, Tatsfield, Surrey, after a brief illness, in his 75th year. He will be lamented by a large number of scientific friends, who have known him not only as the genial curator of the Museum of Practical Geology, but also as a prominent member of many scientific societies and at the meetings of the British Association.

It was some fifty-five years ago that Mr. Rudler was appointed Assistant Curator of the Jermyn Street Museum. He rapidly made his mark as a mineralogist, and became more and more in request as a specialist in that department. In 1876 he was appointed lecturer in natural science at the University College of Wales at Aberystwyth; but in 1879 was recalled to succeed Mr. Trenham Reeks, as Registrar of the Royal School of Mines and Curator of the Museum of Practical Geology, which post he held until his retirement in 1902, when the high appreciation of his services was marked by the bestowal upon him, by King Edward, of the Imperial Service Order.

Beyond his official duties, Mr. Rudler was a busy worker and a voluminous writer. He was at different times president of the Anthropological Institute, also of the Geologists' Association and of the Essex Field Club. He was for years an active member of council of the Geological Society, and was awarded the Lyell Medal of the Society in 1903.

Mr. Rudler's popularity as a science lecturer caused him to be much sought after. His writings were largely in connection with technical works, such as "Ure's Dictionary of Arts and Manufactures," "Thorpe's Dictionary of Applied Chemistry," "Muir's Dictionary of Chemistry," the "Encyclopædia Britannica," etc. Articles and reviews flowed from his pen in a continuous stream for years, and he will long be remembered as a man of wide scientific attainments and high literary ability.

NOTES.

THE committee of users of dyes appointed to confer with the Board of Trade as to a national dye scheme has come to a unanimous decision in favour of the adoption of a scheme which differs in certain important respects from those of the scheme previously made public. The proposal is to form a company with an initial share capital of 2,000,000*l.*, of which 1,000,000*l.* will be issued in the first instance. The Government will make to the company a loan for twenty-five years corresponding to the amount of share capital subscribed up to a total of 1,000,000*l.*, and a smaller proportion beyond that total. The Government advance will bear interest at 4 per cent. per annum, payable only out of net profits, the interest to be cumulative only after the first five years. In addition, and with the desire of promoting research, the Government has undertaken for a period of ten years to make a grant to the company for the purposes of experimental and laboratory work up to an amount not exceeding in the aggregate 100,000*l.* The modified scheme has been received with more approval from users of dyes in Leeds and the district than the original scheme, and the feeling appears to be general that it will meet with a considerable measure of success. The grant for scientific research in connection with the manufacture of dyes is a particularly satisfactory provision of the new scheme.

THE relation between science and industry in this country has been the subject of a number of letters and articles in the daily papers recently, but the real difficulties of the situation from the scientific point of view have not usually been explained. Prof. J. F. Thorpe, however, in the *Times* of February 2, states clearly what the national needs are in this matter. It is often supposed that when business men decide what substance they wish to obtain all the chemist has to do is to look up the details of the preparation of the substance in the German patent literature and then to proceed in the same manner as a chef would do if he wished to make some new kind of pudding. This point of view is due to an entire lack of understanding on the part of the non-scientific person of the principles underlying scientific processes. Essential details are carefully excluded from patent specifications, and it is safe to say that an independent worker would, in most cases, have to devote some months to experiments on the scientific scale before he could find the correct conditions for applying a process to the commercial scale. Prof. Thorpe pertinently remarks in concluding his letter:—"Do the Government imagine, therefore, that any works research laboratory is going to solve these problems and adapt them to commercial conditions within any reasonable period of time? If they do, they are greatly mistaken. The object *can* be achieved, but only by enlisting the services of every trained organic chemist in this country. The Government must organise the knowledge and skill which is, from the industrial point of view, now wasting in our universities, university colleges, and technical schools; moreover, it is only by a scheme such as this that the nation will be able to pick out those men who are fitted by temperament to be directors of commercial processes."

IT is a fine instance of taking things quietly that the Rev. W. M. L. Evans, rector of Saxby, in North Lancashire, should write to the *Times* of January 28 pointing out that the pheasants of the parish were very much excited on the morning of Sunday, January 24, when the naval engagement was in progress. From the way in which the pheasants were "all over the place with their fuss," the clerk of Saxby inferred "there be rare goings on in the North Sea the morn." Without precise records of hours, observations of this sort are not of much scientific value, but they suggest that those who have time and are familiar with the normal ways of birds should keep an eye on similar occurrences. It is well known that birds have a quick and discriminating sense of hearing, and there is nothing essentially improbable in supposing that the Saxby pheasants heard news which failed to reach the parishioners. Several correspondents describe in the *Times* of February 1 observations in support of Mr. Evans's account of the disturbance of pheasants by the North Sea cannonade; and instances are given of similar effects produced on the birds upon other occasions and in other places, including New Zealand, by distant explosions and earthquakes. It may be premature to believe in the extraordinary sensitiveness of the Saxby pheasants, and the case is not strengthened by a reference to the geese of the capitol, but critical and comparative observations on the sense of hearing in birds would be interesting. It is certain, said Bewick, "that nothing can stir in the night, nor the least or most distant noise be made, but the geese are roused, and immediately begin to hold their cackling converse." It should also be remembered that noises inaudible in one zone are sometimes perceived in another more distant.

IN *Popular Astronomy* Prof. E. C. Pickering quotes some interesting letters from Profs. Backlund, of Pulkovo, and Schwarzschild, of Potsdam, with reference to astronomers and the war. None of the Pulkovo astronomers have been called to serve, but Prof. Backlund's son is in the Russian ranks, and of French astronomers, M. Croze, astrophysicist of the Paris Observatory, has been summoned, as well as the son of the director, M. Baillaud, who has six sons and sons-in-law in the war. On the German side, many young astronomers are in the field. Dr. Zurhellen and Dr. Kühl, who were with the eclipse expedition, have been interned in Russia; Dr. Münch, of Potsdam, is wounded and a prisoner in France. Prof. Schwarzschild writes that he is himself at Namur, conducting a military meteorological station in the interest of the German aeroplanes and dirigibles. Prof. Bauschinger, director of the Strasburg Observatory, is a temporary terminus commander in that city. The *Astronomische Nachrichten* contains announcements of the deaths in the ranks of Dr. J. Liebmann, astronomer at the Berlin Observatory; also of Dr. Adam Massinger, of the Heidelberg Observatory, his death cutting short an elaborate investigation of the nebulæ photographed at the observatory. Dr. Martin Matzdorff, assistant at the Strasburg Observatory, a young man of great promise, was killed at Ypres in November.

DOUBTLESS further particulars will be available when the American mail brings over last week's technical papers, but in the meantime it is probable that the long-distance telephone record, namely, conversations between Washington and San Francisco, both *via* New York and Boston, is no more than the natural outcome of the gradual extension of telephone lines with "loading coils" on the Heaviside-Pupin principle. That the feat has been accomplished by means of a new device just invented by Prof. Pupin, as one might gather from the telegram sent by the New York correspondent of the *Times* last week, seems unlikely. The "loaded" telephone line from New York to Denver (a distance of 2000 miles) has been in use for some little time, and the extension of this to San Francisco (making a distance of 3000 miles) is known to have been under construction. Apparently, as an experiment, a considerable *détour* was made, no doubt over other "loaded" lines, and Jekyll Island (Georgia) was included in the circuit; the total distance telephoned over is given as 5000 miles—certainly a record. It is interesting to note that Prof. Graham Bell, the inventor of the telephone, and now more than eighty years old, was able to converse over the line. The *Times* correspondent regards the event as foreshadowing the day when New York can talk with London,

but this is somewhat premature. Although this distance is far less than 5000 miles, yet the problem is a much harder one owing to the enormously greater electrostatic capacity of a cable as compared with a land-line. There is much in Prof. Fleming's prediction that telephony between England and America, when it comes, will first be by "wireless."

SOME anxiety has been felt as to the fate of M. le Chanoine Henri de Dorlodot, Professor of Geology at the University of Louvain, concerning whom his colleagues in this country had been unable to obtain information. They will be glad to learn that he is at Louvain, in excellent health, and that his house and museums are absolutely untouched.

A PUBLIC lecture on the present position of the atomic theory was delivered by Prof. J. W. Nicholson at King's College on January 21. The lecturer reviewed the work of Faraday on electrolytic conduction, the origin of our first perception of the ultimate charge *e*, and proceeded to a historical sketch of the evolution of modern ideas of the atom as a purely electrical structure. An account was then given of very modern work in connection with radio-activity, X-rays, and emission spectra, concluding with the probable structure and number of electrons present in atoms of the simpler elements, and the possibilities of a celestial evolution of the elements which are now disintegrating.

SINCE January 14 several earthquakes have been felt in Italy and elsewhere. Two after-shocks of the Avezzano earthquake were felt in Rome on January 18. During the night of January 18–19, three earthquakes occurred in the province of Cosenza (Calabria), some buildings in the village of Luzzi being slightly damaged. According to the *Times*, various observatories in Italy recorded an earthquake at 2.15 a.m. (1.15 a.m., G.M.T.) on January 27, which lasted ten minutes, and was more violent than that which destroyed Avezzano. As no further account has been published, this earthquake would appear to be the same as that registered in British observatories at about the same time. The West Bromwich seismogram suggests an origin distant about 1500 miles, probably in Turkey or Greece.

IN the issue of NATURE for July 10, 1913, (vol. xci., p. 483) particulars were given of the allocation by the Mansion House Committee of the Captain Scott Fund. It will be remembered that the allocation fell under three main headings: the provision for relatives, for the publication of the scientific results, and for memorials. In connection with the last-mentioned object it is now announced that the committee has entrusted the execution of a monument to Mr. Albert H. Hodge. The monument and the pedestal are to cost 7500*l*. The architectural portion is to be of grey granite. A site has been selected by the committee facing the Thames in the grounds of Greenwich Hospital. A bronze memorial tablet to be placed in St. Paul's Cathedral is being executed by Mr. S. Nicholson Babb.

THE director of the Commercial Intelligence Branch of the Board of Trade, 73 Basinghall Street, London, E.C., has kindly sent us further information upon the subject of the trade in birds' feathers between India and Germany, referred to in a note in NATURE of January 28 (p. 596). He reminds us that the "Report from the Select Committee of the House of Lords on the Importation of Plumage Prohibition Bill (H.L.) 1908," contains much information of interest upon the subject. The Select Committee reported that "it appears clearly from the evidence that the enactments of British Colonies and certain foreign countries, which provide a close season for wild birds, and of India, which prohibits their export, are to a considerable extent ineffective, partly on account of the open market in this and other countries. Mr. Todhunter, who attended on behalf of the India Office, showed the difficulties of preventing illicit exportation." The Report may be purchased, either directly or through any bookseller, from Messrs. Wyman and Sons, Ltd., Fetter Lane, London, E.C., the reference number being H.L. 137, and the price 6*d*. (ex-postage), or it may be consulted at the office of the Commercial Intelligence Branch of the Board of Trade.

IN the *Cairo Scientific Journal* for August, 1914, Mr. W. H. Harding King has collected a good budget of folk beliefs and songs from the western oases. The magical element is prominent in the beliefs of these people. When a child is born grain and salt are trundled about in a sieve to ensure the child against want; the pestle and mortar are beaten to make sure that he may not be frightened by any noise when he grows up; seeds are thrown about in the village as a charm to enable him to travel to any part of the world that he pleases, and the sieve is rolled about so that when he grows up he may run about quickly. When his finger nails grow long they are cut, and the ends of his fingers are dipped into newly ground flour to prevent them from growing again, and as the natives consider it unlucky to open a pair of scissors before the child's face, his nails are either cut behind his back, or bitten off by his parents. To protect trees from the Evil Eye and to ensure a good crop, a bone or the skull of an animal, or a piece of manure or a small doll-like figure are hung on the branches. Natives refresh themselves by stuffing the small pungent onions of the oases into their nostrils; onions which over night have been kept under the pillow are hung with the barley to bring refreshment to the family until the next season.

THE Herbert Spencer Lecture at Oxford last year was delivered on November 18, 1914, by the Hon. Bertrand Russell, on "Scientific Method in Philosophy," and has just been issued in pamphlet form by the Clarendon Press (1*s*. 6*d*. net). Mr. Russell's thesis is that it is from science rather than from ethics or religion that philosophy should draw its inspiration. In fact, scientific philosophy aims only at understanding the world and not directly at any other improvement of human life; and thus it cannot take account of ethical notions without being turned aside from that submission to fact which is the essence of the scientific temper. It is piecemeal and tentative like other sciences, and not like philosophy has been hitherto, where each philosopher had to

begin the work again from the beginning. For further elaboration of the views on logic as the essence of philosophy and the foundations of physics, Mr. Russell refers to his book on "Our Knowledge of the External World" (Chicago and London: Open Court Publishing Co., 1914); reviewed in NATURE of November 12, 1914 (vol. xciv., p. 278). The adoption of scientific method in philosophy compels us to abandon the hope of solving many of the more ambitious and humanly interesting problems of traditional philosophy; but what it does solve it solves with great precision.

IN the *Revue Scientifique*, No. 1, 1915, an interesting summary is given by Dr. Landrieu of the use of tincture of iodine for the antiseptic treatment of wounds on the battlefield. Descriptions are given of several ingenious tubes by means of which the iodine may be carried and applied. Dr. Maumus, in the same journal, also gives an account of tetanus among the wounded.

WE have received the annual report of Livingstone College for 1913–14. This was the last session of the principalship of Dr. Harford, who has worked untiringly for twenty-one years. During this period 548 students have passed through the college, and have gone forth to all parts of the world. The college was instituted in order to give some medical education to missionaries, and it has well fulfilled its object. Mr. Loftus Wigram is the new principal.

WE have received as an excerpt from vol. iv. of the "Scientific Results of the Scottish National Antarctic Expedition" a report on the *Scotia* collection of Atlantic fishes by Mr. R. S. Clark. The fishes were collected between 40° N. and 36° S., near Azores, Madeira, Cape Verde Islands, Ascension, St. Helena, Cape Colony, St. Paul's Rocks, and their main interest is in increasing our knowledge of the geographical distribution of some species, *e.g.* at St. Helena. No new forms were found.

IN the January number of the Transactions of the Herts Natural History Society, Mr. J. Hopkinson gives a summary of the climate of Hertfordshire, based on general observations for twenty-five, and rainfall records for seventy, years. February, March, and April are the driest, and the months from July to November the wettest, October attaining the maximum in the latter respect. The minimum rainfall in any year at any one station during the period under review was 15·79, and the maximum 42·56 in.

BOTH the January and February numbers of *My Children's Magazine*, edited by Mr. Mee, contain admirable and well-illustrated natural history articles specially suited to juvenile readers. The subject in the January issue relates to insects serviceable to man; particular attention being directed to the collection and preparation of silk-cocoons in Syria. Reference is also made to a scarcity of flowers in the south of England, owing to the ravages of the bee-disease. The food-storing habits of various animals form the subject of the article in the February issue.

TO vol. xxv., part 2, of the Bulletin of the American Museum of Natural History, Dr. R. Broom contributes an illustrated catalogue of type and figured specimens of Permian, Triassic, and Jurassic South African reptiles in the collection, as an instalment of the catalogue of the whole series of typical and figured fossil vertebrates in the museum. The South African collection, which is a particularly fine one, was mainly brought together by Dr. Broom himself. The publication is dated January, 1915, but it unfortunately contains the description of a new genus and species (*Youngina gracilis*) which had already been named in the fourth part of the Zoological Society's Proceedings for 1914, published in December last.

SOME fundamental morphological objections to the mutation-theory of de Vries, by Prof. E. C. Jeffrey, and the English black-and-white rabbit in connection with the question of Mendelian unit-character constancy, by Messrs. W. E. Castle and P. B. Hadley, form the subjects of two out of the three chief articles in the January number of the *American Naturalist*. In the former it is asserted that *Oenothera lamarckiana,* and other species of the same genus, which form the main basis of the de Vriesian mutation hypothesis, are (like other members of the Onograceæ) much contaminated by natural hybridism. The species of Œnothera are thus largely, if not wholly, cryptohybrids; and Bateson's objection to the genetical purity of *Oe. lamarckiana* is confirmed and also shown to be applicable to other members of the group. As hybridism is the best explanation of the behaviour of these species in cultures, it follows that the de Vriesian hypothesis, "so far as it is supported by the case of *Oe. lamarckiana,* is invalid."

IN an article on eugenics and the war, in the January number of the *Eugenic Review*, Mr. Theodore Chambers emphasises the all-importance in warfare of supreme care and attention in the treatment of the sick and wounded. In the old days, at any rate, the vastly greater proportion of the deaths in war were due to sickness; and although matters have immensely improved in this respect, "it is necessary to urge that even to-day far too little attention is being given by the nations which consider themselves the most civilised in the world to this aspect of war." Later on he observes that "from a military point of view, a voluntary army is probably far more efficient for its numbers than a conscript one. . . . One willing fighter is worth six pressed men." It is added that as universal training without conscription would raise the general physique of the nation, and in war-time would vastly increase the number of recruits for voluntary service, it is probable "that the best combination from the military and eugenic standpoints would be universal training with voluntary service for war."

THE Yale Peruvian Expedition has added a further contribution to our knowledge of Peru in the publication of an account of the Liverworts, by Dr. A. W. Evans, in the Transactions of the Connecticut Academy of Arts and Sciences, vol. xviii., of April, 1914. Many of the species come from the High Andes

around Cuzco, and some from the forests of the eastern slopes. Of the thirty-one species collected, six were previously unknown. The paper contains good illustrations and useful notes on the geographical distribution of the several species, a small number of which are peculiar to the Andes.

A COMPREHENSIVE account of Sea Island cotton in the West Indies, recently issued by the Imperial Department of Agriculture as Pamphlet No. 74, forms a very trustworthy guide to those concerned in the West Indian cotton industry. The history of the industry is detailed, and chapters follow on the botany, cultivation, picking, and grading, examination of seed cotton and lint, insect pests, and diseases, etc. The pamphlet consists of 118 pages, and is very well illustrated, the general information has been selected with great care, and the compilers are to be congratulated on the preparation of so useful a manual.

THE story of the discovery of the fine cycad, *Encephalaitos Hildebrandtii* by Sir John Kirk, in Zanzibar and East Africa, and the transmission of specimens to Kew between the years 1868–78, forms an interesting contribution to Kew Bulletin No. 10, 1914. The story is told in extracts from Sir John Kirk's correspondence with Kew while he was acting as Consul-General at Zanzibar. Sir John's observations on the remarkable generation of heat in the male cones, made in 1878, are published for the first time; on one occasion a rise of temperature of as much as 16·5° F. was recorded.

THE compensation payable to tenant farmers for unexhausted manurial residues is mainly based on the tables drawn up by Hall and Voelcker with a view to their general application to stock of all kinds. It has been suggested by some valuers that special discrimination should be made in the case of pigs, on the grounds that the feeding of the pig differs greatly from that of other stock, and is largely restricted to the intensive feeding of young animals during the period of most rapid growth. In proportion to its weight the pig eats more dry matter and voids less dung than any other class of farm animal, so that a relatively high compensation value must be made for a relatively small weight of manure. In the current number of the *Journal of the Board of Agriculture*, Prof. Charles Crowther and Mr. A. G. Ruston describe an experiment designed to throw more light on this point. Two groups of pigs were confined in special pens, without litter, for periods of five days in each fortnight of the twenty-three weeks that the experiment lasted. All food consumed during the five days was weighed and sampled for analysis, but the excreta were collected only on the last three days of each period. There was a remarkably close agreement between the figures given by the two groups of animals, which showed an average weekly gain of 6¼ lb. per pig over the whole period of the experiment. The authors conclude that the manurial residues should not be credited with more than 25 per cent. of the nitrogen, 50 per cent. of the phosphoric acid, and 80 per cent. of the potash present in the foods. This means that the compensation allowance in the special case considered should be assessed at only three-fifths of that deduced from Hall and Voelcker's tables.

MR. E. H. CUNNINGHAM CRAIG, in a paper read before the Institution of Petroleum Technologists, has given a brief account of the prospective oilfields of Western Canada. This paper should be a welcome one as authoritative information upon the subject of these supposed oil regions is but scarce, although a number of wild rumours about one or other of them have been current for the last year or two. Unfortunately, Mr. Craig gives no very large amount of geological detail—probably there is not yet a great deal known definitely—but he shows that practically all the oil hitherto discovered in Western Canada comes from the Cretaceous formation, which is well, though irregularly, developed over a very large tract of country. He deals with three main areas, the Flathead and Pincher fields, the Calgary field, and the Vancouver area; the greater part of his paper is devoted to the second of these, which he appears to regard as decidedly promising, and he gives a full account of the wells that have so far yielded oil. Amongst these he describes the Discovery or Dingman well of the Calgary Petroleum Products Co., which has yielded an extraordinary water-clear oil, containing no less than 72 per cent. of benzine and capable of being used crude in the engine of a motor-car. It is evidently too early for any definite opinion to be pronounced as to the possibilities of Western Canada as a producer of petroleum, but Mr. Craig, who has studied the whole area very thoroughly, appears to be very hopeful as to its possibilities.

THE war and the weather during the first three months of the fighting is dealt with in the *Popular Science Monthly* for December by Prof R. deC. Ward, of Harvard University. The author points out the weather influence on war as one of the great controls to be reckoned with by every commander, and he likens the disregard of the weather factor to be about as serious as to forget to provide food, clothing, or ammunition. Some historical instances are given of the influence of weather on war. Mention is made of the weather controls being divided into two classes. In one the conditions are accidental, sudden, or unexpected, and in the other case the conditions are natural or normal, but not necessarily prepared for. The author says to know in advance the general climate of the war zone is very essential in planning a campaign or in organising a single engagement. From the nature of the despatches, he concludes that there was nothing in the meteorological conditions in August and in early September which had any noticeable effect upon the campaign. In mid-September constant reference was made to the difficulties caused by the heavy rains. The normal rains in September and October filled the trenches and often drove the troops out to fight with their bayonets, and the difficulty of moving heavy guns through the deep mud was a serious handicap to both armies, whilst the rivers were also flooded. The roads became quagmires, and in Galicia the soldiers were marching and camping in the snow. With the use of aeroplanes

and airships modern warfare has been rendered more than ever dependent on the weather.

The Central for December, 1914, states that 174 former students or members of the staff of the City and Guilds College, Exhibition Road, South Kensington, are now on active service. The positions held by some of these are mentioned in the nine pages devoted to old students and their doings, which always forms one of the most noticeable and, to most readers, welcome features of the magazine. A well-illustrated article of exceptional interest is that by Mr. A. C. Cookson describing the work which falls to the lot of the maintenance department of a railway.

PART I. of the new volume of the Proceedings of the Physical Society of London extends to 117 pages. The president, Sir J. J. Thomson, opens the volume with the account he gave at the Cambridge meeting of the society of his attempts to produce radiations to fill the gap of about eight octaves between the softest Röntgen radiation and the shortest ultra-violet rays. His address as president closes the issue. It deals with the production and nature of the ions in gases. At the present time the interaction between ions and molecules appears to be explainable either by Maxwell's inverse fifth power law or by the law of impacts of hard spheres. Two papers are devoted to electrical questions—Mr. D. Owen's on an alternating-current bridge method of determining inductance in terms of resistance and capacity; and Mr. A. F. Hallimond's on the voltage ampere curves given by a great number of point contacts when the voltage applied to the contacts is gradually raised. The only paper on heat is Mr. Barratt's on the heat conductivities of a number of glasses, woods, and other bad conductors. Two papers deal with general physics. Mr. B. W. Clack gives the final results of his work on the diffusivities of salts in dilute solutions, and Prof. E. P. Harrison traces the effect of temperature on Young's modulus for wires.

IN the *Revue générale des Sciences* (vol. xxv., p. 777) M. Louis Brunet discusses the position of the combatant nations as regards the power of obtaining supplies of the metals copper, zinc, lead, tin, nickel, and mercury, which play so important a part in modern warfare. The conclusion reached is that the position of the Franco-Anglo-Russian alliance is far better than that of the central European empires, not so much on account of the greater producing power of the alliance, but owing to its mastery of the sea, which has enabled the English and French fleets to prevent in large measure the importation of metals declared "contraband of war" from neutral countries into Germany and Austria.

THE *Times* Engineering Supplement of January 29 gives an interesting account of aeronautics in 1914. Among other notable achievements of the past year are the British record of 135 miles an hour, heights of five miles scaled, or closely approached, by both French and German machines, and flights in seventy miles-per-hour winds by fliers who do not pretend to be "star-pilots." No fewer than nineteen persons flew together in one huge aeroplane of Russian make in 1914. One of our own Army-built stable aeroplanes has climbed at the rate of 1700 ft. a minute—a rate of ascent four times as fast as an express lift in an American hotel. Eight months ago Dr. Glazebrook gave, before the Aeronautical Society, a *résumé* of the experiments which had achieved stability—experiments vouched for by Colonel Seely, who verified them by making uncontrolled flights in person without any previous practice. Though Bryan and Harper had published their mathematical work in 1911, and Lanchester three years before that, it was only these telling practical outcomes of their work that brought these authors into their own in England during the past year.

OUR ASTRONOMICAL COLUMN.

WOLF-RAYET STARS AND THE PLANETARY NEBULÆ.—There are indications that these enigmatic bodies will shortly be fitted into the scheme of stellar evolution. Hitherto, whilst it was felt that they must be more or less related, actual evidence was of the slenderest. Prof. J. W. Nicholson was, however, led by his mathematical investigations of the spectra of *nebulium* and Wolf-Rayet stars to suggest that they were successive stages in the evolution of matter. Perhaps we can now say that this is an observed fact. The *Astrophysical Journal* for December (1914) contains some remarkable preliminary results obtained by Mr. W. H. Wright in the course of the spectroscopic examination of some planetary nebulæ possessing central condensations. A spectrogram secured with the 36-inch refractor (Lick), under exceptionally close following during a long exposure on N.G.C. 6572, showed *the spectrum of the nucleus* crossed by the bright nebular lines of the envelopes, and, moreover, in the spectrum of the nucleus appeared a band 17 Å. wide in place of the line λ 4686. These facts recalled the hitherto unique hydrogen envelope star of Campbell (BD $+30°$ 3639). Detailed study of the spectrum of this body was then undertaken and, as was expected, the fact was established that the hydrogen envelope really gave the spectrum of a planetary nebula.

Here, then, are two cases of planetary nebulæ having nuclei which exhibit the spectra of Wolf-Rayet stars and, together with three other cases (N.G.C. 6826, N.G.C. Index 418, and N.G.C. 40) cited from unpublished observations by Merrill, Campbell, and Paddock respectively, the facts are held to justify the conclusion that such nuclei are in *all cases* Wolf-Rayet stars. The evidence does *not* establish the converse proposition that Wolf-Rayet stars are in all cases the nuclei of planetary nebulæ The author promises a more detailed account of the observations and also the early publication of a list of nebular lines. The materialisation of these promises will be eagerly anticipated

THE SOLAR ROTATION IN 1913.—In the current number of the Journal of the Royal Astronomical Society of Canada (September-October, 1914) Mr. H. H. Plaskett gives an account of the results of a study of the solar rotation which he and Mr. R. E. De Lury secured during 1913. The method was spectroscopic, and the region of the spectrum examined was λ 5600; thirty-one plates were utilised, on each of which were recorded nine rotation spectra; in these spectra displacements were measured for twelve lines. Tables summarise the measures and the results. The results are compared with those obtained for the same region of the spectrum in the years 1911 and 1912 by Messrs.

J. S. Plaskett and R. E. De Lury, using the same apparatus. The 1911 and 1912 values are found to be considerably greater than those obtained in 1913. A measurement of the 1913 plates by Mr. J. S. Plaskett results in the same values as those secured by Mr. H. H. Plaskett. The communication suggests the possible origin of the discrepancies, and discusses them individually. The author finally concludes that there is no evidence of systematic difference of velocity for different elements, and that at present it is impossible to settle the question of a variation in the solar rotation or any similar problem until the personal errors of measurement of each observer have been determined. He gives the formula which represents the values of the solar rotation for 1913.

"L'ASTRONOMIE" FOR SEPTEMBER AND OCTOBER, 1914.—It is satisfactory to be able to state that in spite of the difficulties encountered at Paris in August and the following months of last year, the Bulletin of the French Astronomical Society, *L'Astronomie*, has not broken its continuity. The September and October numbers are now to hand, and those of November and December are completed, and will soon be issued. The September number continues the interesting series of articles on visits to the European observatories, that to the Zurich Observatory being here described and illustrated. Under the title "Jupiter" the observations made on that planet during the opposition of 1913 are described in some detail. Interesting curves are included, showing the displacement of the large red spot in longitude for a period of six months, and the variations of the duration of its rotation for the period 1830–1913. The chief contribution to the October number is a series of accounts of observations of the eclipse of the sun in August last, made from and outside of the line of totality. Some of these, notably that by the expedition from the Meudon Observatory, have already been referred to in these columns.

THE CANADIAN ASTRONOMICAL HANDBOOK.—"The Observer's Handbook for 1915," published by the Royal Astronomical Society of Canada, and edited by Dr. C. A. Chant, is in the seventh year of publication. The present issue is conspicuous by the absence of the brief review of astronomical progress, but this is probably more than neutralised by the addition of useful tables of double and variable stars, and an interesting table, compiled by Mr. W. E. Harper, giving some concise information regarding the brighter stars. The last-mentioned deals with 272 stars and five nebulæ, and gives the chief known facts concerning their distances, spectral types, proper motions, radial velocities, etc. In the section on the constellations charts are given containing the stars down to the fifth magnitude. Mr. W. F. Denning contributes the section devoted to meteors and shooting stars. The other sections are mainly on the lines of former issues.

COPPER SMELTING IN CANADA.

THE Canadian Department of Mines has issued an interesting report of some 184 pages, profusely illustrated, upon the copper smelting industries of Canada, from the pen of Dr. Alfred W. J. Wilson, Chief of the Metal Mines Division. This report forms a valuable record of the position of Canada as a copper producer at the date at which it was written, namely, the close of the year 1912. As the author very truly observes, "the period of time which necessarily elapses between the writing, and the publication and distribution of Government reports is usually too long to make them an important medium for the distribution of new knowledge in an old and well-established industry," and indeed the present report well exemplifies the correctness of this view, there being nothing in it with which copper smelters throughout the world are not thoroughly familiar, its chief value lying accordingly in the fact that it furnishes a trustworthy "record of the status of the industry at the time it was prepared," which Dr. Wilson puts forward as the chief purpose for which it was written.

The work contains an introductory chapter, separate chapters dealing in detail with the works of the Canadian Copper Company, the Mond Nickel Company, Ltd., the Consolidated Mining and Smelting Company of Canada, Ltd., the Granby Consolidated Mining, Smelting, and Power Company, the British Columbia Copper Company, and the Tyee Copper Company, and final chapters of summaries and statistics. From these it appears that at the date mentioned there were in operation in Canada in the seven smelting works of the above six companies twenty-nine large rectangular water-jacket blast furnaces, with a total hearth area of 2580 sq. ft., and a rated capacity of 15,600 tons of charge per twenty-four hours; the largest of these is a 50 in. by 420 in. furnace of the Consolidated Mining and Smelting Company, with a rated capacity of 875 tons of charge per twenty-four hours, but there are no fewer than four of these furnaces with a smelting capacity of 700 tons or more per twenty-four hours, and only two with a capacity below 400 tons. The matte produced in these blast furnaces is blown in converter plants, of which there are five in all, two being operated by the Granby Consolidated Mining, Smelting, and Power Company, at their Grand Forks and Anyox Works respectively, and one each by the Canadian Copper, the Mond Nickel, and the British Colombia Companies. All but the last-named are basic lined, some using the horizontal cylindrical and some the vertical patterns.

The Canadian Copper Company produces a furnace matte with about 28 per cent. of copper-nickel, which is blown in the converters to rich matte, with 80 per cent. of copper-nickel; the Mond Nickel Company runs a furnace matte with 33 per cent. of copper-nickel, which is also blown up to 80 per cent. (38 per cent. copper, 42 per cent. nickel, 15 per cent. iron); these rich mattes are shipped for further treatment and refining. The Granby Consolidated Company was only operating the works at Grand Forks in 1912, the Anyox works not having been started as yet; they were producing furnace matte with 35 per cent. of copper, which was blown up to blister copper of good quality with 99·5 per cent. of copper, containing, in addition, gold and silver; the British Columbia Company smelted a furnace matte with 40 per cent. of copper, which was also blown up to blister copper. Both these companies shipped their blister copper to the United States for refining.

As to the two companies that do not operate converters, namely, the Consolidated Mining and Smelting Company at Trail, and the Tyee Company, the former runs a first furnace matte with 10 per cent. of copper, which is twice concentrated in the furnaces, the second matte containing 15 to 20 per cent. of copper, and the final matte 40 to 42 per cent. of copper; the Tyee Company runs largely on customs ores, and produces a final matte with 40 to 43 per cent. of copper; both these companies ship their mattes to the United States for further treatment. It thus appears that although Canada produced in the above year nearly 78 million pounds of copper, not one pound of this was converted into merchantable copper within the Dominion. The only reference to this fact to be found in the report before us is an

incidental statement by Dr. Wilson that "there are no copper refineries in Canada." It is difficult to understand why Canadian copper producers should be willing to forgo the very handsome profit realised by the refining of their crude products, and why they should be so ready to ship these products to the United States instead of completing the refining process at home.

Dr. Wilson avows as one of the objects of this report that "it may possibly be found useful to parties who are contemplating investments in the development of similar industries in other sections of the country," but it is surely of far greater importance to Canada that it should be in a position to utilise fully its mineral production, and to put it on the market as material ready for use in the arts, and not in an only partly manufactured condition. Surely one of the many economic lessons enforced by the present war is the need for the Empire to be as nearly as possible self-supporting, so that we may be, as far as practicable, independent of other nations for the supplies that we chiefly need. This is not always possible, because even the vast British Empire does not furnish all the natural products that we use, but in the copper smelting industry of Canada we have an example where we are deliberately giving away our natural advantages. Seeing that this is a case where both patriotic motives and commercial interests point in the same direction, it may fairly be hoped that there will be found in Canada men enterprising enough to finish what they have begun, and that the reproach that the Dominion is unable to refine its own copper production will soon be removed. This is certainly not the conclusion that Dr. Wilson has drawn, nor perhaps the one which he wishes to be drawn from his careful and comprehensive report, but it certainly is the main impression that the reader of his report is likely to carry away from its perusal. H. L.

AGRICULTURAL AND HORTICULTURAL RESEARCH.[1]

THE varied research activities manifest at Woburn are reflected in the contents of the fourteenth report. They include experiments in potato spraying, trenching, the distribution of soil particles, the effect of one crop on another, the control of the black currant mite, and the loss of manure in transit. It is not possible within the limits of a short notice to discuss all these subjects, nor perhaps is it necessary. For as is inevitable with interim reports, final results may not be expected. Thus with respect to the experiments in potato spraying with Bordeaux mixture and with Woburn paste, the report, though it advances our knowledge another stage, does not make final revelation of the secret of the prophylactic virtue of copper sulphate against late blight (*Phytophthora infestans*). Mr. Pickering recognises that the problem is complex, and inclines to the view that the spray fluid acts rather by inducing healthier foliage than by destroying the spores of the fungus (p. 30). Although on the scientific side of the question much remains obscure, Mr. Pickering records notable progress on the commercially practical side. He finds that Woburn paste used at the rate of 15 or 16 lb. is equivalent in its effect to Bordeaux mixture made from 8 lb. copper sulphate, and this although the paste contains five or six times less copper than does the mixture.

If we may offer a suggestion it is that Woburn should undertake a series of records spread over a term of years with the view of settling a question which vexes the minds of not a few of our best and biggest growers—whether in the *long run* spraying with Bordeaux mixture is or is not profitable. Those who know only the laboratory side of the subject may scoff at the question, but Mr. Pickering's experience would doubtless confirm the reviewer's, that many hard-headed lowland Scots do not spray, and give as their reason that it does not pay. Evidence from America, where large-scale spraying experiments have been carried out, would appear to put the men in the wrong, but in spite of that and similar evidence in this country, these men maintain their negative position. If, as Mr. Pickering estimates, the benefit of spraying in a year of blight is only about 10–30 per cent., and if, as is well known, spraying to be of much use must be begun before the disease appears, the unconverted grower may have economic justification for his heresy.

Mr. Pickering's experiments in bastard trenching, carried out in conjunction with Dr. E. J. Russell, lead to negative results which are at first sight surprising. For it might be supposed, from what is known of the need of roots for air, that the mere disturbance of the soil would benefit the crop. It has to be borne in mind, however, that the experiment was carried out with fruit trees, and it is at least probable that when the trees were planted the soil in which they were planted was disturbed sufficiently for their needs. Mr. Pickering is right in believing that where a hard pan exists not far below the surface, bastard trenching even without the addition of manure is of value.

When so much is done at Woburn it is almost ungracious to ask for more, but we should like very much to see the effect of the bastard trenching on a crop of vegetables—carrots or beet, for example. It is rash to prophesy in horticulture, but we incline to the belief that the effect, though perhaps not great, would be positive and not negative, as in the case of the fruit trees.

The Annual Report (1913) of the Agricultural and Horticultural Research Station at Long Ashton, Bristol, shows that this comparatively young institution is carrying out a large amount of useful work.

As is natural, much of the report is concerned with problems connected with cider and perry-making. A subject of wider interest is that of the influence of the stock upon vintage quality and other characters of apples. Growers as a class are apt to maintain that the stock exercises a considerable though ill-defined influence on the scion, and there is a good deal of scattered information on the subject. The analyses of fruit juices published in the report indicate that the nature of the stock is without influence on the quality of the juice of the fruit; save that the rates of fermentation of juices obtained from fruit grown on the Paradise stock are in most cases higher than those from fruit grown in the free stock.

For our part we are inclined to believe that light would be thrown on the subject by an investigation of the oxydases of scion and stock; for it is by no means improbable that research will discover that these potent agents may pass along the wood and bast, and thus affect the rate of chemical change in far-distant tissues.

The influence of grass on the growth of orchard trees—a subject brought into prominence by Mr. Spencer Pickering's observations—is discussed by Mr. Barker on the basis of experiments carried out at Long Ashton and in several demonstration orchards in the west of England.

Mr. Barker, beside confirming the view that grass

1 (1) Fourteenth Report of the Woburn Experimental Fruit Farm. By the Duke of Bedford and Spencer U. Pickering. (London: Amalgamated Press, Ltd., 1914.) Price 2s. 9d. post free.
(2) University of Bristol. The Annual Report of the Agricultural and Horticultural Research Station. (The National Fruit and Cider Institute). Long Ashton, Bristol. 1913. Pp. 110. (Bath: *Herald* Press, n d.)

exercises a depressing influence on tree growth makes the new point that trees grown in land which is first cultivated and subsequently grassed are apt to be out-distanced in growth by those which are grown in grass from the start of the experiment. Mr. Barker suggests that this may be due to the trees previously free from the grass feeling the ill-effects of grassing all the more acutely because of their former immunity from those effects. The phenomenon does not appear to conform with current opinion, which holds that, once they are well-established, trees do not suffer from growing in grass.

PARIS ACADEMY OF SCIENCES.

PRIZES PROPOSED FOR THE YEAR 1916.

Geometry.—The Francœur prize (1000 francs), to the author of discoveries or works useful to the progress of pure or applied mathematics; Grand prize of the mathematical sciences (3000 francs), subject proposed, to apply the methods of Henri Poincaré to the integration of some linear differential equations, algebraic, and chosen from the simplest examples; the Poncelet prize (2000 francs), for work in pure mathematics.

Mechanics.—A Montyon prize (700 francs), for invention or improvement of instruments useful to the progress of agriculture, the mechanical arts or sciences; the Henri de Parville prize (1500 francs) for original work in mechanics; the Fourneyron prize (1000 francs), to the author of the most important improvements in aviation motors.

Astronomy.—The Lalande prize (540 francs), to anyone, in France or elsewhere, who has published the most interesting observation, memoir, or work useful to the progress of astronomy; the Valz prize (460 francs), to the author of the most interesting astronomical observation made in the course of the year; the Janssen prize, for an important progress in physical astronomy.

Geography.—The Tchihatchef prize (3000 francs), for the recompense or encouragement of naturalists of any nationality distinguished in the exploration of the lesser-known regions of Asia; the Gay prize (1500 francs), for improvements in instruments or methods of topometrical and topographical surveys; the Binoux prize (2000 francs), for work in geography or navigation; the Delalande-Guérineau prize (1000 francs), to the Frenchman who, as traveller or *savant*, shall have rendered the greatest service to France or to science.

Navigation.—The extraordinary prize of 6000 francs for work increasing the efficiency of the French naval forces; the Plumey prize (4000 francs), for an improvement in steam engines or other invention contributing to the progress of steam navigation.

Physics.—The Hebert prize (1000 francs), for a treatise or discovery valuable for the popularisation and practical use of electricity; the Hughes prize (2500 francs), for a discovery or work contributing to the progress of physics; the La Caze prize (10,000 francs), to the author, French or foreign, of works or memoirs contributing to the progress of physics; the Kastner-Boursault prize (2000 francs), for the best work on the various applications of electricity in the arts, industry, and commerce.

Chemistry.—The Jecker prize (10,000 francs), for work in organic chemistry; the Cahours prize (3000 francs), for the encouragement of young workers already known for researches in chemistry; the Montyon (unhealthy occupations) prize of 2500 francs, and mention of 1500 francs, for the discovery of a means of reducing the unhealthiness of a trade or calling; the Houzeau prize (700 francs), for a young deserving chemist; the L. La Caze prize (10,000 francs), to the author, of any nationality, of the best work on chemistry.

Mineralogy and Geology.—The Victor Raulin prize (1500 francs), for facilitating the publication of works relating to geology and palæontology.

Botany.—The Desmazières prize (1600 francs), for the best publication during the year on Crytogams; the Montagne prize (1500 francs), for work on the anatomy, physiology, development, or description of the lower Cryptogams; the Da Coincy prize (900 francs), for work on phanerogams; the de la Fons-Mélicocq prize (900 francs), for the best botanical work on the north of France.

Anatomy and Zoology.—The Savigny prize (1500 francs), for the assistance of young travelling zoologists, not receiving a Government grant, and who study specially the invertebrates of Egypt and Syria; the Cuvier prize (1500 francs), for a work on zoological palæontology, comparative anatomy, or zoology; the Thore prize (200 francs), for the best work on the habits and anatomy of a species of European insects.

Medicine and Surgery.—The Montyon prize (prize of 2500 francs, mentions of 1500 francs), for works or discoveries judged most useful to the art of healing; the Barbier prize (2000 francs), for the author of a valuable discovery in the surgical, medical, or pharmaceutical sciences or in botany having relation to medical science; the Bréant prize (100,000 francs), for the discovery of a means of curing Asiatic cholera or discovering the causes of this disease. Failing the award of the prize, the interest on the capital sum will be awarded for advances in connection with cholera or any other epidemic disease; the Godard prize (1000 francs), for the best memoir on the anatomy, physiology, and pathology of the genito-urinary organs; the Baron Larrey prize (750 francs), to a doctor or surgeon in the army or navy, for the best work presented to the academy and dealing with medicine, surgery, or military hygiene; the Bellion prize (1400 francs), for work or discoveries profitable to the health of man or to the amelioration of the human species; the Mège prize (10,000 francs), to an author who should continue and complete his essay on the causes which have favoured or retarded the progress of medicine from antiquity to the present day. The interest on this sum can be awarded by the academy as they see fit.

Physiology.—The Montyon prize (750 francs), for a work on experimental physiology; the Philipeaux prize (900 francs), for works in experimental physiology; the Lallemand prize (1800 francs), for work relating to the nervous system in the widest sense of the words; the Pourat prize (1000 francs), for a memoir on the cell constituents which exert the main influence on the water content of the different tissues; the La Caze prize (10,000 francs), to the author, French or foreign, offering the best work on physiology; the Martin-Damourette prize (1400 francs), for a work on therapeutical physiology.

Statistics.—The Montyon prize (prize of 1000 francs, and two mentions of 500 francs). The academy will consider not only memoirs sent in manuscript, but also works already printed and published which are brought to their knowledge.

History of Sciences.—The Binoux prize (2000 francs).

General Prizes.—The Arago medal; the Lavoisier medal, for eminent services to chemistry without distinction of nationality; the Berthelot medal, to persons who have been awarded by the academy prizes in chemistry; the Henri Becquerel prize (3000 francs); the Gegner prize (3800 francs); the Lannelongue prize

(2000 francs), for the relief of unfortunate scientific men or their immediate relations; the Gustave Roux prize (1000 francs), for a young French scientific worker; the Trémont prize (1100 francs); the Wilde prize (one prize of 4000 francs and two of 2000 francs), awarded without distinction of nationality for work in astronomy, physics, chemistry, mineralogy, geology, or experimental mechanics; the Lonchampt prize (4000 francs), for the best memoir on work on the diseases of man, animals, or plants from the special point of view of the introduction of mineral substances in excess as the cause of these diseases; the Saintour prize (3000 francs), for work in the physical sciences; the Henri de Parville prize (2500 francs) for original scientific work or publication; the Victor Raulin prize (1500 francs), for assisting the publication of work relating to geology and palæontology; the Houllevigue prize (5000 francs); the Caméré prize (4000 francs), to a French engineer for improvements in the art of construction; the Jérome Ponti prize (3500 francs); the Bordin prize (3000 francs), the subject proposed for 1916, researches relating to the determinism of sex in animals; the Parkin prize (3400 francs), for researches on the curative effects of carbon in various forms, and more especially in gaseous form of carbon dioxide, in cholera, the different forms of fever or other diseases, or, as an alternative subject, for researches on the effects of volcanic action in the production of epidemic diseases in the animal and vegetable kingdoms and in causing abnormal atmospheric disturbances; the Jean Reynaud prize (10,000 francs); the Baron de Jouest prize (2000 francs), for a discovery useful to the public welfare; the prize founded by Mme. la Marquise de Laplace (a complete collection of the works of Laplace) to the first student leaving the Ecole Polytechnique; the Felix Rivot prize (2500 francs), divided between the four students leaving each year the Ecole Polytechnique with the first and second places in the section of Mines and of Ponts et Chaussées.

THE ENGLISH CERAMIC SOCIETY.[1]

THE English Ceramic Society, to judge from the latest issue of its Transactions, still continues to do excellent work. Although the present number contains no article of first-rate importance, it is obvious from the general character of the communications, and the nature of the discussions by which they are followed, that the members are fully alive to the value of the society in promoting exchange of experience and opinion on the many obscure problems with which the art and craft of the potter is beset. No indication of the health and vigour of the society could be more significant than the manner in which individual knowledge and experience are made to contribute to the general benefit of the industry. Such a spirit has been far from the rule in times past, for in no other industry have trade secrets and little details of practice been more jealously guarded than in potting. The enlightened example of the society will do much to break down this absurd exclusiveness and short-sighted selfishness. If each thus contributes to the common stock, the general welfare is increased, and the position of the industry as a whole is enhanced, to the collective benefit of the manufacturers and the country generally. In this respect we have something to learn from our enemies. The spirit of co-operation has largely contributed to raise manufacturing in Germany to the formidable position it has gained. If we are to maintain, and especially if we are to increase our pre-eminence as the largest traders in the world, this spirit of co-operation and mutual helpfulness must continue to prevail, and to grow.

The communications in the present issue of the Transactions call for no special comment. The "Symposium on Fineness of Grinding" brought out a considerable difference of opinion as to the relative merits of cylinder- and pan-grinding, and as to the influence of the fineness of the particle on plasticity, contraction, texture, porosity, and "crazing"—all of them points which are capable of a satisfactory solution if attacked experimentally in a scientific manner. These are typical of the kind of problems with which the County Pottery Laboratory at Stoke-on-Trent may be expected to concern itself. The discussion on grinding bore unmistakable testimony to the influence of the human element, especially in pan-grinding. That influence was no less marked in the course of the discussion on "firing," and of the relative importance of "tops" and "bottoms," where opinion was equally divided. The average "fireman" may be (and evidently is in the opinion of some) a rather perverse and obstinately conservative kind of individual, wholly wedded to traditional practice, but if this volume falls into his hands, he may at least be able to retort that he knows more about firing than his betters seemed to know about French on the occasion of their visit to the pot-banks of our Ally! *Verb sap.* T.

EDUCATION IN RELATION TO INDUSTRY AND COMMERCE.[1]

Our First Purpose.

WE are now in the midst of the greatest struggle that the British Empire has ever been engaged in. The outcome of the struggle involves not only our existence as a nation, but the existence of those principles and ideals of life and government which we hold dear. Our energies, individual and national, must for the moment all be turned to one purpose, to bring the war to a successful conclusion. The men who are fighting at the front are doing magnificent work, but it is for each of us in his own sphere to do his share in order that at the earliest possible moment the world may be free from the terrors of the war.

In time, peace will come. With that peace there will be renewed the international struggle for trade, and British enterprise must be ready to take full advantage of the great opportunities that will then occur. Individual effort will not be of any great use. Concerted action is essential if we are to retain the foremost place in the world of trade; and just as we are vigorous in the pursuit of the present war, so as a nation must we be vigorous in the pursuit of industrial and commercial supremacy.

The Industrial Army.

How is this supremacy to be attained? It is primarily a question of education. We must have in the first instance an industrial army, capable, alert, and well trained. The production of this army must begin in the elementary schools. The leaving age of school children, for urban districts at least, must be raised to fourteen years, and age must be made the only leaving qualification. Moreover, the children should leave at the end of the educational year in which they reach the leaving age, or, at any rate, they should leave only at the end of the school term in which the leaving age is reached. For this reform we must look to Parliament, as it is impossible for a

[1] Address delivered before the National Association of Education Officers on January 1 by the president, Mr. James Graham.

local authority to make the change in view of the many local interests involved.

With the leaving age at fourteen years, local authorities and teachers, after making a careful selection of the boys and girls who should go forward to a secondary school at the age of twelve, could turn their attention to the children left in the elementary schools, who as a body may be expected to receive very little general education beyond that obtained in the elementary schools. For these children it would be possible to organise special two-year courses which should prove extremely valuable in preparing them for the work they will undertake on leaving school.

Preparation in the Elementary Schools.

A large proportion of the boys from our elementary schools enter some trade or some branch of industry, and for these the courses of study between the age of twelve and fourteen years of age, while remaining on broad general lines, should be somewhat industrial in character. There is at the present time a strong demand for industrial or vocational education in which practical methods and manual training are involved, but it must not be forgotten that the purpose of elementary education is not to prepare for a particular trade, but rather to develop all the child's faculties so that he may be prepared to enter any walk of life. The all-round general education of the child must be the first consideration, and in the suggested courses of study no attempt should be made to teach any specific trade. The courses would be entirely preparatory and general-trades work, and would involve teaching the theory and principles which underlie British trades generally. "Learning by doing" would take the place of "book learning." An attempt would be made to put the whole boy to school, to train the entire faculties of the boy, intellectually, morally, and physically, and so fit him for life. The work which is now generally done in artisan evening schools would be covered by every boy in an urban elementary school, where the work would be done under vastly better conditions, as the teaching would be given to boys who are fresh and vigorous instead of to tired boys who have already done a day's work.

The workshops of the country require boys with self-effort, self-reliance, initiative, and thought, and it should be the object of these courses to provide just that training which would develop these habits. The general adoption of this development in elementary education would create in the near future a supply of intelligent boys, who would rapidly become in the workshops intelligent and skilled workers, ready and able to adapt themselves to the changing working conditions of the trade and of the times; and we should hear no more of the employers' complaint that the present product of the elementary schools is not the type of youth they require in their shops.

In the proposed courses, roughly one-third of the school time of the boy during the age of twelve to fourteen should be devoted to the study of English subjects, one-third to mathematics and technical drawing, and the other third to actual experiments and practical work in the laboratory or workshop. The scheme of instruction would be arranged with the intention of securing an all-round development of the boy's faculties in a thoroughly practical manner, in order that by the time the boy is ready to commence work he may possess not only a general grip of the principles which underlie trades in general, but such intelligence, reasoning power, and adaptability as are calculated to secure for him the approval and good will of his employer.

This preparatory practical training before the boys enter the workshop or factory is the first step in the production of a capable industrial army. I reiterate that at this stage the practical training must be general; there must be no attempt to teach any specific trade, but every effort must be made by curriculum and by method to develop all the faculties of the boy.

Education of Boys in the Workshops and Factories.

We now come to the second age period and deal with the problem of the boys from fourteen to eighteen years of age. The boys have now left the school. They are in the workshops, and specific trade instruction must begin. Opportunities must be provided for the boy to lay the foundation of a livelihood which in the main will persist through life. At the same time it must not be forgotten that the boy is something beyond a potential wage-earner or producer. He is a future citizen, and in the scheme of education for such youths time and opportunity must be provided not only to enable him to understand the occupation which he has entered and from which he is to obtain his livelihood, but also to enable him to understand his duties as a citizen. There should be provided opportunities for mental, physical, and moral training which shall fit him for manhood and for his place in the nation.

The Teaching of Trades.

The modern workshops are highly organised and specialised with a view to enable employers to reduce the cost of production and to compete successfully for orders; consequently it is practically impossible to-day for an English boy to learn the whole of a trade in a workshop. It is in this connection that the technical schools of the country working in close co-operation with the workshops should fulfil their real function. When the boy enters the workshop his education is far from complete, even if he has had the general practical training outlined above. Continued education applicable to his chosen trade must be given, and the problem that confronts us is how best to ensure that the boy shall have this technical education in spite of the fact that the industrial conditions are vastly different from what they were.

In the old days the employer was the sole educator of his apprentice or young worker. Under present conditions it is impossible for the employer to give the young worker all the instruction he requires. The schoolmaster, therefore, has been called in to undertake part of the work. Under this divided responsibility, the work of the teacher is to give the young worker a thorough grasp of theoretical principles and to provide him with such knowledge and training as will enable him to adapt himself to changed conditions, to attack new problems, and to show initiative and skill in his work. The duty of the employer, on the other hand, is to give that advice and assistance to the teacher as will ensure that the work of the school shall not be merely academic but essentially practical, and to supplement the instruction by doing all that is possible to give the young worker ample opportunities for getting an all-round experience of his trade.

At the present time the young worker is expected to get the necessary technical education by attending the school for three or more evenings a week after he has done a full day's work in the workshop or in the factory. It is quite unnecessary to point out the drawbacks and disadvantages of this system. Excellent work has been done in the evening schools by youths of grit and character, who have attended them, and a number of employers have done a good deal by means of suitable inducements to encourage their young workers to take full advantage of the opportunities for gaining increased knowledge and experience—but voluntary attendance at evening

schools and voluntary schemes of co-operation between employers and educational authorities do not really touch the huge problem. The only effective way to train the rising generation of skilled workmen after leaving the elementary schools is to have half-time in the workshop and half-time at the technical school between the ages of fourteen and eighteen. In the words of our friend, Mr. J. H. Reynolds, the solution of the problem is "Half-time at the right time." Good health and physique are as necessary to the skilled workman as is the technical knowledge applicable to his trade, and the youth should have the opportunity of obtaining this technical knowledge without detriment to his health. In other words, he should be allowed to attend suitable courses of instruction for periods of suitable length within the normal working day.

Half-time in the workshop and half-time at the technical school is certainly ideal, but possibly at present it is not practicable. At least some modification of this arrangement must be adopted to enable young workers to attend day courses on three or four half-days a week, and thus get the necessary continued education during the daytime. Only a small proportion of the young workers of the country attend evening schools in spite of all the inducements offered and all the encouragement given, and no one would assert that they derive the greatest benefit from their attendance. The result would be infinitely better if the youth spent sixteen to twenty hours a week during the daytime at the technical school and the remainder of his time at the works.

If England is to maintain her place in the world as an industrial and commercial nation, she will have to adopt this method of teaching trades to her boys. Other nations are doing a great deal in this direction. We must do more than they because we have more at stake, and we must act promptly and boldly. Legislation is necessary; it must be made the duty of the employer to allow to the employee the time required for continuing his education according to the requirements of the trade or business which the boy enters. The need for a further limitation of juvenile labour is urgent, and it is equally necessary to place employers of labour under statutory obligation to enable young persons under eighteen years of age who are in their employment to attend courses of technical and general instruction at certain hours of the daytime when they are not too tired bodily and mentally to profit from the instruction. An Act of Parliament limiting the hours of employment for all young persons under eighteen and placing that limit so low that there shall be ample time during the normal working day for attendance of the young people at suitable courses of instruction is required.

The Leaders of Industry.

An army requires capable leaders, and there must be in connection with the training of an industrial army opportunities for the selected few to become successful leaders of industry. For these no education can be considered too good. A thorough training in the secondary schools and the universities, combined with adequate experience in a workshop or factory, is necessary. Science now plays so important a part in industry that more vigorous efforts than hitherto must be made to secure the highest and most suitable education and training for capable youths, and the future leaders of industry in England must be induced to equip themselves for competition on equal terms with the more highly trained young men of other nationalities.

The value of a thorough general education in the secondary school and university cannot be overstated, and full technical knowledge of the particular industry is equally necessary. The training of the young men must be practical as well as theoretical; actual experience in the workshop or factory is as important as the scientific training at the technical college or university, and service in a recognised office, workshop, or factory must be compulsory for a period either before or after the college course, or during the continuance of the college course. The period of training for the men who are to fill the higher posts in industry should be at least for a period of six or eight years, in order that the student may have time to develop his powers of thought and to obtain a complete knowledge of the theory and principles underlying the industry, together with a first-hand knowledge of the processes of the industry obtained by actual contact with it in the workshop or factory.

Some of the highest posts in industry will be filled by men who, in the first instance, enter the works as youths, and who on account of their unusual capacity force their way through the various grades to fill positions of responsibility. It is of the greatest importance that opportunity should be provided for youths of proved ability to secure the education and training required of those who fill the highest positions in industry if for financial reasons their parents are unable to provide that training. In this connection a duty falls upon the local education authority to make special provision for the benefit of such youths. Scholarships must be provided to enable young workers of proved ability to attend day courses at the technical college or university for three or four years in order that they may obtain a professional training that will prepare them to fill posts of greater responsibility in the future.

In the past, England has had too few specially trained leaders of industry. To organise industry, men, shrewd, enterprising, and with full knowledge regarding the application of scientific methods in the development of industry are required. For these men there must be a most comprehensive and thorough education and training on the solid foundation of a good general education. They must have a sound knowledge of the mutual relation of science and industry and an intimate knowledge of their particular industry in order that all problems may be attacked systematically and on a scientific basis. Men of practical capacity and trained thinkers, endowed with the power of applying their knowledge to the practical necessities of industrial processes are essential in the industrial army, and the absence of a comprehensive scheme for the training of such men must prejudice the future of our country.

Commercial Army Necessary.

It is not sufficient to have a well-equipped industrial army; there must be markets for the products of industry. The goods produced must be sold, and we must have, therefore, a commercial army as well trained and equipped for the work of distribution as the industrial army is for the work of production.

It has often been stated that England is deficient in what is usually called technical education, but we must frankly acknowledge that she is infinitely worse off in regard to commercial education in spite of the development of this type of education during recent years.

The United Kingdom still ranks first among the commercial countries of the world, with its enormous annual imports and exports, its immense home trade, and its great shipping trade. We not only carry the whole of our own commodities, but we do an enormous amount of carrying for other countries. In view of these facts it is strange that commercial education

should have been so strangely neglected in England. Travellers, agents, and consuls representing the interests of British trade abroad are generally foreigners who have been thoroughly trained in the practice and theory of business while at home. The majority of our foreign correspondents and managers of firms with branches abroad are likewise foreigners. For years we have been giving the foreigners a practical experience and knowledge of our manufactures and methods of business which qualify them to meet us as strong competitors. These foreigners come in large numbers; they very often enter our business houses with a view of acquiring information as to the inner working of the firm's business connections, and on going back to their own country they join a rival establishment or set up an establishment of their own.

English firms are driven to the employment of foreigners because young men in England do not pay sufficient attention to commercial education and to the study of foreign languages.

The Training of a Commercial Army.

This state of affairs cannot be allowed to continue. We must produce an army of trained traders, and in the production of this army education must play a prominent part.

The first essential for one who is to enter a commercial career is a sound general education in which the study of English and at least one foreign modern language should be of first importance. Any intending business man should have a secondary-school education and specialised commercial study should not be commenced until the age of fifteen at least. In many good secondary schools commercial sides are organised for the higher forms, and the studies of the pupils are given a certain amount of commercial bias.

The commercial education so given is strikingly inadequate in comparison with the provision in other countries. Unfortunately we in England still retain the idea that a small amount of education is sufficient for a man destined to be a trader, whereas other countries are more enlightened, and they endeavour to provide for the future trader the highest education applicable to his walk in life.

Schools for Commercial Education.

England in this matter has delayed far too long. It is now essential that there should be established in this country schools of commerce which in our English system might well form one side of our secondary schools, with a curriculum specially designed for the higher education of young people who are destined for a business career. The teaching staff must be really competent, and the school must be equipped for teaching the theory of business, and as much of the practice of business as possible, the general aim of the school being to train well-equipped employees of all grades from the competent clerk to the competent employer.

A Typical School of Commerce.

Belgium was the first nation to give practical effect to the idea of establishing a special college for the commercial training of her young men. The aim of the exhibition held at the Crystal Palace in 1851 was to compare the progress made by the different peoples in the development of the industrial arts. It was recognised that England held the first place. But while we rested complacently on our oars, other nations profited by the lesson and began to take steps to promote their home and foreign trade. Belgium recognised that competent men to represent her in the foreign markets were required, and as a result the Higher Commercial Institute at Antwerp came into existence. It was to be to the men destined for a commercial career what the university was to the doctor or the lawyer. Similar institutions have since been founded in France, Switzerland, Germany, Austria, Italy, and even in distant Japan. Before admission candidates must show competent knowledge as tested by an entrance examination. The curriculum embraces the study of all subjects, a knowledge of which is indispensable to the merchant, the banker, or the trader, including at least two foreign languages, book-keeping, commercial documents, geography, history, arithmetic, and algebra, commercial law, and the elements of political economy, as well as physics and chemistry. The course of study is practical as well as theoretical. Transactions of a large commercial house are simulated, the operations of a counting-house are minutely practised and all questions relating to the theory of exchanges are carefully described. Correspondence is conducted by the student in French, German, and English. The principles of international commercial law and customs' legislation are inculcated, and special care is taken to make the student acquainted with foreign markets by furnishing him with reports sent in periodically by Belgians resident abroad. To further the knowledge of all kinds of vegetable, mineral and animal products, there is a well-furnished museum with samples and patterns kept up to date, so that the professor is able to give to his pupils a direct knowledge of the article, in which the latter may one day be called upon to trade. The actual political and economical condition of foreign countries is studied from carefully compiled data and the relative value of raw material from different sources of supply is inquired into and noted. The student is encouraged to take a close interest in the political events of to-day so far as they affect commercial interests, and the latest consular reports from all countries are placed at his disposal, so that he himself later on may be in a position to make a report upon the commercial practice of any country in which he may happen to find himself. Visits to factories, mills, mines, etc., enable the student to acquire an insight into the actual working of those industrial establishments.

Valuable travelling scholarships are given to the best students, who are thus relieved of the necessity of accepting the first situation that is offered to him. He is enabled, in fact, to study the economical condition of the country in which he resides, but he must send home periodically a detailed report of the result of his observations. These reports, after being noted by the Government, are utilised by the students in the prosecution of their studies.

The Training of Clerks.

For those engaged in business who are not able to attend full time at a day school of commerce, arrangements should be made by which they should be able to attend such schools on three or four half-days a week during the normal working hours. The young worker in a house of business is in the same difficulty as the young industrial worker: he cannot get an all-round training; and at present he must get his theoretical knowledge of commerce by attendance at a commercial evening school on three evenings a week. This system is unsatisfactory; but by a part-time attendance at a day school of commerce, he might go through a modified course of instruction which combined with his experience in a business house should make him far better fitted for the post he is filling.

Training for the Consular Service.

In the school for commerce the highest courses are arranged for the special purpose of fitting the student

for the Consular Service. At the present time England is generally represented abroad by a foreigner whose first interests naturally are not British. What we require is that every Consul representing British interests should be an Englishman specially trained for the service, with a full knowledge of British trade, and ready and able to place British interests first.

A Liberal Education Necessary.

Our travellers, managers, agents, and responsible clerks in connection with all branches of industry should be properly trained. They should complete a course of study applicable to their particular calling, including modern languages for commercial purposes, commercial arithmetic, book-keeping and accounts, commercial practice, geography and history of commerce, economics and commercial law. At the same time it cannot be too strongly urged that opportunities must be provided for education apart from the purely utilitarian form.

The period between fourteen and eighteen years of age is a vital period during which the youth should have the opportunity of fitting himself for livelihood and for life. He should have the opportunity of learning in the fullest sense his trade or business and of developing those faculties of mind, body, and spirit that would enable him to fulfil his duties to his neighbours and to the nation. The school course should, therefore, offer beyond the purely technical or commercial subjects other subjects of a liberal character. The youth is not merely a wage-earning industrial or commercial; he is a human being, and his education and training should enable him to occupy his leisure time to good advantage.

Responsibility of Education Officials.

A responsibility rests upon us as education officials. It is for us to see that the educational needs of the nation are really appreciated, and that the fullest educational opportunities are provided for all. If we rightly do our part there should arise in England an industrial army and a commercial army capable of maintaining for our country that industrial and commercial supremacy which is vital to a nation so situated as we are.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The *Cambridge Review* has just published the names of the past and present members of the university who are serving in some capacity in the King's Forces. The number amounts to 7,237, and they are distributed amongst the colleges as follows:—Trinity College, 1,840; Pembroke, 760; Gonville and Caius, 616; Clare, 535; King's, 436; Jesus, 385; Emmanuel, 371; Christ's, 359; St. John's, 337; Trinity Hall, 328; Magdalene, 214; Queen's, 179; Sidney Sussex, 154; Peterhouse, 140; Downing, 126; Selwyn, 125; St. Catherine's, 117; Corpus Christi, 109; Fitzwilliam Hall, 90; Honorary Graduates, 16. With one or two exceptions the numbers run parallel with the sizes of the colleges in normal times, and the list is, with these exceptions, in much the same order as the colleges would be classified if they were arranged on a basis of the number of students.

The General Board of Studies has appointed Mr. K. J. J. Mackenzie, of Christ's College, Reader in Agriculture.

LONDON.—Two appointments to the university professorships were made by the Senate on January 27. Dr. Edward Barclay-Smith, of Cambridge, succeeds Prof. Waterston in the Chair of Anatomy at King's College, and Dr. E. P. Cathcart, of Glasgow, succeeds Prof. Leonard Hill in the Chair of Physiology at London Hospital Medical College.

The D.Sc. Degree has been granted to the following:—Mr. E. L. Kennaway, Guy's Hospital, for physiological chemistry; Miss Ethel N. Thomas, University College, for botany; Mr. J. Kenner, East London College, for chemistry; and Mr. J. Kenyon, external student, for chemistry.

The Hon. R. C. Parsons succeeds Prof. Cormack as one of the representatives of the university on the governing body of the Imperial College of Science and Technology.

MANCHESTER.—At a meeting of the Court of the University held on January 27 Sir Henry Miers, F.R.S., was appointed Vice-Chancellor, in succession to Prof. Weiss, whose resignation takes effect in September. The nomination of Sir Henry Miers had previously received the unanimous approval of the Senate and Council. Since the resignation of Sir Alfred Hopkinson arrangements have been made to lighten the administrative duties of the Vice-Chancellorship, and it is hoped that in the appointment of a distinguished man of science to this office additional strength may be given to the advanced teaching and research work of the University. A proposal will shortly be brought forward to establish a professorship of crystallography, to which the new Vice-Chancellor will be appointed.

OXFORD.—The friends of the late Mr. Arthur Elam Haigh, sometime fellow of Hertford and fellow and tutor of Corpus Christi College, Oxford, will have heard with regret of the death of his elder son, Lieut. Charles Roderick Haigh, Adjutant of the 2nd Battalion Royal West Surrey Regiment, who was killed in action in Belgium on November 7. Lieut. C. R. Haigh has left several large bequests to educational and charitable objects, among them being the establishment of a scholarship at Corpus Christi College and another at Leeds Grammar School, both in memory of his father. There are further bequests to Winchester College, to the Oxford Preparatory School, to Oxford Temperance and Surgical Aid Societies, and to his old regiment.

The University has adopted a series of decrees allow a certain relaxation of the regulations concerning the keeping of terms and payment of dues in the case of those of its members who are serving in the war.

IT is announced in the issue of *Science* for January 22 that Pomona College, Claremont, Cal., has completed the collection of an endowment fund of 200,000*l.* towards which the General Education Board contributed 30,000*l.*; also that Mrs. Russell Sage, who had undertaken to give 20,000*l.* towards a 100,000*l.* dining hall for Princeton University, has increased her offer to 50,000*l.*, provided an equal sum is collected by July 1. Sums amounting to 15,000*l.* have been subscribed.

COMMENTING upon an article in the January issue of the Technical Journal of the Association of Teachers in Technical Institutions on the Massachusetts Institute of Technology in NATURE for January 21 (vol. xciv., p. 580), we reminded our readers that in this well-known college there is a continual weeding out of those students who do not display the requisite ability and application. We might have added that this plan is common in American institutions of higher education, and is adopted in many of our own technical colleges. In the faculty of engineering of the University of Bristol, for example, Prof. J.

Wertheimer writes to say that the system has prevailed for many years, and that it has resulted in a great increase of efficiency and in an improved prestige of the college in the eyes of the heads of the firms which employ students who have gone through their engineering training at Bristol.

THE King has appointed a new Royal Commission for the following purposes:—To inquire into and report on the methods of making appointments to and promotions in the Civil Service, including the Diplomatic and Consular Services, and the legal departments; to investigate the working and efficiency of the system of competitive examination for such appointments, and to make recommendations for any alterations or improvements in that system which may appear to be advisable; and to consider whether the existing scheme of organisation meets the requirements of the Public Service, and to suggest any modifications which may be needed therein. The members of the Commission are as follows:—Sir H. B. Smith (chairman), Duke of Devonshire, Bishop of Southwark, Sir J. P. Hewett, Sir Donald Macalister, Sir J. A. Kempe, Mr. S. J. G. Hoare, Mr. A. C. T. Beck, Mr. A. A. Booth, Mr. A. Boutwood, Mr. J. R. Clynes, Mr. C. Coward, Mr. R. D. Holt, Mr. P. E. Matheson, Dr. A. E. Shipley, Mr. P. Snowden, Mr. Graham Wallas, Miss E. S. Haldane, and Mrs. L. A. E. Streatfeild.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 28.—Sir William Crooks, president, in the chair.—W. W. C. **Topley**: The influence of salt-concentration on hæmolysis. The method employed in this investigation has consisted in varying the percentage of sodium chloride present in a mixture of sheep's red cells, hæmolytic anti-body and complement. The hæmolytic anti-body was obtained from an immunised rabbit, and fresh guinea-pig serum, previously absorbed with sheep's red cells at 0° C., furnished the complement. Where hypotonic percentages of sodium chloride have been employed, the solutions have been made in 7·8 per cent. saccharose solution. The results have confirmed the observations of other workers that, when the percentage of salt is increased beyond the normal limit, hæmolysis is inhibited, owing to the failure of union between the complement and the red-cell anti-body complex, and that, if the amount of anti-body present in the mixture be increased, the effect of the increased salt concentration may to a certain extent be overcome. It has further been shown that, if the salt concentration be decreased below the normal limits, less and less anti-body becomes necessary in order to bring about the union of red cells and complement, and that, in the almost entire absence of electrolytes, guinea-pigs' complement can hæmolyse sheep's red cells without the intervention of hæmolytic anti-body.—G. **Smith**: The life-cycle of Cladocera, with remarks on the physiology of growth and reproduction in Crustacea. As the result of breeding experiments, it is shown that the effects of isolation, crowding, and temperature are the same for *Daphnia pulex* as previously reported for *Moina rectirostris*, viz., isolation combined with high temperature completely inhibits the production of sexual individuals, reproduction being entirely parthenogenetic. Crowding, combined with low temperature, results sooner or later in the production of males and ephippial females.—T. **Goodey**: Investigations on protozoa in relation to the factor limiting bacterial activity in soil. Two different lots of soil were taken and inoculated with cultures of protozoa originally obtained from soil, in order to determine whether the added protozoa would cause a decrease in the numbers of bacteria in the soil. One soil was free from protozoa to begin with, having been bottled since 1846, whilst the other was freed from protozoa by partial sterilisation. Separate lots of each soil were inoculated with cultures of ciliates, amœbæ, and flagellates, and suitable control samples were set up. Periodical bacterial counts were made in order to ascertain if the protozoa were exerting a limiting action on the soil bacteria, and these counts were continued over a period of about eighteen months. The general conclusion drawn from the investigations is that ciliates, amœbæ, and flagellates do not act as the factor limiting bacterial activity in soil.—S. **Hatta**: The mesodermic origin and fate of the so-called mesectoderm in petromyzon. The name mesectoderm has given to a loose aggregation of mesenchymatous tissue, in some places assuming the character of an epithelium intervening between the myotomes and the ectoderm in the head and branchial region of the embryo of petromyzon. As the name implies, it has been confidently asserted that this tissue is derived from the ectoderm. In this paper, however, it is shown that this tissue originates from the ventral edge of the myotome and corresponds to the ventral extension of the myotome in the trunk region which grows downwards towards the mid-ventral line outside the splanchnocœle and gives rise to the ventral muscles of the trunk.—Prof. J. C. **Bose**: The influence of homodromous and heterodromous electric currents on transmission of excitation in plant and animal. The action of an electric current in inducing variation of conductivity may be enunciated under the following laws, which are equally applicable to the conducting tissue of the plant and the nerve of the animal:—(1) The passage of a current induces a variation of conductivity, the effect depending on the direction and intensity of current. (2) Under feeble intensity, heterodromous current enhances and homodromous current depresses the conduction of excitation. (3) The after-effect of a feeble current is a transient conductivity-variation, the sign of which is opposite to that induced during the continuation of current. (4) The normal conductivity-variation undergoes a reversal under a strength of current above the critical value. The heterodromous current then induces a depression while the homodromous current induces an enhancement of conductivity.

Geological Society, January 20.—Dr. A. Smith Woodward, president, in the chair.—Prof. O. T. **Jones** and W. J. **Pugh**: The geology of the district around Machynlleth and the Llyfnant Valley. An account is given of the physical features, general succession, and structure of the area. The rocks are sharply folded, and sometimes overfolded, towards the east. Their axes range approximately north-north-east and south-south-west; the folds in the central area pitch northwards, but north of the Dovey a southerly pitch sets in. Each large fold is composed of a number of smaller folds having parallel axes, and changing in pitch more frequently than the larger folds. Strike-faults of considerable magnitude range nearly parallel with the folding axes, and are in all cases overthrusts towards the east. Of interest are the transverse faults ranging nearly east-north-east and west-south-west. Two of these faults, the Pennal and Llyfnant Faults, are shatter-belts. The Llyfnant Fault displaces several folding axes, and overthrusts to the east on the north side. Its vertical displacement is on an average about 300 ft., but its horizontal displacement is usually more than 3000 ft. It may therefore be called a "tear-fault."—Dr. A. H. **Cox**: The geology of the district

between Abereiddy and Abercastle (Pembrokeshire). The stratigraphy and structure of the greater part of the district is described for the first time. Abereiddy itself has been, since the time of Hicks, a type-locality for the Llanvirn Beds. It has been found that the Ordovician rocks of the district do not succeed one another in a simple upward sequence, but that they have been thrown into great folds and sometimes even overfolded. The limbs of the folds increase in steepness as the pre-Cambrian massif is approached. This folding brings up strips of Cambrian rocks, the presence of which on the North Pembrokeshire coast was previously unsuspected. There is a complete sequence of Ordovician rocks from near the base of the Arenig Series to high up in the Glenkiln Group.

Linnean Society, January 21.—Prof. E. B. Poulton, president in the chair.—W. J. **Dakin**: Structure and fauna of the Abrolhos Islands. Percy Sladen Trust Expedition. The islands are situated 40–50 miles off the coast of West Australia. They are interesting because of the almost complete lack of knowledge concerning the marine fauna of that part of the world. In addition, however, they possess many peculiar features of their own. Although they are coral islands (the most southern in the world), the land fauna is decidedly continental and indicates a comparatively recent connection with the mainland of Australia. Again, although the coast is only forty miles east of the islands, one has to travel some hundreds of miles north of the latitude of the Abrolhos to find a marine fauna on the coast with such tropical characters. The collections have not yet been worked out, but not the least interesting of the discoveries is a new species of Enteropneusta, *Ptychodera pelsarti*, closely allied to varieties of *Pt. flava*. This is the first Enteropneust known from the West Coast of Australia.

Institution of Mining and Metallurgy, January 21.—Mr. Bedford McNeill, past president, in the chair.—J. A. L. **Henderson** and W. H. **Henderson**: Inflammable natural gas as an economic mineral. The authors set out to show that natural petroleum-gas is the only inflammable natural gas of economic value, in its two divisions of "dry" or gas-well gas, and "wet" or "casing-head" gas, which is chiefly produced from oil wells. The former is of chief commercial importance, as it is capable of direct use for heating, power, and lighting purposes as it comes from the well. The occurrence of natural petroleum is co-extensive with that of petroleum, though the reverse is not always true, as is shown by the relative acreages of gas and oil fields in the United States in 1911, which were 11,132,642 and 8,322,862 respectively. The greatest and most extensive natural gas deposits of economic importance, so far as known, are found in the older, drier, and more consolidated porous sedimentary rocks from the Cretaceous downward. In the United States the industry has developed to such an extent that in 1913 the value of natural gas produced almost equalled that of the gold produced. Natural gas has within the last ten to fifteen years become a formidable rival to petroleum in output, and even in value, despite the enhanced prices that the oil has commanded in recent years. In addition to the gas production of the United States, which easily stands first, the authors direct attention to the occurrences in Canada, Russia, Galicia, Italy, Transylvania, and even in England.—J. **Cook**: Investigations in ore milling to ascertain the heat developed in crushing. As the result of carefully conducted experiments with an electrically driven stamp mill the author established the following data: Of the E.H.P. supplied to the motor only 76 per cent. was apparently stored in the raised stamp; the ore crushed was raised in temperature an average of 4·8° C., while the water used was raised an average of 0·438° C. Of the actual E.H.P. put into the motor, practically 61 per cent. was returned as heat in the pulp. Of the energy which reached and was stored in the lifted stamp, practically 80 per cent. was returned as heat in the escaping pulp. In the latter case the author allocates the remaining 20 per cent. unaccounted for as heat to (*a*) loss by friction of the guides, (*b*) loss in sound and vibration, (*c*) loss in radiated heat, and (*d*) the larger proportion, loss due to the energy with which the pulp is delivered through the screens. The test was borne out by the fact that the screens had in places a perceptibly higher temperature than the pulp. The author asks: Is the energy used in tearing the ore particles asunder entirely returned as heat, and do some electrical phenomena exist?

Mineralogical Society, January 26.—Dr. A. E. H. Tutton, president, in the chair.—S. **Kôzu**: The dispersion of felspar. By the most refined methods the dispersions in the three principal directions were determined for various members of the felspar group.—F. P. **Mennell**: Note on the colour of some alluvial diamonds and of pyrrhotite. The colour, usually green, of the diamonds in the gravels of Somabula, Rhodesia, is superficial, and probably due to infiltration, presumably of iron salts, while the stones were lying where they now occur. Pyrrhotite is tin-white in colour when fresh. The cause of its rapid alteration was discussed.—Prof. G. **Cesàro**: Crystals of calomel from Spain. The crystals, which were pale-yellowish in colour, imperfectly transparent, from 1–3 mm. in size, and displaying the forms 100, 111, 311, were most irregularly developed.—Prof. G. **Cesàro**: General formula for the birefringence of a crystal-plate in terms of the angles which its normal makes with the principal optical axes. The approximate formula is obtained by supposing the mean index of refraction to become infinite, while the differences between it and the greatest and least indices remain constant.—Prof. G. **Cesàro**: A numerical relation of the sum of the symmetry-axes situated in the symmetry-planes of a polyhedron. If $N.\Lambda_n$, $P.\Lambda_p$, $Q.\Lambda_q$ . . . are the axes of symmetry lying in the planes of symmetry, then—

$$4\{Nn(n-1)+Pp(p-1)+Qq(q-1)+\ldots\}+1=C,$$

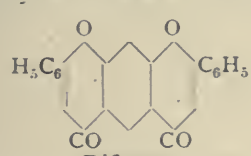
and the number of planes of symmetry is given by $X=\frac{1}{2}(C+1)$.

DUBLIN.

Royal Irish Academy, January 11.—Rev. J. P. Mahaffy, president, in the chair.—S. B. **Kelleher**: A three-dimensional complex variable. Some properties of expressions of the form $P+Q\theta+R\theta^2$ where P, Q, R are functions of three independent variables and θ^3 is equal to unity, but $1+\theta+\theta^2$ is not zero.—R. **Southern**: Summary on marine distribution (Clare Island Survey). This paper is in the nature of a summary of the results obtained by the investigation of the marine fauna of the Clare Island area. The nature of the coast-line and sea-bottom is described, and the various types of habitat and the associations of animals inhabiting them are discussed. The distribution of the fauna from the geographical point of view is then considered. Some observations on the period of reproductive activity of various species are included. A description of the hydrographical results obtained in the course of the survey is given. The total number of marine species of animals obtained in the course of the survey is approximately

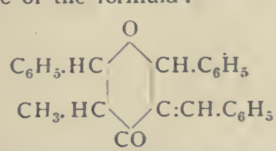
two thousand, a much larger number than has hitherto been found in any similar area.—R. **Lloyd Praeger**: Summary on terrestrial distribution (Clare Island Survey). The work of the Clare Island Survey now closing has occupied just six years, the first three being devoted to field-work and the last four to publication, there being an overlap of one year in the two sections. More than one hundred workers took part, and without exception the authors of the sixty-eight reports in which the results are embodied themselves visited the area. Besides papers on almost every group of the plant and animal kingdoms, the report includes contributions on the history and archæology of the area, on Gaelic names of animals, plants, places, and human families, climatology, and geology. The total number of species of animals obtained is about 5100, and of plants about 3200, total more than 8300. Of these no fewer than 1825 are additions to the fauna or flora of Ireland. More than 400 are new records for the British Isles, and more than 120 are new to science. Two new families and fifteen new genera are described.

January 25.—Dr. F. A. Tarleton, in the chair.—H. **Ryan** and Miss P. **O'Neill**: Studies in the diflavone group.—I., Diflavone. With the view of extending our knowledge of the relations between constitution and colour in the oxygen dyes, the authors have prepared a substance which has, as its formula, two flavone rings in a condensed form. It was obtained from diacetoresorcinol in two ways:—(1) Diacetoresorcinol dimethyl ether was condensed with benzaldehyde to dihydroxydichalkone dimethyl ether which reacted with aluminium chloride to give dihydroxydichalkone and the tetrabromide of the diacetate of dihydroxydichalkone on treatment with alcoholic potash yielded diflavone. (2) Dibenzoylacetoresorcinol dimethyl ether was formed by condensation of benzoic ester with diacetoresorcinol dimethyl ether, and was converted by hydriodic acid into benzoylacetomethoxyflavone, and finally into diflavone. The latter formed



Diflavone

pale yellow crystals, which gave a beautiful blue fluorescence with concentrated sulphuric acid.—H. **Ryan** and Rev. J. **Dunlea**: In endeavouring to synthesise dicinnamoylmethane the authors condensed benzaldehyde with mono- and di-methylacetylacetone by means of gaseous hydrochloric acid. The product in both cases was identical, being a chlorinated body which, on treatment with pyridine, yielded a substituted pyrone of the formula:—



The substance did not form an oxime, but added on hydroxylamine apparently at the unsaturated linkage It formed a dibromo-derivative.

PARIS.

Academy of Sciences, January 23.—M. Ed. Perrier in the chair.—G. **Bigourdan**: Description of a new instrument for the differential comparison of great angular distances in the sky. A movable platform carrying two telescopes is fixed to an equatorial mounting in such a manner that the axis about which the platform can move coincides with position usually occupied by the optical axis of the equatorial. The two telescopes can turn round axes normal to the platform, and are furnished with ocular micrometers. The use of the instrument, which forms a sort of angular comparator, is described. It will prove specially suitable for the direct determination of refraction, the measurement of the annual aberration constant, and correcting the fundamental star catalogues by comparison of large differences of right ascension, independently of clocks and of variation of instrumental constants.—André **Blondel**: The useful effect of projectors. Additional remarks.—E. **Delorme**: New treatment of nerves wounded by projectiles. The general principles underlying nerve operations are stated, together with full details of the methods employed.—J. **Bosler**: The red region of the spectrum of stars of the Wolf-Rayet type. Photographs of the red end of the spectrum of fifteen stars of this type, utilising plates sensitised by means of dicyanine. Comparison of the spectra confirms the view that stars of the Wolf-Rayet type represent waning Novæ of past ages. New stars appear generally in dense star clusters, and the Wolf-Rayet stars also have the same peculiarity.—F. **Devoto**: Observations of Delavan's comet (1913*f*) made at the Paris Observatory. Observations and positions of comparison stars are given for December 24, 28 (two), 29, January 8, 11, 18.—S. **Stoilow**: Quadruply periodic functions.—Paul **Mansion**: Demonstration of the law of large numbers. —Stanislas **Meunier**: A remarkable consequence of volcanic theory.—Emile **Belot**: Orogenic theory arising from the physical theory of the formation of oceans and primitive continents.—Edmond **Gain** and A. **Jungelson**: Maize seeds resulting from the growth of free embryos. The embryos were extracted from the seeds, carefully cleaned from all reserves of albumen, and sown in natural soil. The plants obtained produced seed of normal type.—H. **Jumelle** and H. Perrier de la **Bâthie**: A slightly known Cucurbitaceæ of Madagascar.—MM. **Rivier** and **Dupoux**: A new method for the rapid production of radiographs on ferrotype plates.—P. **Carnot** and B. **Weill-Hallé**: Culture in sand tubes for the rapid diagnosis of typhoid fever, and searching for germ-carriers.—Henri **Coupin**: The organic nutrition of a marine bacterium. A. **Trillat**: Study on the aqueous microbial dusts of inhabited places.

THE REAL JAPAN.

Japan To-day and To-morrow. By H. W. Mabie. Pp. ix+291. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 8*s.* 6*d.* net.

THIS book makes little attempt to give the history of Japan or to describe the country or its political or naval and military development. It is, we think, a successful attempt to understand the Japanese temper, character, spirit, and genius. In material things the Japanese have altered altogether in the last sixty years, but in spiritual things they have altered very little. The traveller describing faithfully what he sees is usually ignorant of the things described in this book, but these are the things which it is most important for the statesmen of other countries to know. Mr. Mabie is an American, and he is anxious that Americans particularly shall look below the surface of things. He shows that the genius of a people eludes the direct search for it, and he looks for its revelation not in universities and courts, but in shops and fields and homes.

"It is a people whose government has been religious, whose religion has been governmental, and whose whole organised life has been like a garment woven out of the substance which it clothes, but does not conceal."

Customs have always had the authority of law. The soul of Japan is in Shintoism, which is no longer a religion; it is not only a living source of poetry, it is a profound national sentiment of tremendous energy. Strangers expressed only admiration for Japan forty or fifty years ago. As the Japanese realised that great resources were absolutely necessary for their existence, they turned to commerce and manufacture; then they were said to have become dishonest and their politeness had become insincerity. We have heard the same undiscerning kind of criticism of European people. The Japanese are in essentials just what they used to be. Their ways of thinking, their ideals, their standards of life, and their interpretations of the mystery of the world are different from ours, simply because for thousands of years they and we have lived unknown to each other. But these differences between us are only superficial, although Mr. Kipling holds another view.

The man who frequents the smoking-rooms of clubs and hotels cannot see the things described by Mr. Mabie, and ninety-nine per cent. of the business men who live in Japan and think they know all about it are quite ignorant of the intellectual movements, the spiritual stirrings in the souls of those among whom they have their home, but with whom they do not live. The Germans specially have shown contempt for the Japanese; even their highest classes have shown in this way their intellectual limitation. The parrot-cry that the Japanese have no originality—that they are merely imitative—comes from unobservant men. The Japanese have a passion for work; their hands and brains are always on intimate terms. One and all they are artists, and artists always possess freedom and the energy of personality. *Jiujitsu*, the endeavour to set skill against force and intelligence against mass is emblematic of one great characteristic of these people, which is perhaps most visible in their art, "the full weight of thought without any weight of expression." The Japanese will probably solve for Europe many of its seemingly insoluble problems.

This book is one that ought to be studied not only by people who wish to know something of the real soul of Japan, but also by all people who wish to keep their own souls alive.

JOHN PERRY.

LAMARCK'S EVOLUTION THEORY.

Zoological Philosophy: an Exposition with regard to the Natural History of Animals. By J. B. Lamarck. Translated by H. Elliot. Pp. xcii+410. (London: Macmillan and Co., Ltd., 1914.) Price 15*s.* net.

MR. ELLIOT has done a valuable piece of work in making a complete translation of Lamarck's "Philosophie Zoologique," which was published in 1809, half a century before Darwin's "Origin of Species," and is undeniably one of the evolution classics. He has enabled students of organic evolution who are unfamiliar with French, or who have been repelled by Lamarck's tedious style, to get a first-hand knowledge of the doctrines of one of the greatest of Darwin's predecessors. Recognising that the main interest of the "Philosophie Zoologique" is historical, Mr. Elliot has given a very literal translation, taking few liberties beyond breaking up some of the very long sentences, and altering words the meaning of which has greatly changed during the past century. A useful list is given of many of the French terms with the translations adopted. It must be confessed that there are many pages, especially those dealing with the classification of animals and with physiology, which are of little importance, but the value of having a complete translation is obvious. The alternative of making a selection of the salient passages is always a hazardous procedure. It seems to us that Mr. Elliot did wisely in translating the whole, and

that he has executed this laborious piece of work with care and skill.

As the author must have been saturated with Lamarck's views for a prolonged period, it is interesting to read his introduction, where the essentials of Lamarck's teaching are explained. We shall refer to a few. It is pointed out, for instance, that Lamarck's picture of a continuous scale of being from Monad to Man (the taxonomic punctuation being simply a matter of convenience) was associated with his denial that species had ever become extinct. Apparently peculiar fossils have, he maintained, their living representatives, though they may not have been discovered.

Reacting from the doctrine of fixity of species, Lamarck went to the other extreme of exaggerating their instability. Evolution he believed to have come about by minute steps only. The factors were two—an innate tendency to complexify and the hereditary accumulation of changes induced by peculiarities in function (use and disuse). These peculiarities may have arisen as responses to changes of environment, but he expressly excludes the direct action of the environment as an operative cause.

In discussing the question of the transmission of modifications, Mr. Elliot refers to an interesting and illuminating suggestion by Prof. MacBride that hormones may afford a clue to a possible *modus operandi* of transmission. Unless we have misunderstood, a similar suggestion was made by Mr. J. T. Cunningham in 1908, and the idea is also implied in a passage in the "Creative Evolution" by Prof. Bergson, with whose "illusions" Mr. Elliot is familiar. We refer to the point simply because these coincidences of thinking are always of interest.

Mr. Elliot says on p. 49 that if environmental factors come into action after birth or before it in the course of development they produce a *modification*, apparently *not* heritable. If they come into action before development begins, they produce a *variation* which *is* heritable. In his exceedingly important experiments on Simocephalus, Dr. W. E. Agar has shown that a change induced in the egg-cells along with the body of the parent had its influence on the individuals developing from these ova, and slightly on the next generation, and then waned away. In the light of this fact and Dr. Agar's interpretation, Mr. Elliot's view requires correction.

One of the interesting conclusions of Lamarck's physiology was that nervous impulse is due to a "nervous fluid," which is an "animalised" form of the electric fluid. He reached this conclusion by showing that no other theory worked, and Mr. Elliot finds obvious satisfaction in showing that this is the *per exclusionem* method used by Dr. Hans Driesch and others to prove the existence of a vital force or Entelechy. The fallacy is the familiar one that we have first to be sure that all the possible alternatives are before us. Mr. Elliot simplifies things by assuring us that "every event, that receives a scientific explanation, is analysed into some particular combination of matter and material energy." A reflex action, for instance, is "of a purely mechanical nature." But this, like the vitalist's declaration that there must be a "vital force," is an assertion that outstrips its evidence, as Prof. Sherrington's work plainly shows.

Lamarck was shrewdly opposed to postulating entities such as a vital principle or even "esprit," and was on the whole mechanistic. Yet we must bear in mind that one of the distinctive features of his teaching was the important evolutionary *rôle* which he ascribed to the "emotions of the inner feeling," which are excited by "needs," and give rise to actions at once satisfying and transforming. Of this and many other matters Mr. Elliot has much that is interesting to say, though we think his philosophy is sadly out of repair.

J. A. T.

GENERAL AND SPECIALISED GEOLOGY.

(1) *A First Book of Geology.* By Dr. A. Wilmore. Pp. vi + 141. (London: Macmillan and Co., Ltd., 1914.) Price 1*s.* 6*d.*

(2) *An Introduction to the Geology of New South Wales.* By C. A. Süssmilch. Pp. xviii + 269. Second edition. (Sydney: Angus and Robertson; London: Oxford University Press, 1914.) Price 7*s.* 6*d.* net.

(1) DR. WILMORE'S "first book" of geology presumably completes the admirable series that includes, under the care of the same publishers, the works of Prof. Watts and Sir Archibald Geikie, and culminates in the latter's monumental "Text-book." The landscape illustrations are clear and well chosen; we may specially mention Mr. Harrison's tors on Dartmoor, and the Sligo peat-bog, with Ben Bulben in the background, by Mr. Welch (of Belfast, not Dublin). Without any appearance of crowding, a remarkable amount of fundamental information is included here in 140 pages. Practical work is encouraged, and the book is well suited for schools. The fact that the dip is the greatest possible angle of those that might be read with the clinometer should be emphasised on p. 32. The fine picture of Vesuvius on p. 43 represents the well known eruption of 1872, not 1892. A figure 2 is missing from the olivine formula on p. 54; water is omitted from that for gypsum on p. 94;

and the use of the word "foliæ" and the classical derivations generally require revision. A new edition of so attractive a book will soon be called for. We note that such modern points of interest as the lava-plug of Mt. Pelée and the wanderings of pebbles from Ailsa Craig find a place in this lucid introduction to geology.

(2) Mr. Süssmilch's work on New South Wales is an enlarged edition of that published in 1911 (see NATURE, vol. xc., p. 590). It deals only briefly with surface-features, and is intended for readers who already possess a knowledge of general geology and of the terminology of the science. Such readers, we have reason to believe, are far more prevalent in colonies where mining development has been active than they are in our own islands, where exploration is practically complete. The success of Mr. Süssmilch's book indicates a good educational level in New South Wales. It is well illustrated by photographs, maps, and sections; among the last, those of the Permo-Carboniferous (late Carboniferous and Permian) coal-basins, in which glacial horizons occur, are of especial interest. The fresh-water conditions under which Triassic and Jurassic strata were deposited are dealt with in chapter xi., and the origin of the artesian water is touched on at the close. The latest publication, by the by, on this important and much-disputed question has been issued by the Department of Mines for New South Wales (E. F. Pittman, on "The Great Australian Artesian Basin"), and contains a detailed criticism of Prof. Gregory's views on the magmatic nature of the supply. Mr. Süssmilch "prefers at present to suspend judgment," and Mr. Pittman's paper, with its remarkably extensive bibliography, must now be consulted by those who are willing to go further.

The vegetation of successive periods in Australia is fully as interesting as the faunas. That of the Cretaceous period is known in New South Wales by conifers alone. The Glossopteris flora marks the Permo-Carboniferous horizons, while a Rhacopteris flora characterises the underlying Carboniferous beds (p. 89). We note that Archæopteris is quoted from the Lower Devonian estuarine shales of the Genoa River and from the Rhacopteris series in the Carboniferous. The author (p. 84) inclines to divide the "so-called Gympie beds," placing some of them, containing *Lepidodendron australe,* with the Lepidodendron beds of Devonian age.

The pictures of fossils are excellent, and the book is a pleasant addition to the growing library of the empire. Misprints are extremely rare; the spelling "Kosciusko" has long received geographical sanction.
G. A. J. C.

OUR BOOKSHELF.

Logic, Deductive and Inductive. By Carveth Read. Fourth Edition. Pp. xvi+417. (London: A. Moring, Ltd., 1914.) Price 6*s.*

As this is the fourth edition—though enlarged and partly re-written—of the work under notice, it is not necessary to review it in detail. It is sufficient to mention, by way of reminder, that for the most part it follows the schemes of J. S. Mill and Prof. Bain, beginning with propositions and terms, and moving through the syllogism to induction, then dealing with causation, hypotheses, and fallacies. Perhaps the treatment of hypotheses might be noticed as specially interesting and good, the difference between hypothesis and theory being well brought out. Also, the nature of proof, *e.g.*, is very neatly put: "If a new agent be proposed, it is desirable that we should be able directly to observe it, or at least to obtain some evidence of its existence of a different kind from the very facts which it has been invented to explain" (p. 270). It is also well pointed out that science is a "way of thinking," and that though we inevitably follow perceptual analogies in our hypotheses—thinking of atoms and æther as perceptible things, which they are not—these hypotheses are useful even if wrong. There is no reason to be afraid of inventing an hypothesis. Ockham's razor may be too vigorously plied. We live by hypotheses in the affairs of daily life. If I lose my fountain-pen, I guess where it is, and then go to verify or disprove. So with science, the discoveries of which are often inspired guesses.

Oxford Outline Maps. Edited by Prof. A. J. Herbertson. (Oxford University Press.) Price 1*d.* net each, 9*d.* net for 12 of one kind, 1*s.* 4*d.* net for 25 of one kind.

THESE outline maps have been drawn for use in the exercises contained in the text-books of geography, of which Prof. Herbertson is the author, issued by the same publishers, but they will accompany usefully other modern class-books of geography. The maps are clear and well chosen, and are evidently the work of a cartographer familiar with the needs of schools.

Air, Water, and Food from a Sanitary Standpoint. By A. G. Woodman and J. F. Norton. Pp. v.+248. Fourth edition. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1914.) Price 8*s.* 6*d.* net.

THE first edition of this book, which was by the late Mrs. Ellen H. Richards and Prof. A. G. Woodman, was reviewed in the issue of NATURE for October 25, 1900 (vol. lxii, p. 620). The book was first written from a "missionary" point of view, but actually became used in colleges and technical schools, and the present authors have changed somewhat the character of parts of the volume. All the discussion on air and water has been rewritten, the section on milk has been recast, and numerous additions have been made throughout.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Penalty on Research.

We are frequently told that there is no difficulty in being accorded the use of small quantities of absolute alcohol, duty-free. While professor at University College, it was possible for me to procure what I required, duty-free, for a permit had been granted to the college. Now, working in my private laboratory here, I am refused the privilege. Having applied for permission to be allowed to buy not more than two gallons a year of absolute alcohol, free of duty, the secretary, in a letter of February 1, says:—"The Commissioners regret their inability to grant you the use of pure spirit, duty-free."

Now, sir, I have lately been doing a good deal of work for various departments of the Government free of charge; and for some of this, absolute alcohol is, if not a necessity, at least a great convenience. Moreover, my laboratory servant, who is, by the way, a teetotaler, is serving with the colours.

I regard this action of the Customs Department as a penalty on research. No doubt it will be said, if an exception (exception to what?) is made in one case, why not in all? The privilege might be abused. I think not. Such a permit might be granted only to persons who are known to be actually engaged in research, and whose *bona fides* is attested.

The question of free alcohol is, you will observe, still unsettled; and I hope that some action will be taken to put an end to such folly. WILLIAM RAMSAY.

Beechcroft, Hazlemere, Bucks.

The Spectra of Helium and Hydrogen.

It has become a general supposition that the validity of Bohr's theory of the spectra of hydrogen and helium would be definitely proved if certain faint components very close to the hydrogen lines given by Balmer's formula could be found experimentally. On the other hand, if the components were not found after exhaustive search, the theory would be disproved. This supposition is quite incorrect, and in view of the remarkable paper by Mr. E. J. Evans in the current number of the *Philosophical Magazine*, which describes the successful discovery and measurement of these components, it becomes a matter of urgency to indicate at once why such components can give no test of any theory of spectral production.

Into the vexed question of the agent producing the line λ 4686, and the Pickering series—whether it be hydrogen or helium—it is not necessary to enter, for the conclusions are the same in either case. We have two alternatives to consider: (1) that the lines are due to helium, and (2) that they are due to hydrogen. Let us, in the first place, take the first alternative, which has been rendered so probable by Fowler in his recent Bakerian lecture. In that case, the line λ 4686 belongs to an enhanced line series with 4N as the Rydberg constant instead of N. It is strictly analogous, as Fowler points out, to his new series of magnesium, commencing with λ 4481, and we must expect an analogous behaviour. Now no spectroscopist questions to-day the universal validity of the combination principle in spectra, developed by Ritz and Paschen, and some well-defined types of combination series are known. In particular, there is a well-marked spark series in magnesium formed by combinations of the type $3f-mf$, in the usual notation, where nf is the variable part of a line in the "4481" series. In other words, the wave numbers in this series—a comparatively strong one—are differences of the wave numbers of lines in the "4481" series. Fowler has measured seven successive members of this series (Bakerian Lecture, p. 253). If we calculate the corresponding series for helium from the "4686" series, we obtain precisely the Pickering series and the new components measured by Evans. This calculation is independent of *any* theory of the production of series. One series must necessarily be accompanied by the other. In this particular combination, the result is even independent of any expression, empirical or otherwise, of the series by a formula. The difficulty of observing the lines in no way contradicts this necessary origin. They may have another origin in addition, and be really twofold, but since this process must produce them even in the absence of any other, their existence cannot in consequence contribute to the establishment either of Bohr's or of any other theory.

The second alternative is to return to Rydberg's view that half the "4686" series is a principal series of hydrogen, and that the other half is a new principal series. The writer must here insist that he is not expressing a belief in Rydberg's view, though, in his opinion, sufficient justice has not been done to this alternative, which, from the point of view of exact formulæ, is not really inferior to the other, although the need for the presence of helium in the experimental isolation of the lines is against it. The important point is that even if this now somewhat discredited view is correct, the new components near the hydrogen lines must exist, and in *exactly* the same calculated positions as before. They exist again as combination tones, of the type $3P-mP$, where P is now the principal series of hydrogen, and can be calculated at once by subtracting the wave numbers of the "4686" series, or, in fact, of just the half of it which Rydberg designated as the principal series. This combination from the principal series is well known in the alkalis lithium and sodium, just below hydrogen in the periodic table. The lines could only be expected to occur, however, when λ 4686 is strong, as in the experiments of Evans.

While, therefore, the isolation of these lines is a great step in the advancement of our knowledge of hydrogen or helium, it cannot prove that they are helium lines, and although they were predicted by Bohr's theory, they were, in fact, previously predicted by the very existence of the "4686" series, whatever its interpretation. While sharing the general admiration for the great simplicity of Bohr's theory as applied to the Pickering and "4686" series, the writer must nevertheless point out the one, and apparently the only, method by which he believes it can be proved or disproved. This is by interference measurements of the first four or five lines in the "4686" series, from which the value of Rydberg's constant can be calculated exactly, and compared with Curtis's value for hydrogen. The lines are not at present measured accurately enough for this purpose.

On the History of a Notation in Trigonometry.

The interpretation of formulas in the trigonometry of plane and spherical triangles is greatly simplified by the expedient of designating the sides by the same letters, respectively, as the angles opposite those sides

—one group of letters being capitals, A, B, C, and the other group small letters, *a*, *b*, *c*. The introduction of this notation is ascribed by Moritz Cantor, in his "Geschichte der Mathematik," vol. iii., 1901, p. 561, to the Swiss mathematician, Leonhard Euler, who first used it in 1753 ("Histoire de l'Académie de Berlin, Année," 1753, p. 231). It is the purpose of this note to point out that this simple, yet important, innovation was made nearly a century earlier.

In the British Museum there is a pamphlet of a dozen small leaves, written in Latin. Upon one side of each leaf there is engraved writing (script). The pamphlet is a collection of formulas for plane and spherical triangles, with drawings. Apparently the process of engraving was resorted to because no type was available for the new symbols used. There is no title-page. The first page contains "Symbola," and, at the bottom, the name "Ri : Rawlinson." The place and date of publication are not given. On one sheet, which is larger than the rest and is folded, there are drawings and time-records to illustrate the passage of the moon over the disc of the sun in an eclipse of January 16, 1655, observed at Oxford. Here the name "Ri : Rawlinson" occurs a second time. Who was this man? It could not be Richard Rawlinson, the antiquarian, for he did not write on mathematics. There is no doubt that the author of the pamphlet is the Rawlingson of whom Anthony A. Wood speaks in his "Fasti Oxonienses," edition P. Bliss, second part, London, 1820, p. 257, placing him in the Oxford list of "Doctors of Divinity" of the year 1661. The reference is as follows: "Sept. 9. Rich. Rallingson or Rawlingson of Queen's coll. chaplain to the duke of Newcastle, was created while the chancellor held the supreme chair in convocation.—He was an ingenious man, well skill'd in the mathematics, but had not preferment confer'd on him equal to his merits. He died in 1668, being then, as I conceive, rector of Pulborough in Sussex."

Thus it appears that the pamphlet was issued between 1655 and 1668. Some of the symbols are the same as those used by Seth Ward, Savilian professor of astronomy at Oxford, in his "Idea trigonometriæ demonstratæ," 1654. All of Ward's symbols were probably originally due to William Oughtred. Ward and Rawlinson used Oughtred's symbols for proportion, A . B : :C . D; they used a slightly modified form of Oughtred's symbols for "maius" and "minus"; they designated by *b*' the complement of an angle *b*. Rawlinson introduced several new symbols. In case of triangles, he designated the sides by the capital letters, A, B, C, and the opposite angles by *a*, *b*, *c*, respectively. This is his most important innovation. The idea of this device was not generally adopted until re-introduced about a century later. Rawlinson went even further. With him, A was the maximum side, C the minimum. Moreover, he distinguished in his notation between plane and spherical triangles by writing the letters in different script. Each letter for spherical triangles was curved in all its parts; each letter for plane triangles had a conspicuous straight line as a part of itself. Rawlinson had symbols for angulus "obliquus," "acutus," "obtusus," "rectus," and "rect. et obl."; he had symbols also for "datum," "latus," "complementum," "compl. com.," "latus op. angu.," "angu. op. lat.," "pars media," "quæsitum," "quadrans," "sinus," "tangens." Rawlinson's symbols for "parallelus," "perpendicu.," "triangulum," "radius" had been introduced into mathematics before 1655, and are still in use at the present time. His pamphlet lays extraordinary emphasis upon the use of symbols. He had what Thomas Hobbes called a "scab of symbols."

During the first half and middle of the seventeenth century British writers introduced symbols into trigonometry to an extent unparalleled by contemporaneous writers in other countries, but our histories of mathematics do not reveal this fact.

Measurements of Medieval English Femurs.

IN a paper lately contributed by Dr. Alice Lee to *Biometrika* (vol. x., Nos. 2 and 3, November, 1914, p. 208), entitled a "A Table of the Gaussian 'Tail' Functions," the author does me the honour to criticise some statistics which I published in the *Journal of Anatomy and Physiology* (vol. xxxviii., p. 238), on the measurements and proportions of the medieval English femur, derived from the study of bones in the crypt of the Parish Church at Rothwell in Northants.

The criticism, which is undertaken from the point of view of the advanced mathematician, I am ashamed to say I can only partly follow, but it turns largely on the very difficult question of accurate sexing, and Dr. Lee brings forward mathematical reasons for believing that my sexing must be inaccurate.

That this may well be so I readily allow, though I am glad to see that when Dr. Lee has rearranged the sexes to suit mathematical requirements, the average measurements seem to be altered by only the fraction of a millimetre, an amount of no possible importance to the practical anatomist or anthropologist.

There is, however, one method of criticism against which my practical experience in crypts makes me anxious to warn mathematicians; it is the futility of expecting that the measurable bones in a crypt will show any proportion to the number of males, females, and children in the population.

Owing to their greater fragility the children's bones become disintegrated in the course of centuries long before those of adult females; while, for the same reason, those of females do not last as well as those of adult males.

Consequently, when Dr. Lee points out that my method of sexing would mean a predominance of 79 per cent. of males in the population, while hers would give a slight preponderance of females, I submit that my estimate is, in the circumstances, more likely to be in harmony with the proportions of measurable bones in the crypt.

If Dr. Lee could superintend the restacking of a crypt full of bones with a view to their preservation, as I have done on two occasions, she would be astonished at the load of damp bone meal and broken fragments which have to be returned to the churchyard. In this I am sure would be found the excess of female bones as well as most of the bones of the children, thus accounting for the preponderance of male bones left fit for measuring.

NOTES ON STELLAR CLASSIFICATION.*

III.

BEARING in mind what has been said about the origin of the special class of bright line stars, I give a diagram showing that they occur exactly where we should expect to find them if the suggested origin is a sound one.

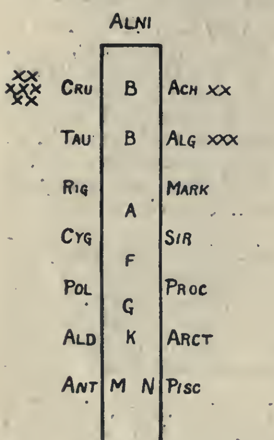

FIG. 5.—Position of the bright line stars at the top of the temperature curve.

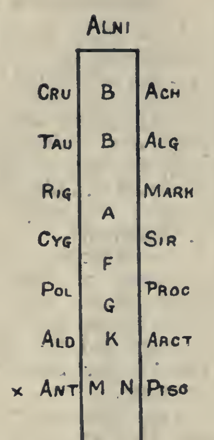

FIG. 6.—Position of the bright line variables at the base of the ascending arm of the temperature curve.

I return to that class of variable stars the changing luminosity of which, according to my hypothesis, is due to the heat and light produced by collisions between meteor swarms (Fig. 6).

Of these stars, in which the bright radiations have been recorded at maximum, one only, *o* Ceti, is included among the eighteen classified at Kensington as Antarian; 225 stars classified as Md (Antarian) are given on the Harvard List.[7] These are chiefly variables of long period. Prof. Pickering has obtained forty photographs showing bright lines, and ten stars have been discovered by means of this peculiarity of the spectrum.[8] Near minimum, when the star is faint, the bright lines are not seen.

There can be no doubt that all are physically similar, and that the position of all is at the base of the ascending arm of the temperature curve. That they are found here and nowhere else is an important test of the view that we have to deal with nebulous clouds consisting of discrete meteorites, as in comets, the gases from which produced by the heat supplied by collisions fill the interspaces at maximum and superadd the bright radiations to the fluting and line absorption seen at all times with varying intensity.

We next pass from these long-period variables with smooth curves, sometimes called "Mira variables," to another class with short periods, and with curves not so smooth, called "Cepheid variables."

The diagram Fig. 7 shows that these occur in the greatest number at a stage higher up the ascending branch of the temperature curve than the Miras. So far bright lines have not been recorded at maximum, but it has been noted that the position of maximum light energy moves towards the violet[9] as the star brightens. Their shorter periods, taken in connection with the fact that they must be more condensed than the Miras judging from their position on the curve, explains this difference of behaviour—there are no interspaces.

The Cepheid variables are not the only class without bright lines. I have already (Bull. I.) referred to the "eclipsing variables." Of these there are two classes, represented by β Lyræ and Algol, in which the shape of the curve is very different. This difference seems to arise from the fact that in the case of the Algols we are dealing with true discs, while in the case of the Lyras this stage has not been yet reached. These conditions are indicated by the position of the Lyras on the ascending and of the Algols on the descending arm of the curve.

Among the Piscian stars at the base of the descending arm we find a number distinguished by their irregular variability. In these we deal with a star rapidly dimming, surrounded by vapours of carbon giving absorption flutings, and of iron giving a multitude of absorption lines. The changes in the density of these vapours, to say nothing of the possible formation of scoriæ, are sufficient to explain the variation and irregularity in the light given out by these bodies. There are no interspaces to produce bright lines.

It is singular that some inquirers seem to regard the Antarian and Piscian stars (M and N) as being similar and so treat them as convertible terms,

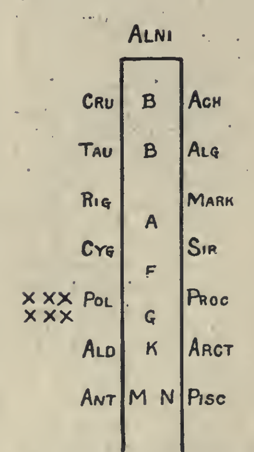

FIG. 7.—Position of the Cepheid variables halfway up the ascending arm of the temperature curve.

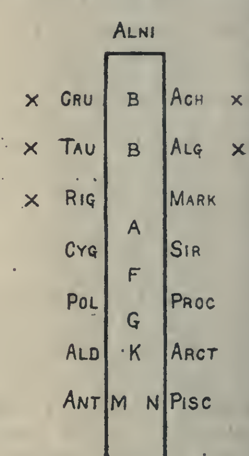

FIG. 8.—Position of the eclipsing variables towards the top of the curve.

while the fact is that the only similarity is their temperature. The following table will indicate their dissimilarities:—

Antarian.	*Piscian.*
Least condensed	Most condensed
Titanium absorption flutings	Carbon absorption flutings
Regular variables	Irregular variables
Bright lines	No bright lines

[7] *Annals*, vol. lv., pt. 1.

[8] *Astr. Nachrichten*, vol. clxxxvii., p. 1.

[9] Albrect in *Astrophysical Journal*, xxv., 332.

I have before referred to Miss Maury's *c* and *b* "divisions." It is interesting to see how the stars composing them arrange themselves on the ascending and descending arms. The facts are given in Figs. 9 and 10.

Prof. Ejnar Hertzsprung[10] has discussed the divisions of Miss Maury's classification, and while he finds that there is no systematic relationship between the *a* and *b* divisions with regard to spectral differences and differences of brightness, yet it is otherwise in the case of the *c* and *ac* divisions. The *c* stars, he finds, are very distant, and are extraordinarily bright. According to him (and previously according to Miss Maury) they seem to suggest different physical constitutions from the other divisions, and he terms them "whales," while the other stars he considers as "fishes." In his paper he gives a list of twenty-four *c* and *ac* stars. All of these included in my catalogue, with two exceptions probably due to errors of classification, fall on the ascending arm of the temperature curve (see Fig. 9).

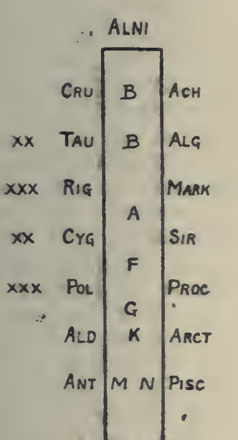

FIG. 9.—Position of the "*c*" stars on the ascending arm.

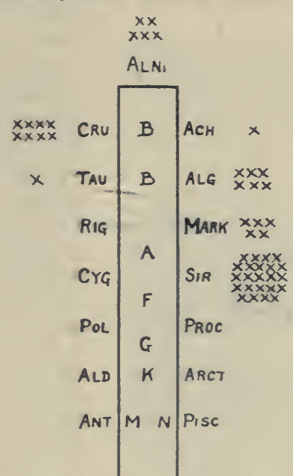

FIG. 10.—Position of the "*b*" stars at the top of the temperature curve and on the descending arm.

They are thus found to be condensing swarms following in a natural sequence the more sparse swarms so rich in variables of the *o* Ceti type.

Their great luminosity is due more to volume than to temperature, and the special characteristics of the lines, as opposed to those of the *a* division, are due to the difference in absorbing conditions in sparse swarms and bodies with forming atmospheres, and also to the fact that the "solar" lines only occur in stars of lower temperature.

The stars of type "*b*," on the other hand, are seen to arrange themselves in an orderly sequence following on those of type "*c*" (Fig. 10). At the top of the ascending arm, where the sequence of *c* stars ends, the *b* stars come in, and extend round through the top of the curve down to the Sirian stage on the descending side. This sequence of the *b* on the *c* stars is a very suggestive one. As a *c* star approaches its maximum temperature, the physical conditions change from those giving rise to type *c* spectra to those from which spectra of type *b* are produced.

We are now in a position to derive some material results from the preceding considerations. In view of the definite manner in which the physical properties considered have shown themselves to be associated with the various groups on one arm of the curve or the other, we are justified in using these physical properties as criteria for locating stars on the ascending or descending arm of the temperature curve.

In the case of the constant bright line stars, Fig. 5 shows that considerations of their physical conditions may be made under the probability that all these bodies are in the neighbourhood of the maximum temperature attained during their evolution. Thus the twenty-six bright line stars mentioned earlier as being contained in the Harvard lists may be considered as being located on the temperature curve.

On the Harvard scheme, with the exception of classes M and N, stars may belong to either, as increasing and decreasing temperatures are neither recognised nor provided for. In classes M and N, as in my hypothesis, we are dealing with the bottoms of the ascending and descending branches, lowest temperatures and vastly differing conditions are involved. Hence we can classify as Antarian or Piscian all stars designated M or N on the Harvard system. We thus obtain from the Harvard Revised Photometry and the Second Catalogue of Variable Stars, about 650 and 70 of these two classes respectively.

Next, regarding the Cepheid variables, the Harvard Second Catalogue of Variable Stars contains thirty-four short period variables with approximately solar spectra. These are Cepheid variables, and may all be placed on the ascending arm, in conformity with the six already classified.

With regard to the eclipsing variables, those with continuously varying light-curves, like that of β Lyræ, will probably lie on the ascending arm of the temperature curve, and those like Algol may be expected to occur on the descending branch.

Finally we have to deal with the "c" and "b" stars. From the manner in which the ten of Miss Maury's Type "c" stars, which have been classified at Kensington, aggregate on the ascending arm, we may place the remaining nine given in her tables[11] in corresponding positions.

From the same source we find about ninety stars of Type "b." Those classified at Kensington are seen to cluster round the top of the curve, and to extend down the descending arm. Hence, when considering the physical conditions of those not so classified, we may regard them as occupying similar positions.

We are thus able to add nearly 900 stars to the 470 already classified on the temperature basis at Kensington.[12]

THE MANUFACTURE OF DYESTUFFS.

IN an article in NATURE of January 21, p. 555, the National Dye Scheme put forward by the Board of Trade Advisory Committee on December 22, 1914, was outlined, and in some of its aspects the development of dye manufacture in this country is of such far-reaching national importance that the subject claims the close and continued attention of all men of science. As stated last week (p. 621), the original scheme has now been replaced by modified proposals, the full details of which are not, however, yet available.

The outstanding feature of the new scheme is that the Government has undertaken to make a grant to the new company, for a period of ten years and to a total amount not exceeding 100,000*l.*, for the specific purpose of experimental and laboratory work, this grant being independent of the Government loan of a portion of the working capital of the company. Chemical research has thus officially been recognised and endowed as an essential factor in solving a national industrial problem; and this most important and far-reaching decision has everywhere been favourably received, and represents a permanent advance in public thought and official procedure. Probably the main factor in moving the Government to assist the development of dye manufacture is the fact that one and a half millions of workpeople are more or less dependent upon the continuance of the dyeing industry. While we realise these special claims to attention, we hope at the same time that similar practical steps will at once be taken to promote the development in this country of glass manufacture and other industries dependent for their success upon progressive scientific knowledge.

The new dye company is to have powers to arrange for the assistance of a committee of experts conversant with the dyeing trade and its requirements. In the absence of details of the scheme, it does not appear that this proposal will adequately meet the claim that the technical expert should be largely represented on the directorate.

A perusal of the Press correspondence on the whole matter indicates that opinion has crystallised to some extent into a general agreement that the first aim should be immediately to develop and co-ordinate our existing manufacturing concerns, and encourage an increased output from Switzerland by arranging for the export of raw tar products to that country, and for transport facilities through France. But these expedients can afford only a very partial relief, and stocks of dyes are rapidly disappearing. It is therefore generally recognised as a matter of great urgency that the new manufacturing company should commence operations, and the first act of the company should be to devise an organised scheme of research on the initial problems of processes and yields.

FIG. 1.— A German coal-tar colour factory.

One of the most instructive discussions of the problem facing the manufacturers of coal-tar dyes in competition with Germany is to be found in an address recently delivered by Dr. W. H. Nicholls before the Philadelphia meeting of the American Association for the Advancement of Science, and printed in *Science* for January 8 under the title "The War and Chemical Industry." Dr. Nicholls, speaking with the authority of one who has been for many years at the head of a large chemical organisation in the United States, throws some interesting sidelights on the reason for American inactivity in this field. American manufacturers were at first assured by "one of the large producers in Germany that it was absolutely certain that American coal did not possess the necessary constituents to make it useful as a basis for the production of organic chemicals." When, in spite of this discouragement, it was actually found that aniline oil could be made at a profit in the States, "down went the price below cost. A tariff of 10 per cent. which was put upon the article was immediately absorbed by the foreign makers, and the price became lower still." The result was that the infant industry ceased to exist, and has only come to life again since the outbreak of the war.

It is emphasised that "to take away the dye business from Germany means attacking the best equipped and the best income-producer of Germany's entire chemical and allied industry"—a branch which, in 1912, with a total capital of nearly 8,000,000*l.*, paid a dividend representing 22 per cent. of the capitalisation. The fact that German works have long ago written off the cost of their

plant, together with their acquired experience and their sales organisations, largely account for the almost complete control which Germany has acquired in this branch of industry, and these are insuperable difficulties to be met by any competing nation unless really effective State-aid is guaranteed in the future.

The accompanying illustration (Fig. 1) from the *Little Journal,* for December, published by Messrs. A. D. Little, of Boston, Massachusetts, shows a typical German coal-tar colour factory. Some idea of the development of the German dye industry is afforded by the history of the Farbwerke Meister, Lucius und Brüning, which was organised in 1862 by two chemists and two merchants, with a staff of five workmen, one clerk and one chemist, and an engine of three horse-power. In 1912 7680 workmen, 374 foremen, 307 chemists, and 74 other higher technical officials were employed by this single firm, the wages paid out being 8·6 million marks, whilst 5·2 million marks were expended in salaries and bonuses. Eleven thousand different substances were manufactured, and the steam engines had a total horse-power of 30,000.

Closely wrapped up with the question of the manufacture of aniline dyes in Great Britain is that of the future of indigo in India, which is discussed in an article in the *Pioneer Mail* of January 8. It is here emphasised that during the past few years the indigo grown in Bihar and Orissa has been falling off in a remarkable way owing to the competition of the synthetic dye; whereas in 1913 63,100 acres were under indigo, the area grown this year is only 38,500 acres. Owing to the war, however, the price of natural indigo has rushed up enormously to more than 700 rupees per maund, a rise of about 300 per cent. on the normal price of the past three years. Thus the few indigo planters who were still producing indigo have been fortunate enough to make very large profits, and if they can continue or increase their production during 1915 they will be in an equally strong position. It is, however, difficult to estimate the ultimate effect of the war upon the indigo industry of India. There is no doubt that trade with Germany will be suspended for some time to come, and some time must also elapse before the manufacture of the synthetic dye can be established in France or England. Moreover, the use of natural indigo will probably be stimulated, owing to the increased requirements of the War Office and Admiralty, so that for some time to come the indigo planters will probably benefit considerably and make profits which will be some compensation for the lean years recently passed through. But there is little doubt that in the long run the synthetic dye, whether manufactured here or in Germany, will very largely supplant the natural material; it will be a repetition of the history of the madder industry. On this side of the question reference may be made to the lecture delivered recently by Dr. F. M. Perkin before the Society of Arts, and published in the *Journal* for January 1, and to the discussion which this paper evoked.

METALS AND WAR.

CONSIDERABLE attention has recently been devoted to the internal resources of Germany as a producer of various metals, more particularly, of course, of such metals as play an important part in the manufacture of war material. It has been shown that the normal consumption in Germany of copper, for example, is about 250,000 tons yearly, whilst the production is only about 25,000 tons, of which 20,000 tons are produced from one mine alone, the well-known Mansfeld mine, so that the possibility of any great increase in the domestic production would appear to be remote. The bulk of the German copper is imported from the United States, which produces more than half of the world's supply of copper, amounting now to about one million tons per annum, so that in normal times Germany purchases about one half of the United States' output of copper. It is obvious that the American producers of this metal must be seriously affected by the loss of so very important a customer.

Although public interest has centred mainly upon copper in this connection, there are other metals of scarcely less importance in this respect; thus nickel is used in the manufacture of armour plate, of special steel for ordnance and numerous similar purposes, and for some purposes can even be used to replace copper, as in the casing of leaden bullets. Germany produces practically no nickel, but has to import all its requirements; it would appear that the imports of nickel and nickel ore, which latter is smelted in Germany, would represent between 5000 and 6000 tons of nickel, of which about 1500 tons is re-exported, so that the German consumption may be taken as approximately 4000 tons per annum, out of the world's total production of some 28,000 tons. Again, manganese is indispensable in steel manufacture. In round numbers, Germany produces about 85,000 tons of manganese ore, and imports normally 650,000 to 700,000 tons, the bulk of which comes from the Caucasus, so that Germany produces only about one-ninth of its normal requirements of manganese, and the cutting off of the supplies of this substance cannot but seriously affect its steel production.

NOTES.

IN answer to a question as to typhoid in the Army, asked in the House of Commons on February 8, Mr. Tennant, Under-Secretary of State for War, said:—"Of the 421 cases of typhoid in the present campaign among British troops 305 cases were in men who were not inoculated within two years. In the 421 cases there have been thirty-five deaths. Of these deaths thirty-four were men who had not been inoculated within two years. Only one death occurred among patients who were inoculated, and that man had only been inoculated once, instead of the proper number of times—namely, twice." This is a marvellous record; and no further answer than it provides is needed to the inhuman efforts made by anti-vaccina-

tionists to induce men to object to inoculation by which such protection is secured. Replying to some carping criticisms against inoculation made by Mr. Chancellor in the House of Commons on February 9, Dr. Addison pointed out that in the South African war there were 58,000 cases of typhoid—more than an Army Corps—whereas in our great force now in France and Belgium, and after six months, including three months of atrocious weather, there have only been 421 cases among our troops. The total losses in South Africa were 22,000, of which about 14,000 deaths were from diseases and 8000 of these were from typhoid. When we compare this immense sacrifice of human life from preventible disease with the record stated above, we can only wonder at the patience of the British people in permitting a prejudiced faction to urge men not to subject themselves to a treatment by which they save others and themselves from suffering and death.

PROF. G. O. SARS, professor of zoology, University of Christiania, has been elected an honorary member of the Challenger Society.

SIR W. WATSON CHEYNE will deliver the Hunterian oration at the Royal College of Surgeons, Lincoln's Inn Fields, on February 15, taking as his subject "The Treatment of Wounds in War."

DR. SIDNEY COUPLAND has been appointed Harveian orator (of the Royal College of Physicians) for 1915; Dr. J. Michell Clarke Bradshaw lecturer for 1915, and Dr. Samson G. Moore Milroy lecturer for 1916.

THE Secretary of the Admiralty announces that the King has approved the award of the Polar Medal to the officers and men who took part in the Australasian Antarctic Expedition of 1911–14, under the leadership of Sir Douglas Mawson.

IT is announced in the issue of *Science* for January 29 that the city of Philadelphia, acting on the recommendation of the Franklin Institute, Philadelphia, Pa., has awarded the John Scott legacy medal and premium to Dr. C. E. Guillaume, of Sèvres, France, for the invention of his alloy invar.

ACCORDING to the *Southern Times* of February 6 the monument on the grave of the late Dr. Alfred Russel Wallace in the cemetery at Broadstone, Dorset, is a fine specimen of fossil tree from Portland, seven feet in height and weighing some two tons. The specimen stands on a foundation of Purbeck stone, and an inscription on it indicates merely Dr. Wallace's name and dates of birth and death.

DR. W. H. HADOW, principal of Armstrong College, Newcastle-upon-Tyne; and Engineer Vice-Admiral Sir Henry J. Oram, K.C.B., F.R.S., Engineer-in-Chief of the Fleet, have been elected members of the Athenæum Club, under the provisions of the rule which empowers the annual election by the committee of three persons "of distinguished eminence in science, literature, the arts, or for public service."

THE death is announced, in his fifty-eighth year, of Prof. L. L. Dyche, of the University of Kansas. He was a graduate of that institution, at which he was appointed in 1885 assistant professor of zoology, in 1886 professor of anatomy, in 1890 professor of zoology, and in 1900 professor of systematic zoology. He had made twenty-three scientific expeditions in various parts of North America, as well as Greenland and the Arctic regions, and had thereby secured for the University of Kansas one of the most valuable collections of mammals in the United States.

DR. BENJAMIN SHARP, who had charge of the department of zoology in Peary's first Arctic expedition, has died at Morehead, North Carolina, at the age of fifty-six. For a time he was professor of invertebrate zoology at the Philadelphia Academy of Natural Sciences, and afterwards at the University of Pennsylvania. He was then appointed corresponding secretary of the former institution, in whose interests he made collecting expeditions to the Caribbee Islands, Hawaii, and elsewhere. He was an industrious lecturer and writer on zoological subjects.

THE occurrence of frost-bitten feet among the troops has been reported from time to time. According to the *Morning Post,* February 5, Dr. Temoin, of Bourges, has investigated the subject, and concludes that the affection is not due to frost-bite, but is a gangrenous condition caused by arrest of the circulation through pressure, cold being a contributing but secondary factor. Wet causes the puttees to contract and retard the circulation, and the feet swell in consequence in the boots, which also somewhat contract. The remedy is to induce the soldiers frequently to take off their boots, and to reduce the period in the trenches.

IN a paper read before the Institution of Civil Engineers on February 9, Mr. F. D. Evans dealt with engineering operations for the prevention of malaria, as carried out in the Federated Malay States. Drainage is all-important, and an inexpensive and thoroughly efficient type of drain has been evolved to meet the conditions, formed of concrete blocks of half-egg shape, laid close but unjointed. The blocks are laid without foundations even on bad ground in flowing water. Should they move out of line or gradient, it is easy to re-set them correctly when the surrounding ground has settled, after which they give no trouble; but re-setting is rarely necessary.

A FEW weeks ago it was reported by cable that Sir Ernest Shackleton would not reach the base from which he intends to start his crossing of the Antarctic continent, in the Weddell Sea, in time to proceed this season. Letters and a diary now published in the *Daily Chronicle* confirm this. The ice has been very late in breaking. Sir Ernest now hopes to get away from the base at the beginning of November next, after wintering there. His present communications have come from South Georgia, and an interesting and useful piece of scientific work has already been done there in the erection of true meridian posts, which will enable whaling and other ships to test their compasses. The voyage to South Georgia appears to have been prosperous, and the expedition has

received an addition to its *personnel*, which must be unusual for a polar voyage, in the shape of a stowaway.

THE Calcutta correspondent of the *Morning Post*, in a communication dated January 7, states that the trustees of the Indian Museum, Calcutta, have addressed to the Government of India the following protest against the acts of vandalism perpetrated by the Germans in destroying Belgian museums and buildings of historical interest: "We, the office bearers of the Board of Trustees of the Indian Museum, desire to protest on behalf of our Board against the unnecessary destruction of libraries, art galleries, museums, and buildings of purely historical and artistic value in time of war. We do so with the knowledge that we have the support of our colleagues in other countries and with the conviction that the collective opinion of the governing bodies of scientific and artistic institutions throughout the world should be regarded as a matter of international importance, and that, on the conclusion of the present war, steps should be taken to lay down definite rules under international sanction for the preservation of artistic, historical, and scientific treasures during warfare."

THE North-East Coast Institution of Engineers and Shipbuilders has conferred its honorary membership upon Lord Fisher, First Sea Lord, in recognition of the part taken by him in bringing about the reform of the position of the rank and status of the naval engineer officer. In asking Lord Fisher to accept this honour the institution wrote: "It was with special satisfaction and pride that the council of this institution learned of the Admiralty order of the 24th December conferring military rank upon the 'old entry' engineer officers of the Royal Navy—satisfaction, in that it is believed that the change will lead to increased naval efficiency; pride, in the realisation of the fact that their professional brothers have won so honourable a recognition of their value in the constitution of 'our sure shield' the Navy. Our institution is convinced that it is chiefly to your lordship's keen perception of the dominating importance of engineering science and *matériel* in the constitution of the modern Navy that the nation is indebted for this wise and generous readjustment of the rank and status of naval engineer officers."

THE explosives industry has experienced a severe loss in the death of Capt. M. B. Lloyd, late of the Royal Artillery, and for the last seven years a director of the well-known firm of Messrs. Curtis's and Harvey. Born in 1865, Capt. Lloyd entered the Army from the Royal Military Academy in 1884, and in 1896 passed first out of the advanced class of the Ordnance College, obtaining the Lefroy gold medal and "honours" in practically every subject, including mathematics—a very rare distinction. On the death of Sir Vivian Majendie in 1898 he was appointed an inspector of explosives at the Home Office, and for a year or more was in charge of the recently established testing station for mining explosives on Plumstead marshes, where he did a considerable amount of useful work in connection with the risks due to the presence of gas and dust in coal mines, the experience he thus gained proving most valuable when he was subsequently appointed secretary of the Departmental Committee on "bobbinite." After leaving the Home Office early in 1908, and joining the directorate of Messrs. Curtis's and Harvey, Capt. Lloyd's exceptional qualifications led to his services being much in demand on technical committees; he was selected to represent the explosives trade on the War Office Committee on the Shipment of Explosives, on the Departmental Committee on the Heat Test, and on an informal committee appointed to consider the best form of construction for "danger buildings," and was made a member of the Home Office Committee on celluloid and its dangers. His premature death will cause a gap difficult to fill.

IN his paper on the "Fortified Headlands and Castles on the South Coast of Munster," reprinted from vol. xxxii., 1914, of the Proceedings of the Royal Irish Academy, Mr. T. J. Westropp has discovered an almost unexplored field in Irish archæology. These Irish coastal forts were constructed at various epochs. In some, like Howth, near Dublin, and Shanoan in Waterford, flint instruments have been discovered; some belong to the Bronze Age; others, again, were built or occupied by Danes, Welsh, or Normans. They differ greatly in form, and the following types are recognisable: simple headland forts with a single wall; complex, with several earthworks or walls; entrenchments or citadels; multiple forts with a single wall; complex, with several earthwith a gangway natural or artificial; headlands with a deep natural hollow at the neck; and fortified shore-rocks, usually isolated at high water. This interesting paper is well illustrated with photographs and ground plans. The completion of this investigation along the other parts of the Irish coasts, for which materials are now available, will be welcome.

IN the latest issue of the Anthropological Publications of the University of Pennsylvania (No. 1, vol. vi., 1914) Dr. G. G. Maccurdy has given an account of a collection of twenty-four skulls of the natives of the eastern end of New Britain—or, as the Germans have renamed the island, Neu Pommern. The natives of this island have heads which are very narrowly compressed from side to side, but in their general feature are clearly close relatives of the Australian aborigines. Dr. Maccurdy finds their canial capacity to be very low, the average for male skulls being 1345 c.c., for female skulls 1214 c.c. Apparently such an estimate depends on the material used in filling the cranial cavity, for Dr. Krause, employing millet as a measuring medium, in place of the shot used by Dr. Maccurdy, found the cranial capacity to be much lower for the natives of New Britain, viz., 1267 c.c. for males and 1180 c.c. for females. Dr. Maccurdy directs attention to a remarkable observation which Virchow made on three skulls from a common grave in New Britain. One was that of a man with a capacity of 2100 c.c., the other of a woman with a capacity of only 860 c.c. Virchow explained the difference as being due to the fact that the man had suffered from hydrocephaly, while the woman had been a subject of imbecility. It would be very in-

teresting to know if the great pathologist's explanation was really the true one—or if such a variation of brain capacity does occur among normal individuals of a native and untutored race.

THE *Journal of Anatomy and Physiology* for January, 1915, contains a paper by Dr. R. J. Gladstone and Mr. Erichsen-Powell on manifestations of occipital vertebræ and fusion of the atlas with the occipital bone in man. Four specimens of this variation are described, and its causes are discussed. Speaking generally, variation about a mean, with compensatory changes in other regions of the body, may be regarded as an established biological principle, which governs or acts on this region, as well as on growth and development in general. The authors are inclined to regard the majority of the variations in the occipito-atlantal region as largely attributable to this cause.

MESSRS. F. DAVIDSON AND CO., of 29 Great Portland Street, W., have sent us a descriptive pamphlet of the "Davon" super-microscope. The idea of this instrument was suggested by the principle governing the micro-telescope (described by Prof. Boys in NATURE, January 22, 1914), which is that of providing the microscope with an image *in air* of a distant object, the air-image being magnified by the microscope. This is accomplished by attaching a tube carrying a stage and focussing screw to the condenser-fitting under the stage of the microscope. The primary microscope slides into this tube, and consists of a tube with stops and an eyepiece and an inner tube, also stopped, carrying the micro-objective; this performs the primary magnification of the object and the image formed by the combination in air anterior to the eyepiece is then magnified by the microscope, to which it is attached, which is termed the "secondary" In this way almost unlimited magnification can be obtained, though, of course, resolution is unaffected thereby. For photomicrography no long-extension camera is required by this arrangement.

A RECENTLY published number of the *Annals of Tropical Medicine and Parasitology* (vol. viii., No. 3) contains a memoir on sleeping sickness in the Eket district of Nigeria, by Drs. Macfie and Gallagher. An endemic focus of sleeping sickness of considerable magnitude was found in this district, but the disease is of a mild type, occurring chiefly in children; the mortality is low, and spontaneous cures appear to be frequent. The trypanosomes can be found in the juice of the lymphatic glands, but have not been detected in the peripheral blood; the parasites differ in some respects, both in their morphology and pathogenic reactions, from the typical *Trypanosoma gambiense*, and the authors regard them as a distinct species (*T. nigeriense*, Macfie), characterised morphologically by the occurrence of a small percentage of peculiar diminutive stumpy forms. The infection is believed to be carried by *Glossina tachinoides*. The memoir is well illustrated, and in an appendix by Dr. Macfie it is shown that *T. pecaudi*, *T. pecorum*, and *T. vivax* are transmitted also by *G. tachinoides* in the Eket district. In another memoir in the same publication Dr. Macfie describes various blood-parasites collected by him in Nigeria. Amongst these are some organisms found in the blood of guinea-pigs and resembling the organism described by Seidelin from human blood under the name *Paraplasma flavigenum*, which is alleged to be the parasite causing yellow fever.

ACCORDING to a recent "count," as recorded in the *American Museum Journal* for January, the total number of fur-seals on the Pribilow Islands (where slaughter is now prohibited) in 1913 was 268,305—a large increase in the matter of "pups" over the preceding year.

IN the *Victorian Naturalist* for December last Mr. J. A. Kershaw, curator of the Melbourne Museum, recounts his experiences during a collecting trip to the Claudie River district, in the north of the Cape York Peninsula, Queensland. One of the incidents was a brief sojourn on Lloyd Island, where the party was much interested in the swarms of nutmeg-pigeons, Blue Mountain parrots, and shining starlings, which resort every evening to the island to roost, and return at early dawn to pass the day on the mainland.

MR. J. R. HENDERSON's administration report of the Madras Museum and Aquarium for the financial year 1913–14 has been issued by the Educational Department for that Presidency. A feature of the year's work was formed by demonstrations in the museum given to local schoolboys; another series of demonstrations being also arranged for teachers. Specimens of three newly described Indian mammals were presented to the museum by the Bombay Natural History Society. The Marine Aquarium maintained its popularity, more than four thousand rupees being taken at the toll-gates. A slime-head (Ophiocephalus) and a ray (Trygon) bred during the year in the central fountain.

WE are indebted to the author, Mr. J. A. Hutton, for a copy of a report on salmon-netting in the Wye during 1914, reprinted from the December issue of the *Salmon and Trout Magazine*. There were expectations that the season's catch would be exceptionally good, but it proved very disappointing, the total number of fish being only 2842, as compared with 6408 in 1913. The catch was, in fact, the smallest taken since 1908. Since the resumption, after a three years' interlude of netting in 1905, there have been great fluctuations in the number of salmon annually netted in the Wye. During the first four seasons the take averaged 2330; in 1909 there was a rise to 4319, while in the next three seasons the average fell to 3304, to be succeeded, as already mentioned, by an unprecedented increase to 6408 in 1913.

WITH the assistance of the Imperial Institute efforts are being made to create a market in the United Kingdom for the ground nuts grown in India and West Africa and their products—oil and feeding-cake. The export of ground nuts combined amounted to more than seven million cwts. in 1912, of the value of nearly 4,000,000*l.*, and hitherto France and Germany have between them absorbed the greater part

of this supply. The cessation of trade with Germany, and the diminution of the French demand, placed Indian producers in a serious position, and though recently the mills at Marseilles have placed orders with India, the demand from France remains below the normal. A quantity of the nuts has recently been imported into Hull from India for the production of ground nut oil, which is suitable for use as an edible oil as well as for soap-making. Abundant supplies are available from India, and when all food-stuffs are rising in price it is important to remember that ground nuts yield not only oil and feeding-cake, but are also valuable for edible purposes. In the United States they sell as roasted peanuts, and in the form of "peanut butter." Blanched kernels are regularly used in West Africa as a vegetable, mostly in the form of ground nut soup, but there are a variety of other ways in which ground nuts, which are both palatable and highly nutritious, can be prepared for the table.

In Bulletin No. 10 issued by the Agricultural Department of the Armstrong College, Newcastle-upon-Tyne, Prof. Gilchrist records the results of rotation experiments made at Peepy in 1910-13, and brings out a point of special interest to both the farmer and the man of science. Three plots received farmyard manure stored for different times at the rate of 12 tons per acre. The various forms of dung were: (1) fresh; (2) dung kept just long enough to be in good condition for application; and (3) old dung stored in a heap for some months. The best return from the four crops of the rotation was given by the manure kept for a short time only before it was applied. The old manure gave a rather better return than the fresh dung. The effect of the different dungs was naturally shown most clearly by the swedes, the first crop of the rotation, on which the dung kept for a short time only (2) showed a gain per acre 65 per cent. better than the old dung (3). This striking difference may be attributed to the heavy loss of readily available nitrogen and phosphate which occurs in farmyard manure when stored in heaps exposed to the weather. Recent laboratory experiments by Löhnis and Hunter Smith showed that fresh dung stored for periods varying from one to twelve weeks and then mixed with soil, subsequently nitrified at very different rates. As the optimum period of storage indicated by these workers was four weeks, it would be interesting to know exactly how long the manure used in Prof. Gilchrist's most successful experiment was kept before application to the plot.

The Monthly Weather Report issued by the Meteorological Office for December, 1914, is of more than ordinary interest, due to its reference to rain, floods, and gales. The frequent and abundant precipitation in many parts of England is said to be without a December precedent. The effects were the more marked because it followed a wet November, resembling the wet spells in 1876 and 1911. Many gales occurred during the month, and some were of great violence, whilst the atmospheric pressure was lower on the whole than in any December since 1876. December 23 and 24 were the only days when the pressure distribution over the country was not cyclonic. Temperature was generally above the normal until December 18, but afterwards it was generally below the normal. The rainfall exceeded the average in all parts of the kingdom, whilst the excess was abnormal over a large area in England. At Kew Observatory the total is quoted as 6·37 in., and was the highest December value since the record began fifty-nine years ago. At Greenwich Observatory the total was 5·96 in., and was the highest December value in the last one hundred years. It is mentioned that at many stations the percentage exceeded 300, the most notable being along the south coast of England and in the Isle of Wight. The highest values given are 331 per cent. of the average at Worthing, 354 per cent. at Totland Bay, and 415 per cent. at Hawarden Bridge. An aurora was observed at Newton Rigg on December 26.

In *L'Elettrotecnica* for October 5, 1914, Lo Surdo gives a complete review of the work done by J. Stark and himself on the electrical analogue of the Zeeman effect, *i.e.* the splitting up of the hydrogen lines of the spectrum by the intense electric field in the Crookes dark space. A brief account of Lo Surdo's experiments was given in Nature for May 14, 1914 (vol. xciii., p. 280). Making use of Stark's observation that the separation of the components is proportional to the field strength the author now seeks to determine the distribution of the field in the dark space. If the discharge tube is parallel to the collimator slit, it is found that the red hydrogen line is transformed into a Y-shaped figure, the upper end of which corresponds to the space nearest the kathode. It is, therefore, concluded that the field intensity decreases more or less uniformly with the distance from the kathode. This agrees roughly with Schuster's direct measurements, but is altogether opposed to those of Graham, who found points of maximum and minimum intensity. It may be remarked that the author appears to be unacquainted with the excellent measurements of Aston on the same subject.

Recent publications of the U.S. Coast and Geodetic Survey include the results for 1911 and 1912 from the magnetic observatory at Vieques, Porto Rico, and the annual report on field magnetic work for 1913. The former publication, in addition to diurnal variations of the magnetic elements relating to local mean time derived from the ten quietest days of the month, now contains diurnal variations relating to Greenwich mean time for the five international quiet days. As usual, there is a list of disturbed days on the scale 1 to 4 (highest disturbance). 1912 was exceptionally quiet, only one day reaching standard 2, and none standards 3 and 4. An interesting but somewhat disquieting statement is that, owing mainly to error respecting the "distribution constant" for the deflecting and deflected magnets, a correction of 10 per cent. is required to the previously accepted scale values for the Eschenhagen vertical force magnetograph. Of the field observations, perhaps the most interesting are from a number of closely adjacent stations in two disturbed areas, one the crater of Kilauea, in Hawaii, the other near Wilmington, in Delaware. Large variations

were observed in each case, especially in declination. The Survey, it seems, has decided that, beginning with 1913, all the results of magnetic observations will be referred to the "International Standard of the Department of Terrestrial Magnetism of the Carnegie Institution of Washington." This entails a reduction of one-tenth per cent. in the values of horizontal force previously published. An interesting question of the near future promises to be what this "international standard" really means, and how it is to be maintained constant.

In view of the recent report to the Board of Agriculture on the possibility of reviving the flax industry in Great Britain, a paper on the field and industrial retting of the fibre read before the Société d'Encouragement de l'Industrie Nationale (*Bulletin*, vol. cxxi., p. 153) by M. Albert Durand, the general secretary of the Comité Linier of France, has especial interest. An account is given in this paper of the different methods of retting of flax now used in France, as well as of the new mechanical and biochemical processes which have been the subject of trials on the large scale. It is interesting to note that M. Durand considers the policy of inaugurating central retting establishments, which was proposed in the report to the Development Commission, as one that could be adopted with advantage in France. The account given of the recent processes of Feuillette and Peufaillet for retting flax, illustrated as it is by numerous photographs, is a special feature of the paper.

Science Progress for January contains a vigorous editorial article on militarism and party politics, a criticism by Dr. H. G. Plimmer of Mr. T. A Cook's recent work on the "Curves of Life," and a survey of the problem of vitalism by Mr. Hugh Elliot. Mr. Rhys Jenkins contributes an interesting article on the international struggle for manufactures as illustrated by the history of the alum trade, Mr. Allan Ferguson gives a summary of recent work on capillary constants and their measurement, and Dr. J. N. Pring reviews the question of the formation of ozone in the upper atmosphere and its influence on the optical properties of the sky. Dr. Edridge-Green deals with colour vision and colour vision theories, a subject which at the present time "is in a state of chaos," and Mr. C. E. Wallis gives an interesting comparison of ancient and modern dentistry.

Engineering for January 15 contains an article on the balancing of high-speed machinery by Messrs. H. D. Wheeler and R. V. Southwell. After giving a clear account of the nature of the problem, the authors describe their optical arrangement in use at Messrs. Lawrence Scott and Company's works for the accurate balancing of high-speed armatures. The armature is supported in ball bearings which can move in a horizontal direction at right angles to the shaft against the action of springs which normally keep the bearings central. The armature is driven by a narrow strap which runs vertically on to and off the armature. At a certain speed depending on the size of the armature and the strength of the springs, the two bearings begin to oscillate in the same direction, showing that one side is heavier than the other. At a higher speed generally about double the former, the bearings again oscillate but now in opposite directions, showing a want of dynamic balance. By means of a circular disc with an involute slot in it, fixed on one end of the shaft, light from the vertical filament of a lamp placed under the bearing is focussed on a screen after reflection at a small mirror which rocks about a vertical axis as the bearings move. By means of the curve traced by the spot of light the proper positions of the balance weights can be found more quickly and more accurately than by the "chalk mark" method.

OUR ASTRONOMICAL COLUMN.

THE RED REGION IN THE SPECTRA OF WOLF-RAYET STARS.—In the *Comptes rendus* for January 25 (vol. clx., p. 124) a note is presented by M. J. Bosler on an investigation which he has carried out at the Meudon Observatory on the study of the red region of the spectra of Wolf-Rayet stars. The advance in the magnitude and efficiency of astronomical equipment renders a more minute study of the spectra of faint stars possible, and the bathing of photographic plates opens up new regions of the spectrum for close inspection. M. Bosler describes here the result of the work on fifteen Wolf-Rayet stars, seventy-five clichés in all having been obtained with exposures varying from two to three and a half hours. In the communication he gives a short table, reproduced below, showing the wave-lengths and intensities of several of the lines in the spectra of these stars, which he considers are of more special interest. In the brief discussion he refers to the spectra of novæ and their points of semblance with these bright-line stars, and is led to the view that the Wolf-Rayet stars are only the enfeebled remains of novæ which have appeared in the course of past centuries. The following table embodies the data in five of the stars mentioned above, the figures in brackets indicating the intensities of the lines :—

B.D. 3821+39°	Mag. 7·1 (7 plates):	711 (3) 691 (2) 6675 (2) 6563 (5Hα) 643 (2) 6395 (2) 624 (1).
B.D. 4001 +35°	Mag. 8·5 (6 plates):	711 (2) 691 (2) 677 (2) 6678 (3) 6563 (5Hα) 643 (1) 6395 (1).
B.D. 4013+35°	Mag. 8·0 (8 plates):	6718 (3) 664 (?) 657 (5Hα) 6425 (2) 6300 (1) 624 (?).
B.D. 3639+30°	Mag. 9·5 (8 plates):	6717 (2) 6570 (20Hα) 630 (?).
B.D. 3571+43°	Mag. 7·5 (1 plate):	6715 (1) 6563 (5Hα) 642 (2).

AID TO ASTRONOMICAL RESEARCH.—In a communication to *Science* (vol. xli., No. 1046, January 15, 1915) Prof. E. C. Pickering directs attention to the great success of research funds, and points out the large returns which can be obtained from relatively small grants to suitable persons. Believing that the greatest return in astronomical output can be obtained by moderate grants to leading astronomers, he has addressed a letter to twelve American astronomers asking them to make a statement showing how they would apply a grant supposing it consisted of one thousand dollars a year for five years. In the communication in question Prof. Pickering publishes the replies he has received, and all without exception would welcome such a grant. An unexpected result of the request was that in nearly every case the principal need proved to be for assistants. The question now arises whether the money can be obtained, but if all cannot be secured, Prof. Pickering suggests that astronomers with fewer assistants should receive precedence. In some cases it is hoped that those interested in a particular observatory may be willing to supply its needs.

THE SPECTRUM OF LIGHTNING.—It is not very often that a very successful photograph of the spectrum of lightning is obtained, but that secured by Mr. A. Steadworthy, and reproduced in the Journal of the Royal Astronomical Society of Canada (September–October, 1914) is of this nature. The easiest way to secure such photographs is by placing a prism or a transparent replica grating in front of the camera lens. In the case of the former the spectrum only is photographed, but in that of the latter images of both the flash and the spectrum are recorded side by side. Mr. Steadworthy employed the first method, using a 60° dense flint glass prism in front of a 2-in. lens of 16-in. focus. The account is accompanied by the measurements of the lines of the spectrum made by Mr. J. B. Cannon, of the Ottawa Dominion Observatory. The wave-lengths of fifty lines are given, and a comparison table is given containing the wave-lengths of the lines measured in the fine spectrum obtained and described by Mr. Fox in the *Astrophysical Journal* (vol. xviii., p. 295). Mr. Steadworthy also secured ten excellent stereoscopic photographs of lightning flashes, some of which are reproduced in his article.

REPORT OF THE SMITHSONIAN ASTROPHYSICAL OBSERVATORY.—The director of the Astrophysical Observatory of the Smithsonian Institution, Prof. C. G. Abbot, has issued his report for the year ending June, 1914. This report contains a brief statement of the equipment of the observatory, the work of the observatory at Washington, and at Mount Wilson. It is shown that progress has been made in the measurement of the effects produced by atmospheric water-vapour on solar and terrestrial radiation. New apparatus for measuring sky radiation has been devised and perfected. A most interesting account is given, including an illustration, of special pyrheliometers for recording solar radiation at great altitudes when attached to free balloons. The highest elevation at which a radiation record has been obtained was about 14,000 metres, or nearly 45,000 ft. The results obtained tend to confirm the adopted value of the solar constant of radiation. A Tower telescope has been erected and put into operation on Mount Wilson. The tower is 50 ft. high and equipped temporarily with a reflecting telescope of 12-in. aperture and 75 ft. focal length. By means of it the variability of the sun has been independently confirmed, and it is stated that changes of the distribution of radiation over the sun's disc occur in correlation with the changes of the sun's total radiation.

ORNITHOLOGICAL NOTES.

IN the report of the council of the Royal Society for the Protection of Birds, embodied in the winter number of *Bird Notes and News*, it is stated that four British lighthouses have now been fitted with bird-perches. The same issue also contains the results of the 1914 competitions for school challenge shields in connection with "bird-and-tree day." Despite a good series of essays from Woburn, the Bedfordshire shield has been withdrawn, on account of the lack of competitors; Lancashire, on the other hand, bids fair to receive the award of a shield during the current year.

In an article on the probable effect of the war in the western area on birds, in *La Nature* for January 16, Dr. E. L. Trouessart expresses the opinion that storks in Alsace and local ground-birds and partial migrants throughout the area of conflict will be the main sufferers. Night-flying migrants, on the other hand, will probably steer clear of the chief areas of conflict, which, looking at the subject in a wide sense, are relatively small. In the neighbourhood of Arras the country was reported to be the resort of myriads of crows in December, attracted doubtless by the rich supply of food.

Among the more notable birds observed in Hertfordshire in 1913, Mr. W. Bickerton records, in the Transactions of the Hertfordshire Natural History Society for January, quail, snipe, and goldcrests as breeding in the county, together with casual visits of the oriole, hobby, and dotterel.

In anticipation of a fuller notice in a forthcoming issue of his *Birds of Australia*, Mr. G. M. Mathews revises the classification of the frigate-birds in vol. ii., No. 6, of the *Austral Avian Record*. Hitherto only two species of these birds have been recognised, *Fregata aquila* and *F. ariel*, the former a widely spread type, split up by some ornithologists into three or four local forms. Mr. Mathews, on the other hand, restricts *F. aquila* to the Ascension Island bird, both sexes of which are wholly black, with no rust-colour on the white heads of the young. The other frigate-birds hitherto classed with *F. aquila* are for the most part identified with *F. minor*, of Gmelin, the typical locality of which is taken to be Jamaica, several subspecies, from the Seychelles, Aldabra, Laysan, the Galapagos, etc., being recognised. The frigate-bird of Christmas Island, Indian Ocean, is described as a new species, with the name of *F. andrewsi*, and is characterised by the under-parts being wholly white in the female and partially so in the male. Lastly, we have *F. ariel*, typically from Torres Strait, characterised by the presence of a white patch on the flanks of the cock, and of which three local races are recognised.

Hybridism in cockatoos forms the subject of an article (illustrated by a coloured plate) by Dr. E. Warren in vol. iii., pt. 1, of the Annals of the Natal Museum, dated September, 1914. A male of the sulphur-crested *Cacatua galerita*, and a female of the slender-beaked *Licmetis nasica*, have been kept for the last eight years or so in a state of semi-confinement in the open air at Pietermaritzburg. During the latter portion of that period the female laid several eggs, two of which were duly hatched. The two hybrids, which are practically similar to one another, are to a great extent intermediate in coloration and plumage between their parents, although nearer to the sulphur-crest than to the slender-beaked species, the resemblance to the former being especially shown by the stoutness and blackness of the beak, as well as by the red loreal patch of the female parent being replaced by orange, and by the total disappearance of the red at the bases of the feathers behind the eyes, so characteristic of the latter. Whether this resemblance of the hybrids to their male parent is due to prepotency in the latter, and the bearing of the whole case on Mendelism, form the subject of a long discussion by the author.

In reference to a recent discussion with regard to birds travelling northwards in autumn on the British coasts, Mr. J. H. Gurney records in the *Zoologist* for December, 1914, that an immense series of flocks of various species were seen flying northwards on October 7 over Cromer, Northreps, and Overstrand, the wind at the time being north. Mr. Gurney is of opinion that such movements are annual, and that after a short interval the wanderers would return south.

During a trip to eastern Siberia in the summer of 1914 Miss Maud Haviland was fortunate enough to come across the curlew-sandpiper breeding at Golchica, at the mouth of the Yenisei. Eggs of this species, it may be recalled, were collected by Mr. H. L. Popham, in July, 1897, on the Kristovski Islands, which are a considerable distance further down the estuary.

According to a narrative published in the January number of *British Birds*, Miss Haviland found the species comparatively abundant in the Golchica district, and procured several skins, as well as a clutch of eggs and a couple of young birds. The last are very similar to young dunlin, but even when a few days old may be distinguished by the shape of the beak. As soon as hatched they leave the dry upland slopes for the sphagnum-bogs that occupy the hollows in the tundra.

R. L.

CLAY AND POTTERY INDUSTRIES.[1]

IN an interesting and valuable introduction, Mr. Graham Balfour, who has been for so many years closely associated with educational work in North Staffordshire, says:—"This volume of collected papers is the first fruits of the Stoke-on-Trent Pottery School, and will in due course . . . be followed by many successors of equal size and value."

The publication of this record of work done by the students and members of the staff coincides with the opening of the New Central Schools of Science and Technology at Stoke-on-Trent, which contain finely equipped chemical, physical, and pottery laboratories and class rooms, and in which the old pottery school finds at last a suitable home.

The school has been conducted by Dr. Mellor for some ten years under conditions which would certainly have damped the ardour of any ordinary man, but this record of work accomplished during these years by Dr. Mellor and his students is a striking testimony to the enthusiasm and ability with which the work has been carried on. It is no longer necessary or desirable that an English pottery student should go to Charlottenburg for his training as a ceramic chemist, for here at hand he has a splendidly equipped school, which has already built up a tradition for research work of the highest importance. The subjects dealt with cover a very large field, but nearly all are of direct practical value to the potter.

Paper xxix. on studies on cylinder grinding is a most excellent contribution, and is a typical example of the thoroughness with which the subjects are treated in their theoretical and practical aspects.

Paper xxiv., on the absorption and dissolution of gases by silicates, by Mr. Bernard Moore and Dr. Mellor, is an extremely interesting and important paper of direct practical value, and the publication of this and other similar work has already beneficially affected pottery practice in this country.

The papers on the nomenclature of silicates and on the chemical constitution of the kaolinite molecule are in another category, but although they are not of direct practical application, they are of great interest to the ceramic chemist, and they show that the outlook of the school is comprehensive and that the work done has an importance beyond the confines of the pottery industry.

The illustrations and descriptions of apparatus—much of which is here described for the first time—are excellent, and it need scarcely be said that Dr. Mellor has used his mathematical ingenuity to advantage in working out and in explaining the problems dealt with. The references to original papers and other published work of German, French, American, and English chemists is a very useful feature of the book.

The papers are naturally of very different values, and their publication in one volume produces a rather uneven "Mosaic" effect, but the impression one gathers from a perusal of the book is the wide scope and thoroughness of the work and its practical value. It is a unique publication in this country as a record of work done by so small a school and in so modest a way.

JOSEPH BURTON.

[1] "Clay and Pottery Industries." Being vol. i. of the Collected Papers from the County Pottery Laboratory, Staffordshire. By several Authors. Edited by Dr. J. W. Mellor. Pp. xvii+411. (London: C. Griffin and Co., Ltd., 1914.) Price 15s. net.

THE IRISH TECHNICAL INSTRUCTION ASSOCIATION.

THE proceedings of the Annual Congress of the above Association, held at Killarney in May last, are of more than usual interest. The operations of the association cover virtually the whole of Ireland, and the congress just held is the thirteenth since the Act of 1902. Without any question these congresses have contributed largely to the development of scientific and technical instruction in Ireland, and incidentally to a keener interest in a more efficient elementary and intermediate education.

The subjects dealt with have been concerned mainly with industrial progress and with the conditions and problems which await investigation and solution in order to ensure a stable advance in the agricultural, industrial, and commercial well-being of the nation. In this endeavour there is the closest co-operation on the part of the Government and other official authorities with the education committees of the various areas, and four of the papers of high importance, dealing with the "Problem of Small Industries," "The Technical Training of Skilled and Unskilled Workers in France and Germany," "An Industrial Survey of Ireland," and "Technical Instruction for Small Holders," were read by officials of the Department of Agriculture and Technical Instruction, and Mr. T. P. Gill, the secretary of the Department, gave an inspiriting review of the progress of technical instruction in Ireland since its initiation in 1902.

The position and future of the Irish woollen trade was the subject of a highly interesting paper by Mr. J. F. Crowley, of Siemens Bros., Ltd., with the object of showing that the industry, now somewhat languishing, is peculiarly suited to the genius, temperament, and circumstances of the Irish people, and that, given the organisation, both industrial and commercial, due technical training and capital, there is no reason why the industry should not take a high place amongst the productive enterprises of Ireland. It is essential to its success that there should be, amongst other measures, a central woollen textile school established in the south of Ireland for the efficient training of the various grades of persons engaged in the industry.

The paper by Mr. Macartney-Filgate, well illustrated by maps, diagrams, and lantern slides, setting forth the varied industries and natural resources of Ireland and suggesting lines and methods of scientific development, was of much interest. Whilst the available coal supply is limited, there is water power available, easy of transformation into electrical energy, to the extent of $1\frac{1}{4}$ million horse power, together with an almost unlimited supply of peat fuel, and examples were given showing how this and the former source of power had been successfully utilised on a large scale, and only needed capital and enterprise still further to develop it. The extraction of oil from shale on a considerable scale has also been successfully begun, rendering it possible to utilise the internal combustion engine for the service of the small manufacturer. Much valuable information was given by Mr. L. J. Humphreys on the efficiency of co-operative effort in his paper on "Technical Instruction for Small

Holders," illustrated by successful experiments on farms of large extent in Essex and Kent.

The deliberations of the congress reveal the necessity of greater efficiency in the sphere of elementary education, so as to ensure the attendance of all children at school until fourteen years of age and of part time education until at least the age of seventeen.

Swan Sonnenschein. *Williams and Norgate.*—On the Cosmic Relations: Being an Outline of the Evolution of the Relations between the Soul and the External Universe, and a Summary of the Recognised Relations that are still so immaturely evolved as to be little understood, H. Holt, two vols.

THE BRONZE-AGE INVADERS OF BRITAIN.[1]

SOMEWHERE about the year 2000 B.C., when the peoples of Western Europe were beginning to learn the uses of bronze and to alter the style of their pottery, a race of invaders began to reach our shores who were totally different from any race which had lived in Britain before that time. The ancient British, although of various strains, were all of them of the long-headed type; they had projecting occiputs; their heads appeared as if compressed from side to side. But those Bronze age invaders had rounded heads, with flat occiputs; their heads had the appearance of having been compressed from back to front. European anthropologists name this round-head type of man "Celtic"; they regard him as an offshoot from the racial type which now attains its greatest purity in the mountainous countries of Central Europe—the "Alpine" type of race. We may take the Bavarian or Savoyard as good modern representatives of the ancient Celtic or Alpine type. They are usually men of short stature, with dark hair and skins, with short and wide faces, regularly modelled features, and rounded heads. The men who invaded England early in the Bronze age and buried their dead in round barrows, were of a different build of body; they were strong, tall, and muscular; they had long faces, rugged features, prominent noses, overhanging eyebrow ridges; we have reason to believe they were fair in hair and complexion. Although these early invaders of Britain had the "Alpine" form of head, it is not among the modern inhabitants of Savoy or of Bavaria that we can hope to find their ancestral stock. We are all agreed that they were continental in origin. Those who have studied our Bronze-age invaders—who have investigated their physical characters, their methods of burial, their domestic animals, their pottery, their weapons and ornaments, are almost unanimously of opinion that we must seek their ancestral home somewhere in that part of Europe which now lies within the bounds of the German Empire. Every year our knowledge of Europe during pre-Roman times becomes more exact, and I propose, once again, in the light of more recent discoveries, and particularly from the point of view of one who is a student of the human body, to seek for the origin of our round-headed ancestry. We shall find that this early invasion of England was but a side eddy of a racial movement which affected almost the whole population of Europe.

How far the British people were exterminated and replaced during the invasions which took place after Roman domination had come to an end is not easily decided. If the Anglo-Saxons brought a new tongue to England they brought no new physical type; in stature and in head form we cannot distinguish them with certainty from the Britons of the period of Roman occupation, nor from the older pre-Roman population. But in this earlier invasion, which began 2000 years before the Roman legions crossed the Straits of Dover, we have not the same difficulty; so distinctive is the head-form of the Bronze-age or "round-barrow" men that we recognise the type at a glance; the type was then new to England. Along all the counties on our eastern seaboard, from Caithness in the north to Dorset in the south, we have found the graves of this distinctive round-headed race. The Hon. John Abercromby, who is our leading authority on British pottery, weapons, and ornaments of the Bronze age, is of opinion that the round-headed invaders were few in number, and that, after gaining a foothold in Kent, they gradually spread northwards and westwards throughout our country. With that conception I cannot agree. The south-eastern part of England was apparently only one of the landing places; the researches which were carried out by Canon Greenwell and Mr. Mortimer leave us in no doubt as to their arrival in eastern Yorkshire; the round-heads became masters of it. The counties which bound the Firth of Forth formed another centre of the invasion; the round-heads conquered that part of Scotland. For our present purpose their extensive settlement in the lowlands of Aberdeenshire and along the southern shores of the Moray Firth are the most important. In recent years Prof. Reid and Dr. Alex. Low, of the University of Aberdeen, have made us familiar with the Bronze-age men of the north-east of Scotland. These more northern invaders had their own peculiar kind of round-headedness, a kind remarkably flat on the crown—just as they had their own kind of graves, their own kind of pottery and ornaments. Sixty years ago that pioneer of anthropology—Prof. Anders Retzius, of Stockholm—identified a certain physical type in Aberdeenshire as similar to that which he had seen amongst the peoples in some of the Baltic provinces of Russia. The invaders who settled on the shores of the Firth of Forth, in Yorkshire, and in the south-eastern part of England have, like their more northern allies, their own distinctive traits in form of head, and in fashions of weapons and pottery. We find a difficulty in explaining the distribution and characters of the "round-head" invasion, if we suppose, as Mr. Abercromby does, that there was only one point of landing, but all our facts find an easy solution if we suppose that the invasion which occurred in the Bronze age, was similar in character and in extent to that which took place in Anglo-Saxon times.

We must presume, then, that those round-headed people, like the Anglo-Saxons, crossed the North Sea; we must presume further that the "round-heads" were then the dominant power in the North Sea. There are certain considerations which make such a presumption difficult to accept. Then, as now, the Continental shores of the North Sea were inhabited chiefly by long-headed peoples. We do know, however, that before the beginning of the Bronze age the "round-heads" had broken through from the hinterlands of Germany and had reached the coast at various points between Scandinavia in the north and Brittany in the south. It is somewhat difficult to believe that a round-headed people were master mariners; sea-power has usually been the appanage of long-headed nationalities; the Spaniards, the Portuguese, the Dutch, Norwegians, and British were, and are, predominantly long-headed. However that may be, we know the round-heads reached the Orkneys, the Hebrides, and the western shores. They spread across the lowlands of Scotland and crossed over to

[1] Presidential Address delivered to the Royal Anthropologcial Institute of Great Britain and Ireland, on January 26, by Prof. Arthur Keith, F.R.S.

Ireland, where they formed numerous settlements in the north and east. The late Sir William Wilde believed—sixty years ago—that they were the aboriginal inhabitants of Ireland, but we know now that Ireland had been the scene of many an invasion before the round-heads reached her shores. The invading race spread over the richest parts of England; they reached Wales.

We are not yet in possession of sufficient evidence to determine how far the round-heads replaced the older inhabitants of Britain. There were several parts of England, Wales, Scotland, and Ireland which they failed to penetrate; at least we have not found in these parts their peculiar "round-barrow" graves. But in other parts their influence was pronounced. In the Museum of Comparative Anatomy at Oxford there are seventy skulls of people buried in round barrows during the earlier part of the Bronze age; thirty of them are apparently pure representatives of the round-headed race; among sixty-seven skulls gathered from the older or long barrows there is not a single representative of the round-headed people. Dr. William Wright found that the round-heads formed 29 per cent. of the people buried in the round barrows of Yorkshire. In the Aberdeenshire graves of the Bronze period Prof. Reid observed that eleven out of twelve skulls were of the rounded type. Were we to argue from the people buried in the peculiar graves of the early Bronze period we should infer that the invaders had influenced the British population to a profound degree. We have reason to believe that the people buried in the barrows or in cist-graves represent not the population as a whole but only a class—the richer or governing class. I had occasion recently to examine a hundred skulls from a disused London cemetery—representative of the working population—and found that only three showed clear signs of a Bronze-age ancestry. It is unusual to see a head of this rounded type on a British artisan. It is otherwise in the classes from which we draw our Civil Servants, our squires, and professional men. In a West End club, chiefly recruited from these classes, the Bronze-age type of head can be traced in about 20 per cent, of its members. I have said that the counties round the Firth of Forth were centres of settlement. Sir William Turner found that 25 per cent. of modern skulls from these counties were of the short or rounded type. The population of Kent, which has been the scene of more than one round-headed invasion in pre-Roman times, is eminently short-headed, or brachycephalic.[2]

We may speak with equanimity of an invasion which overwhelmed our country between 3000 and 4000 years ago; it brought in a strain of blood which still exerts its influence on certain classes of our population, and which has given us some of our most eminent men. I will cite only three instances—the first being Charles Darwin—one of the most acute and best balanced intellects ever bred in England. No one who has examined the bust which Woolner modelled from him in life can doubt his Bronze-age ancestry. His resemblance to Tolstoi is more than a superficial one. The second instance I shall cite from Scotland. We know the head-form of King Robert the Bruce, for a cast of his skull was taken before his remains were re-interred in 1819. An examination of that cast shows that Bruce possessed all the essential features of the Bronze-age race. Lastly, I take an instance from Ireland, where there are many descendants of the Bronze-age invaders, selecting that most lovable of men—Oliver Goldsmith. It is also a matter worthy of note that John Bull, as portrayed by "Mr. Punch," carries in his form of head a distinct impression of a Bronze-age ancestry.

So far as concerns the basis of the British population the invasion of the round-heads remained without effect; the mass of the people retained the long-headedness which had characterised their ancestors in the Neolithic and later Palæolithic ages. When we turn to France and mark the changes which occurred in her population at a corresponding period, we find the end result was totally different, there was a complete revolution in head-form; from being a long-headed people the majority of the French became round-headed. Long before the end of the Glacial period we find long-headed races in possession in France; even when the Glacial or Pleistocene period had ended and the Neolithic age was well begun, the native tribes of France retained the more ancient type of head. But even in the older or Pleistocene period we find some trace of the short-headed race. The skull found at Chancelade, in the Dordogne, in circumstances which convince us that its owner must have lived in one of the later phases of the Glacial or Pleistocene period, possesses certain definite features in its hinder or occipital region, which show affinity to the round-headed type. In the more superficial strata of a gravel pit at Grenelle, a suburb of Paris, a series of skulls have been found[3] which show all the features of our invaders of the Bronze age. In deeper and more ancient strata all the skulls were of the long type. There is good reason for believing that the Grenelle skulls, from both the deeper and more superficial strata, are of Pleistocene age.

Apparently then the round-head invasion of France had begun at a much earlier date than in England. M. Salmon collected measurements of the skulls of 688 people who lived in France during the Neolithic period—or, to make my meaning more clear, in a pre-Bronze age—and found that 58 per cent. were long-headed, 21 per cent. round-headed, the rest (21 per cent.) forming an intermediate group. A late Neolithic sepulchre in the Marne (Petit Morin) yielded a higher percentage of short-heads, viz., 27 per cent., while the long-headed group had become much reduced —34 per cent.

We see then that the round-headed invasion of France took place at a much earlier date than that of Britain. The French invaders, appear to have belonged to a different branch of the round-headed stock. It is true that north of the Seine one frequently sees amongst the skulls of Neolithic France the identical type which invaded Britain; we note the same strong and rugged faces, the same prominent supra-orbital ridges and the same flattened occiputs which characterise our British invaders. We suppose these northern forms must have come, like our ancestors, from across the Rhine. But the majority of the round-heads which then invaded France were of a different type; their foreheads were full and wide and destitute of great brow ridges; their faces were short and wide and of a less massive cast; their occiputs were rounded rather than flattened. They represent exactly what modern anthropologists have in mind when they speak of the "Alpine" race or type. The type deserves that name, for it evidently issued from the western flanks of the Alps and spread gradually over the whole of France. The revolution in head-form never passed beyond the Pyrenees. Long before the arrival of Cæsar in Gaul, the majority of the French people had become of the round-headed type. From Cæsar's time onwards the people who lived between the Loire and the Seine have been regarded as the representative of the true Celtic race. Our

Celtic-speaking people—the British "Celtic fringe"—belongs to a very different European stock.

The anthropological history of Italy is not unlike that of France. Very few remains of the people who lived in Italy before the dawn of the Neolithic period are known, but such as have been found lead us to believe that the early inhabitants were long-headed and apparently members of the dark-haired stock which inhabited the lands surrounding the Mediterranean—members of Prof. Sergi's "Mediterranean Race." Italy, like France, was apparently invaded from the flanks and passes of the Alps. In some of the graves of Lombardy, belonging to a later phase of the Neolithic period, we find skulls of a short-headed people. Some of these have the massive faces, the great supra-orbital ridges and the peculiar occipital flattening which characterise the Bronze-age invaders of Britain—but others, apparently the more numerous—are of the true Alpine type, the type which has left its influence on France. Long before the Etruscans and Romans had risen into prominence, the round-heads had permeated the northern half of Italy. I have lately examined the collection of crania which Dr. Niccolucci gathered from ancient Etruscan and Roman tombs—they are preserved in the Museum of the Royal College of Surgeons; fully a fifth of them manifest distinct traces of a round-headed ancestry. Collections of modern Italian crania show that the population has become increasingly brachycephalic since Roman times. In that Italy does not stand alone; it has been so with the population of France, Germany, Russia, Austria, and Greece. The anthropological surveys which have been carried out by Dr. Ridolfo Livi on army recruits drawn from all parts of Italy prove that in the southern half of the country the long-headed, dark-haired Mediterranean race is still the dominant population. But northern Italy is eminently round-headed.

It is generally agreed that the ancient Greeks were long-headed, and were members of the Mediterranean race, but apparently before they reached the heyday of their civilisation and of their power, a wave of round-heads had already penetrated the Balkan peninsula and reached the shores of the Mediterranean. The vast majority of the peoples inhabiting the Balkan Peninsula and the Austrian Empire manifest a high degree of brachycephaly. It was not always so along the valley and across the plains of the Danube. For instance, Prof. Toldt, of Vienna, did not find a single round-head in a collection of skulls gathered from ancient graves in upper Austria; 80 per cent. of the modern population is round-headed. So far as we can yet judge, the Danube Valley, in its width and length, was inhabited by a long-headed population in the Neolithic period. There is, however, an exception—the skull discovered fully thirty years ago by Prof. von Luschan at Nagy-sap, in Hungary, deeply embedded in the loess of the Danube, and presumably pre-Neolithic in date. Apparently before the Neolithic period had ended the round-heads of the true Alpine type began to penetrate the modern bounds of the Austrian Empire. The inrush of German-speaking peoples in post-Roman times did not stay the growing dominancy of the round-heads. Prof. Matiegka, of Prague, found that the remains of people buried in Bohemia during the ninth century A.D. yielded 14 per cent. of brachycephalic skulls, those of the sixteenth century yielded 70 per cent.; modern graves 85 per cent. The diverse peoples of the Austrian Empire—they are really more differentiated in speech than in racial type—have thus become dominated by a round-headed stock in comparatively recent times.

North of the Carpathians the story is the same. On the plains of Russia there are numerous mounds or tumuli—"kurgans"—containing the remains of ancient Russians. Seventy years ago Russian anthropologists began to investigate these mounds; they found from their contents that some of them dated back to the Neolithic period, others were of the Bronze age. They found, too, that the people buried in the older mounds were of the long-headed type—not unlike the men whose remains lie in our long barrows. The best modern representatives of this type are the inhabitants of Scandinavia—I shall speak of this form as the Scandinavian type. I have examined lately a series of accurate casts—forty in number—made from skulls found in these ancient Russian mounds. Twenty-seven of these are of the Scandinavian type; only eight of them are round-headed. Of these eight, five show the features of our invaders of the Bronze age—the massive face, the strongly marked supra-orbital ridges, the flattened occiput. The remaining three are more of the Alpine type. The vast majority of the people within the bounds of European Russia are now brachycephalic; only in those Baltic provinces which lie to the south of the Gulf of Finland has the ancient Scandinavian type succeeded in surviving. In Finland, itself, the Scandinavian type has been replaced by the modern brachycephalic Finn. So far as we have gone the western parts of Russia afford the most probable cradle for the British invaders of the Bronze period.

The anthropological history of Germany is very similar to that of western Russia. To the eye of the anthropologist the modern German Empire falls into three very distinct, but very unequal parts. There is, in the first place, the western or coastal area—embracing Oldenburg, Holstein, Hanover, and parts of Westphalia, where the Scandinavian or Anglo-Saxon form of head is still the dominant type. From the evidence afforded by ancient graves, we have no doubt that the coastal or western German does represent the Neolithic population of Germany, and he does not differ materially from the ancient long-headed native of western Russia. Then there is the second or southern area, including Bavaria, Wurtemberg, Baden, and the upper areas of the Rhine Valley. The modern population of these lands is eminently brachycephalic. Anthropologists are agreed in regarding them as typical representatives of the Alpine race. When and how the change in head-form was effected in South Germany we do not know definitely, but ancient graves, even down to the time of the disruption of the Roman Empire, yield skulls of the long or Scandinavian type. Bavaria, Wurtemberg, and Baden have undergone a revolution in head-form, not unlike that which has overtaken the Austrian Empire and France. In all of them the primitive population has become "Alpinised." In the remaining part of the German Empire—the part which may be described as Prussian, and which contains at least two-thirds of the total population of the Empire—a transformation in head-form has occurred, very similar to that which has overtaken the earlier inhabitants of Russia. German anthropologists have made no attempt to estimate the extent to which the modern Prussian population has assumed the Russian or Slav form of head, nor has any special endeavour been made to ascertain when the change took place. Prof. Welcker of Halle, found that out of a small collection of thirty German skulls eighteen were brachycephalic. In an ancient Prussian cemetery which had been used between the ninth and twelfth centuries, 30 per cent. of the skulls were of the long type and 18 per cent. of the round. Four centuries ago Vesalius regarded flatten-

ing of the occiput—such as frequently occurs in our Bronze-age invaders—as a characteristic feature of the German head.

We look in vain for the ancestors of our Bronze-age invaders among the modern peoples who live along the German or Dutch shores of the North Sea. When, however, we turn to the investigations carried out by Danish anthropolgists during the last seventy-five years we find a key to our problem. The classical researches of Nilsson brought to light in the Neolithic graves of Denmark a people with exactly the same rounded form of head as that of our British invaders. It was at first believed that these round-heads were the original inhabitants of Denmark, but later discoveries showed that the long-headed race of the long-barrow or Scandinavian type—which also occurred in Neolithic graves—was the older form. Our Bronze-age ancestors had reached the Danish peninsula in the Neolithic period. Recently Prof. Nielsen has published a very instructive table, showing how the head-form has altered at various periods in Denmark. His table is as follows:—

	Dolicho-cephalic	Meso-cephalic	Brachy-cepalic
Neolithic period	30	44	26
Early Iron period	60	29	3
Modern	12	55	33

The table shows that after the Neolithic invasion round-heads became almost as common as long-heads in Denmark. It will be remembered that the round-barrows have revealed a similar proportion in England. A further parallel between Denmark and England is seen in the fate of the round-heads. By pre-Roman times the long-head had again asserted its dominance in both countries; in Denmark the round-heads form only 3 per cent. of the pre-Roman grave skulls. But after the Roman period the histories of the two countries diverge; the high proportion of long-heads disappeared from the Danish population, so that now they form only about 12 per cent. There can be little doubt as to the cause of the recrudescence of round-heads in Denmark. Her land-frontier is open to Germany and her population has undergone a change in head-form similar to that which has overtaken the people of Prussian Germany in post-Roman times.

In Denmark, then, we may recognise two invading waves of round-heads; but it is the oldest—the Neolithic wave—containing men marked by all the physical characters which we recognise in the English round-barrow men which interests us here. That was the first wave of round-heads to break through the long-headed population in Western Europe and reach the shores of the North Sea. Before the next wave broke, the Danes had apparently become again a long-headed people. Denmark was not the only country to suffer from the first invasion. Our "round-barrow" race had formed the settlements in the south of Sweden and on the south-western coasts of Norway. Even now, as in parts of England, the descendants of that early invasion can be traced in the lands in which the round-heads settled. The round-heads also reached the lands at the mouths of the Elbe, Wesser, and Ems. Oldenburg, between the estuaries of the Wesser and the Ems, has yielded Neolithic graves. Out of four skulls from such graves one is similar in form to that of our Bronze-age invaders. Apparently, too, they reached the coast by way of the Rhine. At least the Dutch people living in districts near the mouth of the Rhine show a much higher degree of brachycephaly than their neighbours either to the north or south. We have already traced the entrance of our Bronze-age type into northern France in the Neolithic period. They, too, reached the coast of Normandy.

We have made a tour round Europe in search of the native land of our Bronze-age invaders. We have merely found secondary settlements along the eastern shores of the North Sea and the possible points of their embarkation. Their native land we have not discovered. Our predecessors, when in difficulty over the origin of a European race, fell back on Asia; they had an infallible belief in the racial potentiality of that continent. There is now a distinct change amongst European anthropologists in their attitude towards such problems. They believe that our own continent may have produced its own races. But so far we have searched in vain for the cradle of the European round-headed stock; we have found neither the beginning of the dark-haired true Alpine type nor of the fair-haired northern form from which our round-barrow men sprang. But it is lawful for us to infer that the centre of dispersion is the probable cradle of origin. Now all the evidence at our disposal points to the central mountainous region of Europe as the centre of dispersion. It is therefore in the plains along the northern flanks of the central mountainous region of Europe that we may expect to find the cradle of our round-headed British ancestry.

The conquest of Europe by the "round-heads" is one of the most amazing revelations of prehistoric research. The outlook for the future of the fair-haired, long-headed stock does not, at first sight, seem very promising. Prof. Gustav Retzius, when he delivered the Huxley Lecture before this institute in 1909, gave expression to such a view. "There lie," he said, "in the circumstances to which I have called attention, a very real danger of the north European long-headed race not being able to hold its own. Just as it has been ousted during the past thousand years from Germany and other countries in Central and Eastern Europe by the dark-haired, small-statured round-heads, it will probably have to yield in Britain too, and be reduced in numbers, perhaps by degrees disappear entirely out of the fatherland of their ancestors and of themselves, by reason of the ever-increasing might and power of industrialism with which they seem ill-fitted to cope successfully in the long run. The prospect is depressing, it cannot be denied, but the development of things in the world is not seldom harsh and unmerciful."

Prof. Retzius's statement is that of a man who commands the respect and esteem of all anthropologists; he speaks of the fate of his own—the Scandinavian—racial stock, and is therefore predisposed to take the most hopeful outlook possible. It is beyond denial that in France, Austria, Russia, and in the greater parts of Germany and Italy a round-headed stock has ousted a long-headed one. Scandinavia, England, and Spain have escaped this domination by reason of their comparative isolation. Yet I dare think the future of the big-bodied, fair-haired, long-headed European stock may be more prosperous than Prof. Retzius is inclined to think. In the first place we have clear proof that at one time—some 4000 or 5000 years ago—the round-headed stock did break through and reach the western shores of Europe. It leavened England, but became submerged; it met a similar fate in western Germany and in Holland. In the earlier centuries of the present era the long-heads in north-western Europe must have undergone a recrudescence in numbers and in power. They broke eastwards on the plains of the Vistula and Danube; they imposed their speech on the conquered peoples, but the vanquished imposed on them their features of face, head, and body. They broke westwards into France, and lost both their

tongue and their head-form; they crossed the North Sea and kept both their tongue and their shape of head. Sea power is also a potent factor in anthropology, and so far such power in Europe has been in the hands of long-headed stocks. What the long-head has lost in Europe he has gained in countries which lie beyond the seas, by virtue of his command of the sea. It is too soon to speculate on what the head-form of these new trans-oceanic settlements is to be—but all the signs point rather to a victory of the long-heads.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—The following advanced courses of lectures, to which admission is free, are now being delivered:—A course, with practical work, in dynamical meteorology, at the Meteorological Office, South Kensington, S.W., by Dr. W. N. Shaw; a course on the Protozoa, at the Lister Institute of Preventive Medicine, Chelsea, S.W., by Prof. E. A. Minchin; a course on metabolism in infancy, at Guy's Hospital, Borough, S.E., by Dr. M. S. Pembrey and Mr. J. H. Ryffel; a course on certain aspects of British ecology, at University College, Gower Street, W.C. The remaining lectures of the last-named course are by Prof. R. H. Yapp (fen vegetation), Prof. G. S. West (the occurrence and distribution of fresh-water algæ), and Mr. A. D. Cotton (the algal vegetation of the salt-marsh and seashore).

MANCHESTER.—The Council of the University, with the approval of the Board of Agriculture and Fisheries, has appointed Mr. W. Percy Middleton Stock Officer for the counties of Lancashire and Cheshire. Mr. Middleton will be attached to the Department of Agriculture, and will be given an office in the University buildings as well as an office in a central position in each of the two counties.

OXFORD.—The annual report of the Committee for Geography, just published, gives a full account of the work done in the geographical department during the past year. The number of students working at geography was forty-one (twenty-three men and eighteen women). Lectures to the number of 124 were delivered by the professor (Dr. A. J. Herbertson, Wadham College) and his assistants, the subjects including natural regions of the British Empire, economic geography, Central Europe, the geographical distribution of man, climate and vegetation regions, topography of Europe, the Oceans, the British Isles, meteorology, influence of the geography of Greece on its political history, and the art of geographical description. Besides these, special lectures were given by Prof. T. Edgeworth David, Sir Ernest Shackleton, and others. Many field excursions were undertaken, and the report includes a long list of gifts to the library and collections. A successful vacation course was held in August, which was attended by 160 pupils (54 men and 106 women).

SHEFFIELD.—Dr. A. J. Hall has been appointed to the post of lecturer in medicine.

THE Central Committee for National Patriotic Organisations, 62 Charing Cross, W.C., has issued, at the price of *2d.*, a list of publications bearing on the war. It comprises the titles of works likely to be useful to those persons anxious to understand the immediate causes and remote origins of the war, of volumes dealing with the war itself or with naval and military matters generally, and of pamphlets on these subjects sold at *6d.* or less. Full particulars are given as to where the volumes may be procured, and the pamphlets may be purchased through the Central Committee.

IT was announced to the students of Stevens Institute of Technology at their annual dinner in the Hotel Astor on January 23 that their ten-day campaign to raise 272,000*l.* had yielded 232,854*l.*, and that an extension of time had been granted in which the remainder might be collected. *Science* says that Dr. A. C. Humphreys, president of the institute, made the confident prediction that the whole amount would be raised by the end of the week. From the same source we learn that the Harvard University corporation has set aside 20,000*l.* to pay Belgian professors who have been driven from their land by the war and may give courses at Harvard University next year. Mr. J. R. Magee has left 4000*l.* and a certain further residuary portion of his estate to Haverford College, to be added to the general endowment fund.

THE Association of Teachers of Domestic Subjects has issued its annual report for 1914. During the year important work was accomplished by the association. Miss Ailsa Yoxall's book on the "History of the Teaching of Domestic Economy" was completed for the association; it was reviewed in the issue of NATURE for November 19 last (vol. xciv., p. 308). A long-considered salary scale received its final form, and suggested a rate of pay which, if adopted by education authorities, would bring domestic subjects teachers into line financially with those of general subjects. We understand the suggested scale is receiving sympathetic consideration by various education authorities. The report contains detailed accounts of the activities of the different branches of the association throughout the country, and these provide satisfactory evidence of a widespread desire to improve the teaching of the important practical subjects with which the members are particularly concerned.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 4.—Sir William Crookes, president, in the chair.—Prof. G. H. **Bryan** and R. **Jones**: Discontinuous fluid motion past a bent plane, with special reference to aeroplane problems. The present investigation is based on the theory of discontinuous fluid motion, and in particular on the recent developments of that subject by Sir G. Greenhill. Its object is to obtain a hydrodynamical estimate of the effects of camber on the lift and drift of a lamina moving through a fluid, the motion being two-dimensional, and regarding the lamina as an aerofoil. Instead of considering continuously curved laminæ, the investigation deals with laminæ the front and rear portions of which are plane, but which meet at a dihedral angle. The method is applicable to surfaces with two or more bends. The general conclusions are in agreement with experimental results, that a moderate degree of camber is beneficial in increasing the lift without a corresponding increase in drift.—Prof. A. **Fowler**: A new type of series in the band spectrum associated with helium. The band spectrum associated with helium, as previously described by Curtis and Goldstein, includes bands with single heads and bands with double heads. A preliminary analysis of this spectrum has led to the following conclusions:—(1) The doublets do not follow the ordinary law of band spectra, but can be arranged in two series of the type hitherto exclusively

associated with line spectra, and can be represented by the usual formulæ involving the Rydberg constant. Nine bands of the main series, and four of the second fainter series, have been identified. (2) The two series may be likened to the principal and diffuse series in the case of line spectra, but the usual relation between such series is not certainly indicated, and no equivalent of the sharp series has yet been traced. (3) The doublet separations are not in accordance with those associated with line spectra; they diminish in passing along the series, but do not vanish at the limit. No regularity in the arrangement of the single bands has been recognised.—T. R. **Merton**: The spectra of ordinary lead and lead of radio-active origin. Wave-length measurements have been made of some of the principal spectrum lines of ordinary lead and the lead in pitchblende residues. It might reasonably be expected that small differences in the wave-lengths would be found, more especially in the case of any lines which belong to doublet or triplet series, since, according to the views of Prof. Hicks, an atomic weight term enters exactly into the separations of such doublets or triplets. No series have yet been discovered in the spectrum of lead, but it is probable that they exist, and an estimate of the order of the differences of wave-length to be expected, according to Prof. Hicks's views, is given. No differences of this order have been observed, the spectra taken in juxtaposition showing no differences of wave-length, whilst the wave-length measurements of seven of the most prominent lines in the two leads agree to 0·03 Å.U. A special comparison of the line $\lambda=4058$ Å.U. with the interferometer shows that the wave-lengths of this line in the ordinary and radio-active lead are identical to within 0·003 Å.U.—A. O. **Rankine**: The viscosity of the vapour of iodine. The paper records the method used by the author for measuring the viscosity of iodine vapour at four different temperatures ranging from 124° C. to 247° C. The basis of the method is the distillation of iodine from one vessel to another through a narrow capillary tube, the temperature of which could be varied. One of the vessels contains solid iodine, and is raised to 100° C., thereby establishing the driving pressure. The other vessel is immersed in a freezing mixture, so that the iodine which is transpired as superheated vapour is condensed there, the mass so transpired being determined by weighing the vessel, which is removable. The method gives, in repeated experiments, very consistent results, and the values obtained may be taken as accurate to about ½ per cent. The range of temperature variation is not large enough to make the results suitable for testing the validity of Sutherland's formula, but it is found that they are, at any rate, not inconsistent with that formula.

Physical Society, January 22.—Sir J. J. Thomson, president, in the chair.—Dr. A. **Russell**: Practical harmonic analysis. Making the assumption that the graph of a periodic function is given, the problem of the best way of determining the Fourier constants in the series equation which represents it is considered. The ordinary method of procedure is to neglect all the harmonics above a certain order and determine the coefficients of the harmonic terms by making the curve represented by this equation pass through a number of arbitrarily selected points on the given curve. This is the method used, for instance, by Runge and Grover. A serious defect in this solution is that the values found for the amplitudes of the harmonics, more especially for the higher harmonics, may be very different from their true Fourier values. The method gives no indication of the magnitude of these errors. Gauss pointed out many years ago that the solution of this limited problem could be written down at once mathematically, and that it was of importance in certain interpolation problems in astronomy. Another method has been suggested recently by Silvanus Thompson. He uses certain series formulæ for finding the Fourier constants. The author suggests other series formulæ of a similar kind, and gives numerical examples to illustrate the accuracy attainable by the use of infinite series formulæ. T. **Smith**: Measuring the focal length of a photographic lens. The focal length of a compound lens is obtained solely by focussing on the camera screen the image of a distant object on the lens axis by the complete lens and by each of its components separately. One additional focussing of the same object when the separation of the components is altered determines the focal lengths of each component. The method is both accurate and quick, and requires only a camera and the lens.

Challenger Society, January 27.—Dr. G. H. Fowler in the chair.—D. J. **Matthews**: Hydrographical observations on the ice patrol *Scotia* in the North Atlantic, 1913. The *Scotia* cruised in the ice-area from April 9 to August 3, 1913, and crossed the Labrador current fourteen times between the latitude of Hamilton Inlet in 54° N., and the southern part of the Newfoundland Banks in 44° N. Observations of salinity and temperature were made down to a depth of 550 fathoms, including seven complete sections across the current. The Labrador current had a temperature generally below 0°, except at the surface, and a salinity of 32·5 to 33·5 per thousand, while the Atlantic water to the eastwards reached 34·5 per thousand or more. The boundary between the two water-masses was marked by the isohaline of 34·00 in the region northward of the Banks; further south the conditions were more confused. The characteristic temperature minimum was found in all water of polar origin except on the Banks, where it was disturbed by the shallows. Measurements of currents and of the drift of bergs were made by means of mark buoys, either anchored to a sinker on the bottom or to a drag working at a depth of 1000 fathoms. The velocities observed were all low, generally less than half a mile an hour, and calculations by Bjerknes's method from differences of density gave similar results. Off Cape Race a slow northerly set was observed instead of one of about one mile per hour to the south and west, as is usually experienced here. On the Banks measurements were made with the Ekman current-meter at depths of five and twenty-five fathoms at two stations; the observations were repeated at frequent intervals during thirteen hours, and showed that the current is almost entirely tidal with a very small easterly resultant. Prof. Barnes's observation that the proximity of an iceberg can be detected by a slight rise in the temperature of the water could not be confirmed, as similar rises were recorded when no ice was near.—C. Tate **Regan**: Colour-changes in a flat-fish, *Platophrys podas*.

Linnean Society, February 4.—Prof. E. B. Poulton, president, in the chair.—Ruth C. **Bamber**: Report on fishes collected by Dr. Crossland from the Sudanese coast of the Red Sea. This collection consists of ninety-one species, of which two are new to science and two others require re-description. Most of the others are typical Red Sea coastal fishes, and were obtained by Dr. Crossland at various localities on the Sudanese coast between Suez and Suakim.—Dr. Marie C. **Stopes**: A fossil of doubtful affinity. The fossil was found *in situ* in the Lower Greensand at Luccomb Chine, in a horizon in which a number of new plants as well as the famous *Bennettites Gib-*

sonianus have been discovered. The specimen in transverse section of an area of 20×35 cm. shows a uniform structure of most beautifully petrified tissue, which appears to be quite unlike any known fossil. Photomicrographs were exhibited showing the details of the tissues, which, in many respects, are like a giant phloem. The name *Vectia luccombensis* is proposed.—Dr. H. **Drinkwater**: Brachydactyly as an example of Mendelian inheritance. Brachydactyly (shortness of fingers and toes) has been studied by Dr. Drinkwater in four distinct families. In affected people, all the fingers and toes are short, and the stature is reduced. The chief defect is an extremely abortive condition of the second phalanx, which becomes ankylosed to the third, in two families. In the other two it is not ankylosed, and the fingers are not so short (Minorbrachydactyly), but the toes are alike in the four families. The epiphyses of the second phalanges are absent in the shortest fingers. The abnormals transmit the abnormality to about half their offspring. The normals never transmit the abnormality: it is bilaterally symmetrical and never skips a generation. It is a Mendelian dominant.

MANCHESTER.

Literary and Philosophical Society, January 12.—Mr. F. Nicholson, president, in the chair.—Prof. W. H. **Lang**: Studies in the morphology of Isoëtes. Part 2, the analysis of the stele of the shoot of *Isoëtes lacustris* in the light of mature structure and apical development. The author gives the results of a re-examination of the stele of *Isoëtes lacustris*, special attention being paid to points disputed or left obscure by previous investigators. From within outwards the following tissues can be distinguished: (1) central column of primary xylem; (2) peripheral zone of xylem, including the bases of the leaf-traces abutting on the central column of xylem; (3) parenchymatous xylem-sheath; (4) primary phloëm, continuous with phloëm of leaf-trace; (5) secondary prismatic tissue; (6) meristem of the anomalous secondary tissue; (7) cortical tissue. In some stems the meristem and the secondary tissue are completely wanting. The procambial tissue immediately behind the growing point gives rise to the central column of primary xylem. The other primary tissues of the stele are differentiated in the inner portion of the radiating rows of procambial cells surrounding the central region; the cortex is derived from the outer portion of this radiating tissue. There is thus a radial seriation of the elements from the outer xylem to the cortex quite independent of any secondary growth. The inner xylem is regarded as centripetal in relation to the poles of the leaf-traces applied to it, these being the only equivalents of protoxylem. The outer xylem lies between and outside the protoxylem poles. It is thus comparable, on the one hand, with the outer primary xylem of the Filicales, and, on the other, corresponds in position to the normal secondary xylem of the Lepidodendreæ. On this view a stele of Isoëtes would contain tissues corresponding to the centripetal primary xylem, the normal secondary xylem, and the anomalous secondary xylem (found in some species) of Lepidodendreæ.

PARIS.

Academy of Sciences, February 1.—M. Ed. Perrier in the chair.—Armand **Gautier**: The soldier's ration in time of war. The work of Atwater on the heat actually evolved in the human body by the constituents of food, proteids, fats, and carbohydrates, is made the basis of the discussion. This is supplemented by data derived from the study of two peasant families carried out over a period of twelve months, of railway workers, and of Belgian agriculturists. The average, in calories, for the daily food ration of workers in the north of Europe is 4349, for the French climate 3947, the difference being partly due to the higher temperature and partly to the higher weight of the inhabitants of northern Europe as compared with the French. The French army ration gives 3190 calories, and the author considers that in cold weather this should be supplemented by at least 900 calories, and argues that a portion of this, at least, should be in the form of wine.—G. **Gouy**: The Brownian movement according to Lucretius. An extract from "De rerum natura," in which the movements of motes in air strongly illuminated is ascribed to the action of the invisible movements of the atoms. —MM. **Brandt** and Darmezin **du Rousset**: A new form of polar extremities for electro-magnets used in surgery. A general description, without details, of flexible poles capable of being used in the extraction of magnetic fragments from wounds.—L. **Gay**: The solubility of hydrates.—José Rodriguez **Mourelo**: The phototropy of inorganic systems. Strontium sulphide. A study of phototropy, or the change of colour under the influence of light and of phosphorescence of strontium sulphide containing various proportions of manganese, or of manganese and bismuth together. The experimental results are given, the theoretical discussion being reserved for a later communication. —Lucien **Liais**: Waterproofing tissues by impregnation of the constituent elements. Observations on the measurement of the strength of tissues. Instead of waterproofing the woven material, the rubber solution is introduced on the thread during weaving. The method has the advantage of preserving the ordinary appearance of the finished material, and as compared with the ordinary waterproofing process the material is more resistant to wear by friction.—R. **Chudeau**: The geology of the Timbuctoo-Taoudeni-Kidal and Gao regions.—G. **Arnaud**: The suckers of Balladyna, Lembosia, and Paradiopsis.—Maxime **Ménard**: The localisation of projectiles and the examination of the wounded by the X-rays. A discussion of the comparative advantages of the radioscopic and radiographic methods. The former cannot guide the surgeon during the actual operation, may cause grave burns to the operator, and even when carefully conducted may fail to discover certain foreign bodies. A modification of Hirtz's radiographic method is described as advantageous, and details of eight operations chosen from a total of eighty-eight are given.

VITAL STATISTICS.

Vital Statistics Explained: Some Practical Suggestions. (The Chadwick Library.) By J. Burn. Pp. x+140. (London: Constable and Co., Ltd., 1914.) Price 4*s.* net.

IN a preface to this work Sir William Collins, as chairman of the Chadwick Trust, explains that the volume is based upon a course of lectures delivered at Liverpool, under the auspices of that trust. Mr. Burn pays a high compliment to the present Registrar General on the improvements introduced by him into the annual reports of his department, and says that it is now for the first time "possible to discuss and analyse the enormous mass of statistics in a coherent and intelligent manner."

The author deals first with the Census as an index to the development of national life. A comparison of the twelfth census, taken in 1911, with the first, taken in 1801, shows a wonderful advance. Mr. Burn thinks that nearly all the information that can be relied upon is now collected. He deprecates further elaboration. "Merely to ask an extra question on the census paper does not ensure a correct answer being given."

The leading facts that are shown by the Census returns and the reports of the Registrar General are: (1) a steady decline in the marriage rate during the last thirty years; (2) a steady increase in the mean age at marriage for both sexes; (3) a reduction in the birth-rate, both as regards legitimate and illegitimate births; (4) a reduction in the infantile death rate. While these observations are closely related, they point to a number of contributing causes.

The success which has attended the measures that have been taken of late years for sanitary improvement is shown by the statistics of death from various diseases. Small-pox is practically non-existent. Phthisis and tuberculosis have decreased by more than 50 per cent. during the sixty years since 1851. On the other hand, the deaths from cancer have greatly increased. All these statements have to be qualified by the possibility of differences of definition in successive records.

After a brief chapter on the preparation of mortality tables, in which he suggests that in addition to the national tables, municipal and occupational tables should be prepared, Mr. Burn proceeds to show how such tables may be put to practical use by medical men and other persons, and the light they might throw upon causes of death and upon the prevention of disease. For this purpose he has examined the rates of mortality of the industrial branch of the Prudential Assurance Society, of which he is actuary, and as these are derived from twenty million policies, he claims that they fairly represent the population of the United Kingdom, a claim which may at any rate be supported if limited to the industrial classes. He arrives at the satisfactory result that there is a steady and continuous improvement going on in the vitality of the country.

The proper method of graduating a mortality table so that the crude results of the enumeration may be smoothed into a symmetrical curve without destroying the trend of the facts, has exercised the minds of actuaries for some time. The late Mr. Woolhouse, Dr. Sprague, Mr. George King, and others have learnedly discussed it, and the method now generally adopted is that which the German actuaries call by the fanciful name of "osculatory interpolation." In an appendix to his volume, Mr. Burn gives a description of this method, so lucid and so simple that any person might employ it without having a knowledge of the mathematical principles upon which it is based. He has certainly the gift of clear exposition, and his little book is calculated to be useful to many persons to whom actuarial science has not hitherto offered any attraction.

TECHNICAL METHODS OF CHEMICAL ANALYSIS.

(1) *Technical Methods of Chemical Analysis.* Edited by Dr. G. Lunge and Collaborators; English translation edited by Dr. C. A. Keane and Collaborators. Vol. iii, part i, pp. xxxi+538. Vol. iii, part ii, pp. xv+539—1125. (London: Gurney and Jackson, 1914.) Two volumes. Price 3*l.* 3*s.* net.

(2) *Technical Gas-Analysis.* By Dr. Lunge. Pp. xv+407. (London: Gurney and Jackson, 1914.) Price 15*s.* net.

(1) THE two sections now issued of volume iii. of this important work complete the English edition of Dr. Lunge's great monograph published in German in 1910–11. The English edition, however, differs in certain material respects from that on which it is based, inasmuch as certain German processes are inapplicable, from the very nature of the case, to British procedure, and it is unlikely, owing to special conditions, that they will ever become applicable. Hence particular sections of the work have had to be entirely re-written by British experts from the British point of view, and to this extent these may lay claim to be original productions. At the

same time the remaining sections of the work have been revised by British authorities, and, wherever necessary, modified in the same sense. In addition, each section has been brought up to date by the inclusion of all relevant matter of importance.

The sections on mineral-oils, lubricants, oils, fats, and waxes, and the special methods of analysis employed in the oil and fat industries were contributed or revised by the late Dr. Lewkowitsch—an acknowledged authority on this class of subjects. Dr. Lewkowitsch also revised the English translation of Dr. Dieterich's article on resins, balsams, and gum-resins. The same author's article on drugs and galenical preparations has been revised by Dr. Power, who has also taken charge of Dr. Gildemeister's contribution on essential oils. The sections on tartaric and citric acids have been entrusted to Mr. Davis, whilst the general subject of organic preparations—a somewhat vague class—has been dealt with by the Editor. This section is concerned more particularly, although by no means exclusively, with pharmaceutical preparations, and is based upon an article by Dr. Messner of the firm of Merck and Co., of Darmstadt. The important section on rubber has been revised by Dr. Caspari, who, however, has nothing to say concerning synthetic rubber, from which we may infer how small has been the influence of the "boom" on "artificial rubber" on the actual production of this substance.

Vegetable tanning materials and leather have been revised by Prof. Procter, an acknowledged authority on the scientific aspects of tanning; whilst sugar, starch, and dextrin have been dealt with by Mr. Arthur R. Ling—no less an authority on these particular subjects—who has also re-written, in conjunction with Mr. Cecil Jones, a valuable article on brewing materials and beer. Paper has received the attention of Messrs. Cross, Bevan and Bacon; textile fibres that of Prof. Hübner, of the Manchester School of Technology; while Messrs. Rawlins and Rule have revised Prof. Eibner's article on inorganic colours. It will be seen, therefore, from this list of names that Dr. Keane has spared no pains in securing the collaboration of competent authorities on chemical analysis as applied to technical products and processes.

The book, like its predecessors, should find a place in the library of every consulting and analytical chemist, as well as in that of every well-equipped works laboratory. A very commendable feature of the work is the admirable bibliography which accompanies each article.

Another feature, even more valuable, is seen in the extent to which individual revisers have brought their special experience to bear upon the sections entrusted to them, thereby greatly enhancing their merit. This makes the English edition of the work doubly valuable, as compared with the German original, since each article has passed, so to say, twice through the refining fire of expert assayers.

(2) Prof. Lunge's book on technical gas analysis is in a sense the third edition of his well-known handbook of technical gas analysis, originally based upon the late Prof. Clemens Winkler's "Anleitung zur chemischen Untersuchung der Industrie-Gase." During the dozen years which have elapsed since the publication of the second edition of the handbook the subject has received an extraordinary development, and great changes have occurred in procedure and apparatus. The application of technical gas analysis has been largely extended, and its value as an analytical agent in industrial processes, and even in connection with hygiene, has been widely recognised. Hence the time had arrived when the comparatively narrow limitations of Clemens Winkler's treatise had to be discarded, and the book under review is, therefore, practically a new work, differing wholly in groundwork and arrangement from that on which it was originally based. So far as we have been able to discover, all branches of the subject have received adequate treatment. The bibliographical references are copious and up-to-date. Lastly, the book is well printed, excellently illustrated, and the indexes of authors' names and of subjects are remarkably full.

T.

TWO BOOKS ON THE EARTH.

(1) *Geology of To-day.* A Popular Introduction in Simple Language. By Prof. J. W. Gregory. Pp. 328. (London: Seeley, Service and Co., Ltd., 1915.) Price 5*s.* net.

(2) *College Physiography.* By Prof. R. S. Tarr. Published under the editorial direction of Prof. L. Martin. Pp. xxii+837. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 15*s.* net.

THESE two books are professedly written for two different types of reader; but the college student may well read Prof. Gregory's "popular introduction" from end to end, while the lover of "simple language" will find nothing to alarm him in the work of the late Prof. Tarr.

(1) Prof. Gregory has brought the latest results and the current discussions of geologists before every thoughtful person to whom the earth appeals. We possess a number of popular text-books on geology, but "Geology of To-day" justi-

fies its title, and stands entirely apart. The alarming illustration with which it opens, representing a statue of Louis Agassiz plunged head-downwards in the ground, is not symbolical of the tendencies of the text. The author traces the growth of geological philosophy without exulting over the imperfections of those who have gone before. The hardy old *pièces justificatives* are quoted, but are supplemented by observations of very recent origin. On p. 141, for instance, Day and Shepherd's work on the volcanic gases of Hawaii is cited in refutation of the critical thesis so enticingly maintained by Brun; but how many of our current text-books have got so far as mentioning Brun? He certainly never shook Tarr's faith in the potency of steam as a volcanic agent ("College Physiography," p. 444), and Prof. Gregory's references are all the more welcome as recording a really memorable, if short-lived, controversy.

The chapters on "How mountains are made," with its review of the possible influence of radium, and on "How mountains are upheld," with its lucid exposition of isostasy, are good examples of Prof. Gregory's method. The section devoted to life-history, occupying nearly half the book, contains no detailed description of stratified formations, but consists of essays on "The Origin of Life," "The Interpretation of Fossils," "The Evolution of Mammals," and so forth. Miss Alice Woodward has contributed some spirited original drawings of incidents in the life of fossil vertebrates, and Hagenbeck's models at Hamburg are also utilised. In these chapters the terrestrial and fluviatile origin of the Old Red Sandstone conglomerates is well stated (p. 204); we are introduced to Gigantosaurus of East Africa, the super-dreadnought of land-animals (p. 259); and to the beaked flints from the English Pliocene (p. 306), for which the author is quite willing to accept a human origin.

On glacial matters he preserves considerable caution; here only his geology seems not quite of to-day, though it is that of a very recent yesterday. To describe (p. 212) the evidence of Permian glaciation as indicating that "the climate of parts of the Southern Hemisphere was therefore colder than it is at present," must be regarded as a very moderate statement. In his memorable journeys in Spitsbergen, Prof. Gregory (p. 227) was unfortunate in not coming across modern boulder-clays. The precise parallel between the material left behind by the von Post glacier and that of deposits in the British Isles would, for instance, have reassured him. Too little seems made of the fact that sheets of boulder-clay represent the unmeltable residue of glaciers that, in their lower portions, consist half of ice and half of stones. During the melting of such glaciers there is no copious flow in the lower layers sufficient to sweep away all the finer particles. The loamy matter settles downwards in the interstices of the abundant and striated stones.

The fine series of photographs of Javan volcanoes is very welcome. So is the whole of this stimulating volume. The author does not accept (p. 81) the opinion of German writers as to the origin of their own word *feldspath*; but A. Brongniart attempted the same thing in 1807 in his "Traité de Minéralogie" (p. 355) without success.

(2) The handsome book by the late Prof. Tarr and Mr. L. Martin is of the serious and detailed type suggested by its title. It owes much to the extensive and observant travels of Prof. Tarr, and particularly to his work on glaciers and recent uplifts in Alaska (pp. 214, 390, etc.). The illustrations are numerous, and some of the diagrams would bear enlargement, those on river-erosion, for instance, being not too clear (p. 557, etc.). The view of Innsbruck on p. 525 represents the snow of spring or autumn, but not "The Alps rising above the snow line." The illustrations, however, generally supplement in a valuable way those of European text-books. The treatment of the features due to stationary and shrinking ice-sheets is especially interesting (ch. ix). The last seven chapters, dealing with the atmosphere and terrestrial magnetism, are due to the faithful and experienced editor, Mr. L. Martin, who has worked and travelled with Prof. Tarr.

GRENVILLE A. J. COLE.

MATHEMATICAL TEXT-BOOKS.

(1) *Pendlebury's New Concrete Arithmetic.* By C. Pendlebury and H. Leather. First Year. Pp. 57. Price 4*d*. Second Year. Pp. 54. Price 4*d*. Third Year. Pp. 57. Price 4*d*. Fourth Year. Pp. 56. Price 6*d*. Fifth Year. Pp. 71. Price 6*d*. (London: G. Bell and Sons, Ltd., 1914.)

(2) *A First Course in Mathematics for Technical Students.* By P. J. Haler and A. H. Stuart. Pp. vi+125. (London: University Tutorial Press, Ltd., 1914.) Price 1*s*. 6*d*.

(3) *A Course of Geometry Theoretical and Practical: a Class-book for Secondary and Technical Schools.* By A. H. Bell. Pp. viii+127. (London: Rivingtons, 1914.) Price 2*s*. 6*d*.

(4) *A Treatise on Dynamics.* By Dr. W. H. Besant. Revised and enlarged by A. S. Ramsey. Fifth edition. Pp. xv+443. (London: G. Bell and Sons, Ltd., 1914.) Price 12*s*.

(5) *Examples and Test Papers in Algebra.* By W. J. Walker. Parts ii. and iii. Pp. viii+

163+338. (London: Mills and Boon, Ltd., 1914.) Price 1s. 3d.

(6) *Elementary Mathematical Analysis: a Text-book for First Year College Students.* By Prof. C. S. Slichter. Pp. xiv+490. (New York and London: McGraw-Hill Book Co., Inc., 1914.) Price 10s. 6d. net.

(7) *Stability and Equilibrium of Floating Bodies.* By B. C. Laws. Pp. ix+251. (London: Constable and Co., Ltd., 1914.) Price 10s. 6d. net.

(1) THIS set of books on arithmetic consists chiefly of examples, carefully graded in difficulty. No answers are given; teachers who use these books will look for an edition in which they are supplied. The course includes mensuration, percentage, and interest.

(2) The authors of this small text-book have succeeded in creating a "workshop atmosphere" around this elementary course; not only are the problems of a practical nature, but the student is frequently referred to drawings of simple forms of mechanism, which illustrate and furnish the data of the example set him. The range of the book includes practical arithmetic, mensuration, graphical work, and simple algebraic processes.

(3) This book is framed on the lines recommended by the circulars of the Board of Education, particularly in the first forty pages. It is claimed that the requirements of the ordinary leaving-school examinations are met, but the book is so small that most teachers will find it necessary to supplement it. There are comparatively few examples, those given being mainly numerical. Regarded as an introductory course, this small volume is of distinct merit.

(4) Dr. Besant's treatise on dynamics is well known to many generations of Cambridge men, and its re-issue in an enlarged form will doubtless be welcomed. Mr. Ramsey, who undertook a few years ago, at the author's request, the editing of part i. and the writing of part ii. of his treatise on hydromechanics, has also found time to edit and supplement this remaining volume. The increase in size is considerable, partly owing to additions to the text, but more to the very large number of problems which are now incorporated. Numerous illustrative examples are fully worked out, and notes are frequently appended to them, which the student will find instructive. We have no doubt that men reading for the second part of the Mathematical Tripos will find this volume most helpful.

(5) This collection of examples and papers is conservative in type. There is little note of originality either in arrangement or material. With regard to bookwork, only the chief theorems are inserted, and there is little explanatory matter. Part ii. includes progressions, variation, and gradients; part iii. contains the logarithmic and exponential series.

(6) This book, designed for first-year college students in America, corresponding roughly to the last stage in the secondary schools of this country, is intended to show the application of simple mathematical principles and operations to practical life. No great manipulative power is demanded of the reader; the author's object is to inspire him with new ideas and broaden his outlook. The central theme of the book is functionality. This is applied to power functions, exponential functions, and periodic functions; the fundamental transformations are treated from a kinematic point of view, by translation, rotation, and shear. The text is interesting throughout, and the author has collected an admirable set of practical exercises.

(7) This treatise for engineering students deals with the stability of bodies floating either in air or water. There are two introductory chapters which summarise the principles of rigid dynamics and hydrostatics, specially needed for the course. The author then passes to the stability of ordinary ship-forms, and this occupies nearly half the book, dealing with, among many other things, stability curves, trim curves, stability at high speeds, effect of wind and waves. In the next chapter he turns to submarines, the action of rudders, transverse stability, etc., and this is followed by the consideration of floating docks, aircraft, and caissons. The chapter on aircraft will probably be of interest to a wider circle than any other part of the book, and may be read independently. The clearness of the diagrams deserves a special word of praise.

OUR BOOKSHELF.

A First Book of Commercial Geography. By T. Alford Smith. Pp. viii+151. (London: Macmillan and Co., Ltd., 1915.) Price 1s. 6d.

MR. ALFORD SMITH's book has many useful characteristics. It is clearly written, has good maps and diagrams, and a number of appropriate pictures, and includes well-chosen and suggestive examination questions. The scope of commercial geography, however, as specified here, may not appeal to all. The statement, for example, that in order to understand commercial geography it is necessary to know what processes an article has to undergo in order to become an article of commerce, needs cautious application; it is a fault of some larger and more advanced works in this subject that, in the direction especially of manufacture, they wander far outside geographical limits. And perhaps, on the other hand, there is lacking in the book under notice a sufficiently forcible exposition of the principles

of geographical, and especially climatic, control over the distribution of products and the activities of man in making use of them. Thus, the regional division of the world according to climate and vegetation is only briefly, and not completely, referred to. It may be that some geographers have made climatic control a sort of fetish; it should not be that, but it deserves a very important place in the study of commercial geography, and calls for precise expression—as an illustration of this necessity it may be suggested that the statement in the present work that in Australia "wheat is grown up to the 20-in. line of rainfall" misses the real point of the conditions of rainfall which determine the wheat-growing area there. It should be noticed that Mr. Alford Smith inserts tables of statistics, wisely averaged, and among them details at considerable length of several large ports of the United Kingdom.

Atlas of Japanese Vegetation, with Explanatory Text. Edited by Prof. M. Miyoshi. (Set xv., 102–107.) (Tokyo: Maruzen Company, Ltd.; London: W. Wesley and Son, 1914.) n.d.

THIS continuation of Prof. Miyoshi's well-known atlas includes six beautiful collotype plates from photographs of the vegetation of the luxuriant mountain forests in the province of Shinano. Nothing could convey a better idea of the wonderfully varied plant communities of Japan than this carefully selected series of photographs with the accompanying descriptions, the latter being in English and in Japanese. From its geographical position, especially its great range in latitude, Japan shows a much more varied flora than any other country of similar area, from the tropical vegetation of Formosa to the alpine floras of the high mountains and the semi-arctic flora of the extreme north. The descriptions, though brief, contain much that is of interest; for instance, we learn that when the curious "luminous moss," *Schistostega osmundacea,* was discovered in one of the habitats depicted in the atlas, the Japanese Government immediately acceded to Prof. Miyoshi's request that the locality should be made a nature reserve. It is interesting to note that in this series several species of wide range in the temperate regions and familiar members of the British flora are described as growing along with characteristic Japanese flowering plants, the latter including various species well known in Britain as cultivated plants.

Materials of Machines. By A. W. Smith. Second edition. Pp. v+215. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 5*s*. 6*d*. net.

THIS book furnishes a very elementary treatment of the manufacture and properties of materials used in the construction and operation of machines. In the first part the author deals with fuels, refractory materials, electric furnaces, and the metallurgy of iron, steel, copper, lead, tin, zinc, and aluminium in rather less than ninety pages of a small book, and remarks in his preface that an understanding of this is essential to the study of the second part, which in 102 pages treats of the testing of materials, the iron-carbon equilibrium, cast iron, wrought iron, steel, its heat treatment, and non-ferrous alloys. The final ten pages are devoted to the selection of materials for the various parts of a steam-engine. Seeing that the metallurgical section of the book deals exclusively with the extraction of the metals named from their ores, and ignores their mechanical treatment, the only connection between parts i. and ii. relates to the metals and alloys, *e.g.*, cast iron and cast steel which are used in the cast state. Considering that the great bulk of the various steels used in machines are "worked," this omission must be regarded as unfortunate. It is certainly an astonishing thing that the author, who is an American, should apparently not know the modern processes of extracting copper which have been developed entirely in his own country, and should have described a process which originated in Swansea, and has been superseded by them. To describe the metallurgy of copper in fewer than five pages as attempted by the author is a task that few metallurgists would undertake.

Nerves. By Dr. D. F. Harris. (Home University Library.) Pp. 256. (London: Williams and Norgate, n.d.) Price 1*s*. net.

PERHAPS the most difficult field of physiology to reduce to simple form and language, so that it may be understood by the non-scientific laity, is that of the nervous system. Any attempt in this direction, which is accurate, is sure of a welcome. Prof. Harris, in the small volume under review, has certainly succeeded in his attempt to explain in non-technical language the place and powers of the nervous system. He does not deal with the question of the morphology and pure physiology of the cerebrum and spinal cord, nor does he consider psychology—as physiology and psychology have been dealt with already in other volumes of the series. In reality the author deals mainly with the reflex arc and its value to the organism; he also briefly discusses the causes and the value of sleep to the organism, and considers, very shortly, the conditions of "nervousness" and "excitability," their nature, and the possibility of their prevention.

On the whole the author's statements are extremely clear and trustworthy, although some of his generalisations are apt to be too sweeping. For example, it will not be generally conceded that "the transcendent nonsense of the post-impressionist painters arose from absinthe-poisoned blood" acting on an abnormal nervous system. Nor is the evidence that muscular activity is the result of the propagation of a special form of energy generated from the Nissl granules of the cerebral cells held to be, to say the least of it, convincing. Still the book is interesting and is worthy of its place in the series.

LETTERS TO THE EDITOR.

Fine Chemicals for Research Purposes.

IN view of the shortage of fine chemicals which are used for research purposes, we thought it advisable to issue a circular to the principal laboratories in the kingdom asking for lists of chemicals not in immediate use, so that it would be possible to put the holders of such chemicals in touch with those chemists who were in urgent need of them. The replies which have been received so far have been in most cases to the effect that the holders wish to keep their own stocks in hand, but are willing to use our bureau for the purpose of purchasing others. As this attitude is one which entirely defeats the object with which the inquiry was started, may we direct the attention of chemists to the fact that it is impossible for them all to hold and to purchase at the same time. An equitable series of exchanges is all that can be arranged at the present time; and it should be remembered that even 50 grams of some particular substance may make all the difference between the carrying on or the hanging up of a piece of research work.

A Penalty on Research.

I AM sure that the biologists of the country will support Sir Wm. Ramsay's protest in NATURE of February 11, on the penalties incurred by men of science for the use of alcohol in their investigations. A few years ago I received a consignment of specimens of natural history in alcohol from a foreign Government expedition for scientific study and description. After some correspondence with the Customs House authorities I was allowed *as a concession* either to pay the full duty on the alcohol, or, in the presence of an officer, to pour it down the sink in the University laboratory, and replace it by methylated spirit at my own expense. Comment is unnecessary.

The Prices of Chemicals.

A WELL-KNOWN firm of dealers in chemicals and laboratory apparatus gave a quotation some days ago for the supply of an ounce each of dulcite and adonite. They proposed to charge 9*l*. 10*s*. for the former and 6*l*. for the latter. In the price list of chemicals issued by the same firm some months before the war the prices were respectively 45*s*. and 18*s*. Is there any good reason (except greed) for this increase of price? Presumably this firm, or some other English firm with which they deal have held a stock of these sugars since before the war. The substances are indispensable in public health bacteriological work, and is it not possible that some university laboratory can undertake their preparation and distribution at cost price?

J. J.

The University, Liverpool, February 3.

WE are in receipt of your letter of February 8 with regard to the price of dulcite and adonite. We very much regret that your correspondent has not gone more fully into the matter before making charges against firms who are trying to help British industries at a critical time. We should welcome a visit from your correspondent as he may not know the difficulties which have been experienced in obtaining the raw material for the manufacture of dulcite. Dulcite originally was a by-product, and was sold at 4*s*. 6*d*. per oz. The price before the war rose in stages from 4*s*. 6*d*. to 15*s*., then to 25*s*., then to 35*s*., and finally to 45*s*. per oz., which was the price ruling on August 1. We had at that time only a small stock of both dulcite and adonite, consisting of about 8 oz. We purchased a further supply of both these chemicals on or about August 18, but at considerably advanced prices, the supplies being obtained from wholesale chemical merchants in this country. We thereupon raised our prices to 100*s*. per oz. in the case of dulcite and 36*s*. per oz. for adonite; this gave us the same rate of profit as we had obtained from dulcite and adonite before the war.

This supply lasted us until December, when we were able to obtain a very small quantity of these two chemicals from small laboratories who had gone to the expense of manufacturing, and the prices being considerably advanced, necessitated the selling prices being raised accordingly.

At the present moment we have no dulcite of any description in stock, and have not had for some weeks. The total amount which we had for sale at a higher price did not exceed two ounces.

We have made arrangements with a firm of chemical manufacturers to manufacture for us dulcite and adonite at a price which will allow us to revert to the prices ruling between August and December last, but although delivery has been promised us several times we have not yet received delivery of even ½ oz., and we shall be only too pleased to buy any quantity of dulcite and adonite at the present moment, irrespective of price; our main point is to be able to supply chemicals which are urgently needed, and not to obtain exorbitant profits, and in the case of these two chemicals we may state we have been to considerable expense in endeavouring to obtain the necessary raw material for the manufacture of dulcite and adonite.

A FIRM OF DEALERS IN CHEMICALS.

February 9.

British Supplies of Laboratory Ware.

As chairman of the British Laboratory Ware Association I have had my attention directed to a circular letter issued by the British Science Guild, dated January, 1915, to schools, colleges, universities, and technical institutes, and also to circular No. 885 issued by the Board of Education, dated January 11, 1915, and which I note is referred to in NATURE, page 580, January 21, 1915.

These circulars have been issued under a grave misapprehension, and are likely to give a very misleading idea of the present situation in reference to supplies of laboratory glassware, and I think that it is very important that any anxiety on behalf of the readers of NATURE should be immediately allayed. I therefore beg to place before you the following information :—

The British Laboratory Ware Association, which consists of about 75 per cent. of the apparatus supply firms in the United Kingdom, was formed a few days after the outbreak of the war, in order to co-operate in connection with the production in this country of

laboratory glassware, porcelain filter papers, etc., not hitherto produced in this country.

The association is not a ring or financial combine, but is merely arranged for the pooling of information and for saving as much time, and preventing as far as possible duplication of correspondence with works, in the way of inquiries and information; the standardisation of sizes for moulds where works undertake to make; and the elimination of difficulties which would occur if all the various firms were working independently.

So far, after months of correspondence, interviews, conferences, meetings, and considerable expense, the association has solved the problem in connection with glass ware, and in a few weeks' time the various firms constituting the association will be in a position to supply the most useful sizes of glass beakers and flasks in an English-made glass similar to Jena glass, which has been tested by well-known English men of science, and can be definitely and safely recommended.

The same holds good for porcelain evaporating basins, beakers, crucibles, and covers, etc., and also for an English-made filter-paper equal to the German quality of Schleicher and Schull No. 595, and further qualities of these filter papers will be forthcoming very shortly. Also, as time goes on, further items will be added to the list, as negotiations are brought to a successful issue.

You will therefore see that a great deal of important and valuable work has been done, and that the problem of glassware has been to a very great extent solved so that an English-made glass equal to the well-known Jena glass will be on the market and can be supplied in a few weeks from the present time by the various firms constituting the British Laboratory Ware Association.

C. A. MERCER,
Chairman of the British Laboratory Ware Association, Ltd.
34 Camomile Street, E.C., London, February 8.

Problems of Radiation.

THE study of the production of homogeneous Röntgen radiation reveals some of the most interesting and suggestive facts bearing upon the problems of radiation. A few of these will be briefly indicated.

The emission of a fluorescent X-radiation by an element exposed to a primary X-radiation of shorter wave-length necessitates the absorption of a greater amount of energy from the exciting primary beam. It is possible definitely to assign a given portion of the energy absorbed from the primary beam as connected with the emission of a particular fluorescent radiation (Barkla and Sadler, *Phil. Mag.*, 1909.) The element exposed to this primary radiation emits also a corpuscular radiation, a portion of which is definitely associated with each fluorescent X-radiation. From measurements of these associated quantities, certain broad conclusions have been found to hold at least approximately in all cases hitherto dealt with; they hold within the limits of experimental error in the one case carefully investigated. These are :—

(1) The number of quanta of fluorescent X-radiation emitted is equal to the number of high-speed electrons in the corpuscular radiation (the associated corpuscular radiation).

(2) The total energy in the corpuscular and fluorescent radiations is equal to that of the primary beam absorbed.

These are not merely hypotheses which by trial may be found to be consistent with quantitative measurements of the energies of the two secondary radiations, but are the only rational conclusions which can be drawn from experiments on *some* substances. The deviations which have been observed in other cases are subjects for further investigation; the nature of these will be indicated later.

These conclusions may be described in greater detail as follows :—

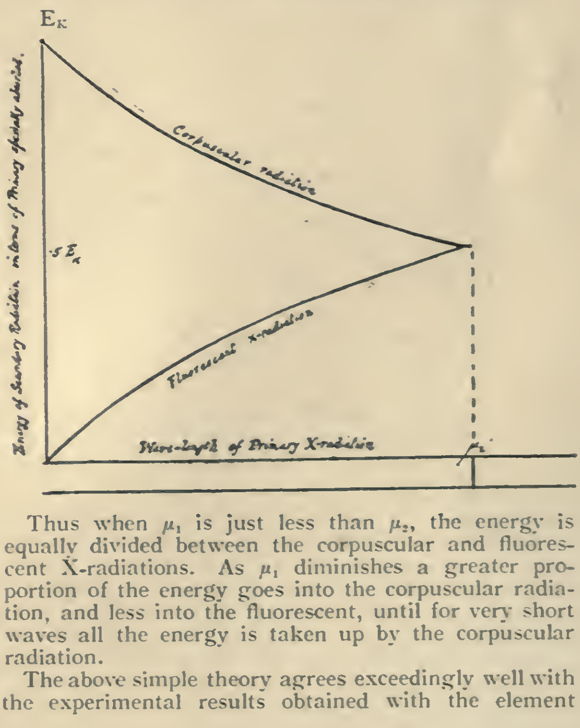
If a primary Röntgen radiation of wave-length μ_1 fall upon an element with a characteristic radiation of wave-length μ_2, then provided μ_1 is less than μ_2 the primary radiation is specially absorbed, and the element emits the particular fluorescent X-radiation, together with an associated corpuscular radiation. If we denote the energy of the primary specially absorbed in connection with the emission of the fluorescent radiation (of Series K, say) by E_K, the energy of the associated corpuscular and fluorescent radiations by C_K and F_K respectively, then $E_K = C_K + F_K$. Also as the energy of each electron in the corpuscular radiation is approximately (possibly accurately) that of a quantum of the primary radiation (we make the usual assumption here, that there is only one velocity of ejection; good reason can, however, be given for this) :—

$$\frac{F_K}{C_K} = \frac{\text{energy of fluorescent radiation}}{\text{energy of corpuscular radiation}} = \frac{\text{energy of quantum of fluorescent radiation}}{\text{energy of quantum of primary radiation}} = \frac{\mu_1}{\mu_2}$$

hence :—

$$C_K = \frac{\mu_2}{\mu_1 + \mu_2} E_K \text{ and } F_K = \frac{\mu_1}{\mu_1 + \mu_2} E_K$$

So we obtain expressions for the energies of fluorescent radiation (series K) and the associated corpuscular radiation in terms of that of the specially absorbed primary energy, for primary radiation of any wave-length. Plotting energies of secondary radiations and wave-length of primary radiation, we get the curves shown in the accompanying diagram :—



Thus when μ_1 is just less than μ_2, the energy is equally divided between the corpuscular and fluorescent X-radiations. As μ_1 diminishes a greater proportion of the energy goes into the corpuscular radiation, and less into the fluorescent, until for very short waves all the energy is taken up by the corpuscular radiation.

The above simple theory agrees exceedingly well with the experimental results obtained with the element

bromine—the one on which the most trustworthy data have been obtained. Instead of the fluorescent radiation in the particular case carrying away 50 per cent. of the energy of the primary radiation specially absorbed, experiments indicate about 47 per cent. and approximately an equal value for the corpuscular radiation. But there is evidence that with elements of higher atomic weight a limiting value of about 50 per cent. would be obtained. The indication of such a limit gives strong support to the whole theory. On the other hand, from an element of low atomic weight, the experimental value for the fluorescent radiation comes below 30 per cent., and there are indications of even lower values.

It would, however, be remarkable if such a simple theory gave perfect agreement for all elements, and correspondingly all X-radiations. The facts indicated appear of fundamental importance; deviations—real or apparent—will receive investigation and discussion later.

Other important conclusions based on the investigation are that the absorption by an atom is not necessarily in whole quanta of the primary radiation; we have evidence of absorption of primary radiation in quantities of any magnitude between one and two quanta of the primary radiation, or just possibly in fractions of one quantum.

The transformation of primary radiation into fluorescent radiation in certain cases at least is accompanied by little, if any, appreciable loss of energy within the atom.

The energies of X-radiations differing widely in penetrating power are approximately if not accurately proportional to their total ionising powers.

Details of these investigations will be published shortly. C. G. Barkla.

Physical Laboratory, The University, Edinburgh, February 8.

The Green Flash.

So much has been written about the green-ray at sunset that I am somewhat diffident about adding anything. But as I find myself unable to accept the orthodox explanation of the phenomenon usually seen I write this note. This phenomenon, as seen by me on several occasions during the last summer on my way to Australia, always consisted in the last segment of the red sun before disappearance becoming a bright green (without any transition through intermediate tints); this green was as nearly as could be judged the complementary to the red of the sun itself. On one occasion I shut my eyes immediately after the green tint appeared, and it *remained visible.* There could be no doubt that what I saw was the purely subjective after-image of the disappearing segment of the sun. Of course, if this is so, it should be easy to set up a laboratory experiment to imitate the natural phenomenon; and on returning I asked Mr. E. Talbot Paris, research student in this department, to arrange an experiment in illustration. An eccentric hole was made in a disc mounted on an axle. Red glass or gelatine film was fixed over the hole, and a bright light placed behind illuminated the film and produced thereby a miniature sun, which by slow rotation, could be made to "set" behind an interposed card. At the instant of setting, the artificial sun exhibited an exact reproduction of the phenomenon of the green-ray. It was easily possible in this way to obtain a red-ray using a green sun, or a blue-ray with a yellow sun, and so on.

It is easy to give the rationale of the effect. The positive light gradually diminishes as the artificial sun passes below the horizon; and it only requires a little adjustment of the rate of disappearance in order that the negative after-image excited at a previous instant when the segment was brighter, shall overpower the simultaneous weaker positive image of the remaining segment itself.

It would not be fair for me to dogmatise and assert that this is the only phenomenon which comes under the head of the green-ray. But it is certainly the only one which I succeeded in seeing; and *it must always be present even on the possible rarer occasions when colour changes arising from dispersion are also evident.* It is certainly also what many others saw. At the same time, it must be added that the phenomenon as observed by different persons, even on the same night, was so variously described as to lead one to suppose that the subjective element is sometimes present to even a greater degree than is implied in the above note. Alfred W. Porter.

Physical Department, University College, London, February 7.

Trenching Ground and Spraying Potatoes.

In the notice in Nature, of February 4, of the fourteenth report of the Woburn Experimental Fruit Farm it is suggested that the negative results obtained by us in bastard trenching might have been different had we experimented on vegetables, instead of fruit trees. No doubt the suggestion is correct; and a chance observation last year gave a striking illustration in point. Brussels sprouts were grown in a piece of ground partially occupied by trees; the ground had all been dug, but there were four patches of about four square yards each where it had been practically trenched, by the removal of trees and the digging out of their roots. In each of these patches the sprouts were two to three times larger than those in the intermediate dug ground. Universal experience indicates that a good depth of rich soil is essential for successful vegetable growing; this can only be obtained by trenching and liberal manuring, and nothing in our results should be taken as discountenancing such a practice.

It is also suggested that we should accumulate results on potato spraying to see whether such treatment pays on the average. We are doing so, and those already obtained are nearly sufficient for the purpose. They extend over eight seasons, and are on a fairly large scale, though the diversity in conditions, adopted for other reasons, renders it somewhat difficult to deduce a fair average from them. As it stands, this average is 7·8 per cent. increase on the weight of sound tubers as a result of spraying. Putting the average yield at 7 tons to the acre, and the net price realised at 3*l.* 10*s.* per ton, the value of the increment will be 1*l.* 18*s.* Two sprayings would cost, for materials, labour and use of plant, about 18*s.* to 1*l.* 13*s.*, according to the substance used, and this would leave a margin of profit of from 5*s.* to 20*s.* per acre.

Spencer Pickering.

Harpenden, Herts.

Early Representations of the Giraffe.

The discussion in Nature during the past year concerning the first mention in literature of the opossum and kangaroo has suggested a similar inquiry with regard to certain other well-known animals of the New and Old World.

When one examines into the sources whence were derived the illustrations in early printed books on

natural history, it is found that many are copied after drawings in old manuscripts.

A good example is furnished by Conrad Gesner's figure of an ichneumon, taken from an ancient MS. of Oppian, as the author declares.

FIG. 1.—Giraffe from mural painting at Villa Pamfili, near Rome. (After Keller, from Jahn).

In the case of the giraffe, what is thought to be the earliest portrait taken from life and engraved in a printed book, occurs in a work published in 1486 by Bernard de Breydenbach, a canon of Mayence, under the title of "Opusculum sanctorum perigrinationum." The figure is, however, inferior to those

FIG. 2.—Giraffe and Cercocebus, from ancient Egyptian monument at Thebes. (After Ehrenberg).

of the same and other African mammals which are introduced in the Ebsdorf and Hereford maps of 1282.

Pictorial representations of the giraffe by Roman artists have been preserved from the time of classical antiquity, and still earlier designs have come down to us in the form of ancient Egyptian hieroglyphics and inscriptions. That some of these were remarkably faithful likenesses may be judged from the two accompanying figures, one of which is reproduced from O. Keller's "Die antike Tierwelt" (1909), and the other from a memoir by C. G. Ehrenberg, "Ueber dem Cynocephalus und den Sphinx der Aegypter," published in 1834.

C. R. EASTMAN.

American Museum of Natural History.

The Economic Status of the Blackcap.

MR. COLLINGE does not meet the question whether the good the blackcap does in the spring balances the value of the fruit it takes in the summer. But he mentions having found a few aphids in the stomachs even in the fruit season, from which it may be inferred that more would be eaten, when there was no fruit in the spring. Now considering the enormous reproductive powers of the female aphis and that every female destroyed in the spring represents a diminution of many hundreds of the most mischievous pests that the farmer has to contend with in the summer, it seems only reasonable to conclude that the bird does *at least* as much good as harm. But the latter is seen while the former is not.

ALFRED O. WALKER.

Ulcombe, Kent, February 5.

MY experience of the blackcap is that the good it does in the spring by no means balances the harm it does during the rest of the year in fruit-growing districts.

The aphids found in the stomachs were all pea lice (*Macrosiphum pisi*, Kalt.), and were probably obtained accidentally when feeding upon peas.

I have elsewhere pointed out (*Journ. Board Agric.*, Sept., 1912) that all birds, other than doves and pigeons, feed their young upon an animal diet, of which insects form a large proportion, whatever may be the character of the food of the adult; the blackcap would, however, seem to form an exception, judging from the four nestlings I examined, whose stomach contents consisted of seeds or remains of fruit and fruit pulp.

WALTER E. COLLINGE.

8 Newhall Street, Birmingham.

The Rusting of Iron.

I DO not know if any account of experiments such as the following on the rusting of iron has appeared in print before, but if not they may be of interest to others of your readers besides myself. Briefly, they are as follows:—

(*a*) A small flask (100 c.c. flask with long narrow neck does well) is filled to the bottom of the neck with potassium ferricyanide solution, and then the neck is filled to the top with ordinary water. A long bright iron nail is then suspended in the water without disturbing the ferricyanide solution, and in a few minutes a blue colour will make its appearance in the neighbourhood of the boundary between the water and the ferricyanide. The formation of Turnbull's blue goes on regularly, and it settles to the bottom instead of iron rust.

(*b*) A bright iron nail is placed at the bottom of a solution of potassium ferricyanide in a similar flask, and in a short time spots of blue make their appearance on the nail instead of the usual deposit of iron rust.

The explanation according to the ionic theory seems obvious.

E. J. SUMNER.

The Grammar School, Burnley, Lancs, February 5.

STAR CLUSTERS.

OF all the telescopic objects in the sky none are more beautiful or more fascinating than the condensed, globular star clusters. Their bewildering complexity renders them unsuitable for direct study at the telescope, but photography has now brought them within the range of systematic investigation. The technical problem which they present is by no means easy, and demands high resolving power for success. The fine examples reproduced herewith, M3 and M13, have been very kindly sent from the Mount Wilson Solar Observatory, and illustrate admirably the work of the famous 5 ft. mirror constructed by Mr. G. W. Ritchey.

Considerable attention was given to the star clusters by Sir John Herschel, whose attempts to depict them by hand met naturally with small success. Certain curious irregularities which he believed to exist in the distribution of the stars may be attributed to a purely subjective origin, or they may be accounted for by the absorptive influence of external dark nebulous masses. No great importance is now attached to them, and in the main the stars may be considered as distributed with radial symmetry. But one curious feature noticed by Sir John Herschel has been confirmed by later study. The stars in a cluster tend to divide into two classes of magnitude, a brighter and a fainter, separated by a distinct interval. Can this be a visible division of stars presumably at the same distance and of nearly equal age into the two classes of giant and dwarf stars inferred by Hertzsprung and H. N. Russell?

About twenty years ago Prof. S. I. Bailey, at that time at Arequipa, devoted considerable study to photographs of the chief globular clusters. His work proceeded on two lines. On one hand he made systematic counts of the stars recorded, thus laying the foundation for statistical investigations of their arrangement in space. And on the other he investigated the magnitudes of the stars, and was thus led to the remarkable discovery that several clusters contain a high proportion of variable stars, a ratio of 1 in 7 in the extreme case of M3. His detailed results for the clusters ω Centauri and M3 have been published in two beautiful memoirs. The type of variation is of a distinct character, though a few isolated examples have been found elsewhere in the sky, with a period of about twelve hours and a rapid rise to maximum. In the case of M3 the variation is singularly true to one type, the range between maximum and minimum being two photographic magnitudes. Some clusters, notably M13, are almost entirely devoid of such variables; where they do occur they are apparently confined to the stars of the brighter order of magnitude.

The question of the distribution of stars in clusters was discussed by Prof. E. C. Pickering. Using counts on the clusters ω Centauri, 47 Tucanæ and M13 (Herculis), he formed the important conclusions: (1) that the law of distribution is essentially the same for different clusters, (2) that the bright stars and the faint stars of a cluster obey the same law. He represented graphically the curve of apparent (projected) density for different distances from the centre, and attempted without success to reproduce it by assuming laws of the form $1-r^2$ and $(1-r)^n$ for the density in space. The latter form was also tested by Mr. W. E. Plummer with much the same result on an extensive series of measures of the stars in M13.

FIG. 1.—M3 Canes Venatici. Exposure 4h.

The next important contribution to the subject is due to H. v. Zeipel, who measured the positions of the stars in M3 (Can. Ven.). By adapting the solution of a certain integral equation studied by Abel he showed how the law of distribution in space may be deduced numerically from the observed distribution as it is seen in projection. Later he compared the law of density in space arrived at in this way with that which obtains in

FIG. 2.—M 13 Herculis. Exposure 17h. (3 nights).

a gravitating spherical mass of gas in isothermal equilibrium. The result represents the density of the cluster satisfactorily near the centre, but in the outer regions the cluster is less dense than the theory requires.

The physical conception thus introduced suggested other possibilities. A sphere of gas in adiabatic, instead of isothermal, equilibrium might be chosen as the standard of comparison. A series of states exists, depending on the constant ratio γ of the specific heats of the gas, which have been extensively studied by Lord Kelvin and others. Emden's "Gaskugeln" is a work dealing exhaustively with the subject. In general, the law of density cannot be expressed in finite terms. But there are exceptional cases in which the differential equation possesses a very simple solution. One of these, discovered by Schuster, corresponds to the value $\gamma = 1{\cdot}2$. Here the law expressing the density at the distance r from the centre takes the form:

$$3a^2N/4\pi(a^2+r^2)^{5/2},$$

where N is the total mass or number of stars. This is finite, although the distribution extends to infinity. If a finite boundary be expected it is impossible to fix one by the counts, and attempts to do so have been proved illusory by the occurrence of characteristic variable stars beyond the supposed limit. However this may be, a comparison of the law with Bailey's counts of the ω Centauri cluster showed immediately an agreement within the limits within which radial symmetry is observed. I next compared the law with Pickering's curve of the projected densities, based on the clusters ω Centauri, M13 and 47 Tucanæ (bright and faint stars treated separately). The accordance was again excellent, and left little doubt that the law represented much more than a mere formula of interpolation. When, however, v. Zeipel's counts of M3 were examined, the outer region was found to conform with the law, while the inner revealed a higher density than was to be expected. As v. Zeipel had, on the other hand, succeeded in representing the central distribution by the isothermal law, it was suggested that the true standard of comparison was a central isothermal core surrounded by an adiabatic envelope, a composite state of equilibrium actually contemplated by writers on the thermodynamics of the subject. Afterwards, by the use of similar methods, Prof. Strömgren proved that M5 (Serpentis) possesses a structure which, whatever the cause, is identical with that of M3. v. Zeipel remarked that the excessive central condensation was more marked among the bright than among the faint stars.

The problem has again been discussed by v. Zeipel in an elaborate memoir, using in this instance counts of the stars in M2 (Aquarii), M3, M13 and M15 (Pegasi). He first finds solutions corresponding to these values of γ:

(M2) 1·200, (M3) 1·156, (M13) 1·183, (M15) 1·179

Thus M2 conforms with the same simple law, which I had found to hold so perfectly for ω Centauri. On the other hand, M3 is again seen to depart from it, and even with the new value of γ the representation is far from good. The law of density here contemplated is a solution of the equation:

$$\frac{d^2(r\rho^{\gamma-1})}{dr^2}+r\rho=0,$$

and satisfies a physical condition in being regular at the centre. The general solution, however, possesses a singularity at this point, and contains an additional arbitrary constant. Thus the particular law given above is only a special case of the general solution for $\gamma = 1{\cdot}2$, which, as v. Zeipel shows, can be expressed in elliptic functions. Accordingly, he abandons the central condition, and introduces the additional constant which is to be determined, together with γ, for each case. With this modification of the theory the values of γ became:

(M2) 1·194, (M3) 1·198, (M13) 1·203, (M15) 1·197,

so that within the limits of uncertainty in every case the distribution of the stars is consistent with a solution of the above differential equation when γ is assigned the value 1·2.

The analogy between the distribution of stars in a condensed cluster and the density in a spherical mass of gas of a particular type in adiabatic equilibrium thus seems to be fairly established. Even if it be supposed that the cluster is the outcome of an original nebula the question still remains why the distribution of matter should persist long after its condition has completely changed, or why the arrangement should resemble what might be expected of certain vapours (*e.g.*, chloroform). The answer given by v. Zeipel on the basis of a strict mathematical analysis is that this is in conformity with a kinetic theory which applies to an aggregate containing a high proportion of Keplerian binaries. This may be a bold application of the law of large numbers, but it is certainly an interesting conception. Since there is every reason to believe that all short period variables are binary systems the observed occurrence of these in clusters lends support to the view, though they can only represent the exceptionally close systems. The investigations here described refer exclusively to the highly condensed clusters. But there exist also clusters showing states of concentration in varying degree until probably all visible trace of organic connection is lost. In Strömgren's view the whole series represents an order of evolution by which the dense clusters grow out of more scattered forms. Whether the results will throw light on the wider problems of the structure of the sidereal universe seems doubtful in view of certain conclusions drawn by Poincaré, Jeans and Eddington as to the relevance of the kinetic theory. But taken by themselves they present questions of the highest interest which are likely to repay further study. H. C. PLUMMER.

ON COLOUR SENSITISED PLATES.

I.—IN GENERAL AND ORTHOCHROMATIC PLATES.

IT used to be customary to draw three curves above a diagrammatic spectrum, heat, luminosity, and actinism curves, the last representing the power of light to produce or facilitate chemical change independently of the temperature change. This custom survives to a certain extent, though only one of the curves, namely, the heat curve, is definite. The luminosity curve depends upon the human eye, and eyes vary, sometimes even in the same individual, with regard to their sensitiveness to light and colour. Still, it is possible to draw practically useful luminosity curves in a general sense, and by taking an average human eye, in perhaps almost an absolute sense.

But the "actinism" curve is essentially different, for here we may be concerned, not with a single organ and its possible variations or degrees of perfection, but with every substance that exists on the face of the earth or that can be prepared by artificial means. And if we limit our considerations to the very few substances that are practically utilised in photography, we find that "actinism" extends from well into the infra-red down to the Röntgen rays, which are far below what is generally known as the ultra-violet. "Actinism" extends over a range of eleven or twelve octaves for practical photographic purposes, while luminosity extends over scarcely one octave, and for practical purposes even less than this, and yet some people speak of the photographic plate as colour-blind!

The whole of this eleven or twelve octaves has not yet been dealt with photographically, because in the extreme ultra-violet (the "Schumann region") at wave-lengths a little less than 200 $\mu\mu$, the absorbing power of air and gelatine prevents the passage of radiations through them. But this appears to be due to absorption bands, as radiations of still shorter wave-length (Röntgen rays) pass freely through these media. By getting rid as far as possible of air and gelatine, the photography of the ordinary spectrum has been extended down to wave-length 100$\mu\mu$, or even less. There are other difficulties than the air and gelatine to contend with in investigations of this region, but with these we are not immediately concerned.

Although it is necessary sometimes to bear in mind the enormous range of sensitiveness of photographic materials, even from a purely practical point of view, if we exclude the Röntgen region, and regard only those circumstances that concern the photography of objects, whether terrestrial or celestial, and whether by daylight or artificial light, we have to consider only about two octaves of radiations, or rather more if the far infra-red is taken into account. This range may be still further curtailed when daylight or glass apparatus is used, on account of the absorptive power of glass and the atmosphere, and what remains may often be sufficiently described by indicating five regions, namely, ultra-violet, blue, green, red, and infra-red. The "blue" will include the indigo and violet, and the "red" will include the orange, and the yellow is negligible as in a good spectrum it is represented by little more than the sodium D lines.

In order to photograph coloured objects so that their luminosities shall be correctly represented in the print, we want to get the curve that represents the action of the spectrum on the plate to coincide with the luminosity curve of the spectrum, and then we want a printing method that will preserve these tone values. The alternative of getting equal and opposite errors in the negative and the print so that the one shall correct the other, may have a degree of possibility about it. The fact to be emphasised is that the getting of a correct negative is not the whole business. Indeed, the getting of the two curves to correspond is not the whole business so far as the negative is concerned, for they may correspond at one exposure of the plate to the spectrum and not at another, because the steepness of the gradation of the deposits produced on the plate by equivalent ranges of exposures to the various parts of the spectrum is not the same. These difficulties are mentioned to show that, from a practical point of view, "ortho-

chromatic" or "isochromatic" photography, or whatever it may be called, cannot yet even be regarded as an absolute matter; but where the discrepancy in the use of "ordinary" plates is of the order of a thousand to one, there is plenty of room and need for improvement, before getting, as it were, within sight of perfection.

When the spectrum is photographed on an ordinary plate, the green and red, which are bright to the eye, produce little or no effect; they might as well be black, while the blue and ultra-violet, which are dark and black to the eye respectively, produce a considerable effect, as if they were bright. Similar results are obtained with ordinary objects; slate roofs, being bluish, come much too light; bricks, being red or reddish, come much too dark; grass and green foliage too dark, and so on. The plate is sensitive to all these colours, but it is very much too sensitive to blue, or not sensitive enough to green and red. By causing the light that falls upon the plate to pass through a colour filter that will reduce the brightness of the blue light to about one-thousandth part of its intensity, and increasing the exposure proportionately, the green and red will be given an opportunity to act, and the result will be much improved. To increase exposures to one thousand times the usual length may sometimes be possible (say two minutes instead of the tenth of a second), but the undesirability of such an increase need not be pointed out.

Ordinary Plate. Iso- Plate without screen. Iso- Plate with screen.

FIG. 1.

Dr. H. W. Vogel, in 1873, discovered that by the application of certain colouring matters, it was possible greatly to increase the sensitiveness of plates to green and red light. About ten years later the application of this principle began to be made a commercial matter, and Messrs. Edwards and Co. secured the patent rights in this country. These isochromatic or orthochromatic plates were a great step in advance. The three illustrations (Fig. 1) were prepared many years ago from a design for which the writer was indebted to Mr. B. J. Edwards. The cross and the disc in the original are of such dark shades of blue, that from a distance of from one to three yards, according to the sensitiveness to blue of the eyes of the person looking at the card, they appear quite black, while the ground colour is a bright yellow. On the ordinary plate the yellow comes out darker than the almost black blue. The improvements obtained by using an orthochromatic plate, and then by the use of a colour filter to reduce the blue light in proportion to the yellow, are shown in the reproduction.

There are two or three matters in connection with the use of such means as these to get variously coloured objects represented according to their luminosities that may be pointed out as well from this example as from any other, bearing in mind that they represent general principles. Such plates as these ("ortho-" or "iso-chromatic") are often, if not generally, stated to be sensitive to yellow. This is misleading. Spectrum yellow, as already stated, is negligible in these matters. All objects that are yellow are yellow because they absorb blue, and send red and green light to the eye. Yellow light is a mixture of red and green. These plates have their sensitiveness increased to green and not to red. If, therefore, we so arrange our colour filter as to get full correction for yellow, that is, that yellow and blue shall be correctly represented according to their luminosities, we throw the correction that ought to be borne by the green and red jointly entirely on to the green, and this colour is therefore over-corrected. Greens will therefore be represented too light. On the other hand, the increased sensitiveness does not extend over the whole of the green, it is chiefly in the yellowish-green, and the curve of sensitiveness shows an important depression in the region that may be roughly indicated as being between E and F. Pure yellowish-greens tend, therefore, to be over-corrected on this account also, but what is perhaps of more importance is that a green that comes in this depression of sensitiveness will be under-corrected and come out too dark. This is not a mere theoretical difficulty, for M. Callier, who is a most careful investigator, finds that the green of pine trees largely corresponds to this deficient sensitiveness, while that of grass corresponds rather to the specially sensitised yellowish-green. Therefore these two greens are represented as more different in brightness than they really are.

These facts illustrate the difficulties that result from the fact that specially sensitised plates have not an evenly graded sensitiveness. There is the maximum for the plate, and a new maximum for the new compound introduced. Such irregularity might be compensated by a complex colour filter, but of course only approximately and with much trouble and considerable increase of the necessary exposure.

The "ortho-" or "iso-chromatic" plates of commerce are generally of the type just discussed, and are sensitised by erythrosin or a similar substance. In a second article we shall refer to "panchromatic" plates and other matters.

CHAPMAN JONES.

WHALING IN SOUTHERN SEAS.

MR. THEODORE E. SALVESEN makes a very interesting report[1] on the whale fisheries of the Falkland Islands and dependencies. Whaling in southern seas began, he tells us, with the eighteenth century, the first British fleet of twelve vessels sailing in 1725. They went after sperm whales or cachalots (*Physeter macrocephalus*) and southern right whales (*Balaena australis*), which were harpooned from rowing boats. In the first half of the nineteenth century there were as many as 500–600 whalers so employed—wooden sailing ships, complete in themselves, the blubber being rendered into oil on board. But this kind of vessel is now practically unknown, its place having been taken by the modern steam whaler; and the venue has changed, in the far south at any rate, from sperm whale and right whale to the finners. The sperm whale is seldom met with in the waters round the Falkland Islands and dependencies, its normal habitat being in warmer zones, and the southern right whale is no longer specially sought after, since the price of baleen has fallen so low. Thus attention has been directed to the blue whale (*Balaenoptera sibbaldii*), the largest living animal in the world, to the finner whale (*B. musculus* or *physalus*), to the small fish whale (*B. borealis*), and to the humpback whale (*Megaptera boops*)—all of them often called "finners." As they are more active than the sperm whale and the right whale and only awash for a very short time when breathing, and as they sink after being killed, they were left entirely unmolested in the old days. But now their turn has come.

It was a Norwegian captain, Svend Foyn, who worked out, in the north, about 1866, the method of capturing finner whales, and his devices, with improvements, are now in use by all the modern whaling companies. The whale-catcher is worked by steam, not by men with oars; the whale gun is a finely fashioned cannon; the harpoon carries a shell, the whale line is connected with springs or accumulators; if the whale be not mortally wounded the gunner plays it as an angler his salmon; to keep the carcase afloat it is inflated with air by means of a steam air-pipe from the engine-room! Everything is specialised. And another difference as compared with old days is that the reduction of the carcase is accomplished in a factory on shore or in a large vessel (up to 7000 tons) moored in a harbour.

Floating factory S.S. *Restitution* of North Shields, Possession Bay, South Georgia. From "Report on the Scientific Results of the Scottish National Antarctic Expedition."

Besides the baleen, which no longer pays well or at all, and the oil which is graded into qualities according as it comes from the blubber, the fat of the tongue and kidneys, the flesh and bones, and the refuse, there remains the dried flesh and bones.

[1] "Scientific Results Scottish National Antarctic Expedition," iv. (1914) pp. 475–486, 10 plates and map.

The absolutely fresh flesh is used to form whale meat meal, a nutritious and wholesome food-stuff, containing 17½ per cent. proteid, largely used for feeding cattle. From the remaining flesh and about a third of the bones whale guano is made; and from bones alone, bone meal.

The modern whaling operations were started by Captain C. A. Larsen in 1904; and his satisfactory results led to the formation of a large number of companies, which now carry on, in the dependencies of the Falkland Islands, the largest whaling business in the world. The season from November 1, 1912, until the end of April, 1913, yielded, at South Georgia, about 5000 whales (52 per cent. humpbacks, about 42 per cent. finners, and about 6 per cent. blue whales). These produced about 200,000 barrels of oil and about 8000 tons of guano. At the South Shetlands and Graham Land the much shorter season yielded also about 5000 whales; at the South Orkneys the still shorter season yielded about 800 whales; at the Falkland Islands only 87 whales were brought in. The total production was about 430,000 barrels of oil—more than half the world's output for that season—and 8375 tons of guano, the gross value being about 1,350,000*l.* sterling. The industry gives employment to about 3500 men. The report is a business-like document, very lucidly presented by one who evidently knows what he is talking about. No indication is given of the probabilities of continuance. We hope that the shortness of the season will suffice to give the finners a chance for many a year to come.

CHEMISTRY AND INDUSTRY.

WE live in an age of specialisation; in no era has the statement that "monomania is the secret of success" approached more closely to the truth. Business is an instinct, chemistry a science, and although it is conceivable that it is of advantage for the chemist to possess some business instinct, and for the business man to have some knowledge of chemistry, the combination in one person of acute business instinct and scientific genius is so rare as to be negligible. Both these great qualities are needed for the solution of our industrial problems—the nation lacks neither the one nor the other, but they reside in different individuals who possess entirely different types of mind. Co-ordination is the sole solution.

It has been stated that the German chemical industries have been built up by men who possess both business acumen and scientific ability. This is not the case. Men of science, such as Caro, Bernthsen, Gläser, and Graebe, and business men such as Brünck, have collaborated, and the collaboration has been successful.

Again, it is remarkable that this country should have adopted the view that there is some essential difference between the scientific chemist and the technologist; the former is dubbed "theorist," and is ignored; the latter is the "practical man," and is belauded. One of the chief reasons for German success lies in the fact that they have realised that the terms man of science and technologist are complementary, that the one must discover while the other adapts.

No chemical process, unless it is based on mere rule of thumb, can be discovered without the aid of the knowledge and experience which can only be gained by many years of scientific training. Such discoveries have to be made and worked out, in the first instance, on the laboratory scale, and this is the province of the scientific chemist. The discovery having been made, and the conditions for production, dictated by considerations of economy, having been determined, it is then the business of the technologist to adapt the process to commercial conditions. It is the lack of a true appreciation of these matters which has hampered the development of scientific industry in this country, especially in those directions in which highly trained specialised knowledge is required.

At the present time many potentially useful discoveries are made in the chemical laboratories of our universities, university colleges, and technical schools, and there are isolated instances in which enlightened manufacturers have made use of them, but in the majority of cases the scientific worker has found by sad experience that little financial profit accrues to him even though he goes to the trouble of obtaining patent protection. He is so rarely a man of business that, if he cooperates with a manufacturing firm, his elimination, from a financial point of view, is usually an easy matter. In consequence, the greater number of scientific chemists, to whom the joy of discovery is everything, and the adaptation of minor importance, prefer to publish their discoveries in the scientific periodicals, where they serve as useful suggestions to others both at home and abroad.

This unfortunate and wasteful condition of affairs can be altered if some body in authority would undertake to organise the scientific ability which is available in our educational institutions. The function of this organising body would be to receive from and to make suggestions to manufacturing firms, and to allot the problems to the scientific laboratories. The scheme would in no way affect the works laboratory, which would still fulfil its proper function of adapting the scientific details to commercial conditions. Moreover, the works laboratory could be recruited from the scientific laboratory, as is the case in Germany, by the enrolment of those men who show themselves fitted by temperament for such work.

It must not be imagined that this article is in any way a plea for the curtailment of research in pure science, which means research of a purely abstract kind, having for its object the discovery of the natural laws underlying the science, and which is, of course, absolutely indispensable. It is merely stupid to decry this form of research or to speak of its apparent lack of utility; if the laws of organic chemistry had not been determined by abstract research there would have been no coal-tar industry.

It is, then, by such a scheme as is here outlined that the scientific army of the nation can be marshalled to meet the present national emergency, but there is yet another aspect which will require immediate attention if we are to carry on the work without unnecessary hindrance.

One of the chief differences between the German and English patent laws is that while in this country a patent specification is held to be addressed to a person skilled in the art, say, to a skilled workman, in Germany it is sufficient if it is understood by an expert. This factor, apart from any intention to deceive on the part of the patentee, is responsible for the frequent "insufficiency of patent specification" which characterises both German patent specifications, as well as British specifications based upon German inventions. It is, indeed, very rare to have a German patent granted on the full text of the specification which was originally submitted to the German Patent Office. The outcome of this is that when the invention has been found novel and patentable by the examiner, the specification is promptly cut down and stripped of all such matter as he considers to be more or less obvious to an expert.

Again, the high cost of legal procedure in this country, and the fact that the Comptroller has no power to refuse the grant of a British patent for alleged insufficiency or want of subject matter, are responsible for the obtaining, particularly on the part of large German chemical companies, of a great number of "block" patents, the whole object of which is to block the development of chemical industry in this country.

It is certain that a good many chemists and chemical manufacturers are fully aware of the fact that a large number of British patents granted to Germans are merely "bluff," and could readily be invalidated were it not for the exceeding high cost connected in this country with such legal procedure; it is for this reason, also, that many small inventors stand absolutely no chance against large companies, which, in view of the high cost, are alone able to go before the Court.

Under Section 27 of the Patent Act an effort has been made to enforce the manufacture of patented inventions in this country by what is generally known as the "compulsory working" clause. It seems to be now admitted that this arrangement has not worked in practice, and its failure is due mainly to the lack of organisation, in this country, of the scientific ability which is vital to all modern industries.

In conclusion, I should add that I am indebted to Mr. J. E. Pollak, of the firm of Messrs. Dicker, Pollak, and Derrimann for the above information respecting the working of the patent laws.

JOCELYN THORPE.

NOTES.

WE regret to see the announcement of the death on January 24, at seventy-six years of age, of the astronomer, Prof. G. F. J. Arthur Auwers, of Berlin, foreign member of the Royal Society and associate of the Royal Astronomical Society.

DR. T. WESLEY MILLS, emeritus professor of physiology, McGill University, Montreal, died suddenly in London on February 14.

THE council of the British Medical Association has decided that the annual meeting, which was to have been held at Cambridge this summer, shall not take place. The statutory annual general meeting of the association, and the annual meeting of representatives will, however, be held.

GOOD progress is being made, says the *Pioneer Mail*, with the scheme for the establishment of a School of Tropical Medicine in Calcutta, with which the name of Sir Leonard Rogers is associated. An excellent site has been secured close to the Calcutta Medical College, and the buildings are in course of erection. The first subscription list shows that a lakh and three-quarter rupees has been obtained already, and another half-lakh is practically secure.

M. LOUIS MOISSAN, son of the late Prof. Henri Moissan, and assistant at the Ecole supérieure de Pharmacie at Paris, who died on the field of battle on August 10, has left to his school, in addition to the scientific estate of his father, the capital sum of 200,000 francs for the foundation of two prizes—one for chemistry (prix Moissan), and one for pharmacy (prix Lugan), in memory respectively of his father and his mother, *née* Lugan.

THE Royal Astronomical Society has taken the first step towards placing itself in line with a number of other scientific societies by deciding at the anniversary meeting on Friday last, February 12, "That this meeting approves of the admission of women as Fellows and Associates of the Society, and requests that all steps necessary may be taken to make their election possible." The meeting was almost unanimously in favour of the proposal—fifty-nine fellows voting for it to three against—and a supplementary charter will now be applied for in order to put the resolution into force.

AT its annual meeting, held in Saint Louis on December 28 last, the Federation of American Societies for Experimental Biology—which includes the Physiological Society, the Society of Biological Chemists, the Society for Pharmacology and Experimental Therapeutics, and the Society for Experimental Pathology—passed the following resolution addressed to the men of science belonging to the nations of Europe now at war:—"That we extend to the scientific men within these nations the hope of an early and enduring peace, which will leave the nations with no permanent cause of rancour towards each other, and which will ensure to each the glories of scientific and humanitarian achievement in accordance with its own conception of these ideals."

THE council of the Royal College of Surgeons has given permission to the Royal Anthropological Institute and Prehistoric Society of East Anglia to hold a combined meeting in the museum and theatre of the college, Lincoln's Inn Fields, W.C., on the afternoon of February 23. Many recently discovered specimens will be shown and discussed, proceedings commencing at 2.30. An evening meeting will be held on the same

day in the rooms of the Royal Anthropological Institute at 50 Great Russell Street, W.C., at 8.15, when Mr. Charles Dawson will give a descriptive and illustrated account of the various cultures found in the deposits of the valley of the Sussex Ouse—particularly of the implements recently discovered at Piltdown. Mr. Dawson will also bring forward new evidence bearing on the origin of eoliths, and will exhibit Catalonian silk amulets in the form of prehistoric weapons.

UNDER the auspices of the London Manx Society a meeting was held in the Geological Society's Rooms, Burlington House, on February 13, to celebrate the centenary of the birth of the distinguished naturalist, Edward Forbes. He was born at Douglas, in the Isle of Man, on February 12, 1815, and died at Edinburgh, where he held the University chair of natural history, on November 18, 1854. The president of the Geological Society (Dr. A. Smith Woodward) presided, and addresses were given by Sir Archibald Geikie and Prof. Edward Hull, who had personal memories of Forbes. Sir Archibald Geikie suggested that an Isle of Man Museum might be regarded as a most appropriate memorial of Forbes in the island of his birth, and could be made to include illustrations both of the natural history and of the antiquities of the country. Mr. A. P. Graves added that the associations of Manx literature might also find a place in such an institution. After the meeting the members of the London Manx Society visited the Museum of Practical Geology, Jermyn Street, where Forbes worked for many years as naturalist to the Geological Survey. In the evening, a second meeting and conversazione were held in the St. Bride's Institute.

SEVERAL correspondents have sent us descriptions and sketches of a sun-pillar capped with an arc of a secondary halo, observed during the afternoon of February 11. Writing from Stonyhurst College Observatory, Mr. W. McKeon states that at 0h. 30m. p.m. the ordinary halo of 22° radius was observed, capped by a bright "arc of upper contact," which not only accompanied the halo throughout the whole afternoon, but outlived it by quite thirty minutes. "At 3.15 p.m. a hazy beam of white light began to project upwards from the sun. This gradually brightened and lengthened until by 4.30 it reached the bright arc of contact 22° N. By this time the halo proper was quite faint, while the 'solar pillar' supporting, as it were, the arc of contact, was very bright, and stood out most conspicuously. Just before 5 p.m. the 22° halo had quite vanished, at which time the 'arc' and 'pillar' changed to a strong pink, and continued thus, without the halo, as a most striking object until 5.25 p.m., when both together suddenly faded away." The origins and characteristics of these and related optical phenomena in the atmosphere were discussed in articles in NATURE of June 13, 1912, and April 3, 1913.

"ALDERMAN ARCHIBALD said he did not think the principle was right; it was really a political question." We quote from a report of a meeting of the Middlesbrough Education Committee, at which a circular letter was read from the British Science Guild, asking if a general undertaking would be given to purchase British glass for school laboratory purposes for a period of three years after the war. Seventy per cent. of the public schools represented on the Headmasters' Conference are willing to afford this support to manufacturers contemplating expenditure upon plant for the production of the glassware hitherto obtained mostly from Germany and Austria, but Alderman Archibald suspects that the effort being made to encourage the establishment of these factories is a political move in which the Middlesbrough Education Committee would be unwise to take part. We have fortunately been relieved of the disputes of party politics for the past six months, but apparently the guardians of education at Middlesbrough think that a body like the British Science Guild has been got at by political propagandists, and is trying to forestall legislation of some kind; for the Committee decided without discussion to take no action for the present. Meanwhile the supplies of glassware for laboratories are getting low, and, following Alderman Archibald, nothing must be done to stimulate enterprise in its manufacture here because the attempt to meet an educational want is "really a political question." That an education authority should commit itself to such a view is a pitiful sign of local inability to understand national needs.

THAT the protective treatment against typhoid fever is indeed protective, we all are agreed. Not one man in a hundred thousand disbelieves this plain fact; the only question is whether the treatment ought to be made compulsory. Soldiers take non-compulsion as evidence that the authorities are not sure of the great value of the treatment. "If you believed in it, really believed in it, of course you would make it compulsory." That is the argument; and a very sound argument it is. We may be sure that compulsion would meet with no serious opposition among the men themselves, and would make no appreciable difference to recruiting. Of course, clear instructions ought to be given to all men how to take care of themselves after the treatment. For two days, a man ought to keep quiet; he ought to avoid exposure to the risk of pneumonia; and he ought to leave off all alcohol. If a man, for two days after each of his two doses, will keep quiet, and keep warm, and keep teetotal, he may be absolutely certain that he will have very little trouble from the treatment. All experience, ever since the South African war, has gone to emphasise the danger of direct infection from the surface-soil. It is man who infects men. When the hot weather comes he will have the assistance of swarms of flies; there will be not less typhoid but more. Happily, vast numbers of our troops are already protected; and the "conscientious objector" is likely to feel the "pressure" of his own comrades in the ranks. If the Government adopts some measure of compulsion, it will be a very popular action. It would bring the Government gratitude and censure in the proportion of the sack to the bread in Falstaff's tavern-bill.

THE gold medal of the Royal Astronomical Society was presented, at the meeting of the society on February 12, to Prof. A. Fowler in recognition of his spectroscopic investigations of sunspots, stars, and comets, and related laboratory researches. In a short survey of Prof. Fowler's work, the president, Major E. H. Hills, referred to his association with, and extension of, the study under laboratory conditions, initiated by Sir Norman Lockyer, of various elements represented in celestial spectra. By these means he discovered that many of the band lines peculiar to the sun-spot spectrum are due to magnesium hydride, the existence of which, together with flutings of titanium oxide and calcium hydride, indicate that spots are regions of reduced temperature. This view was further supported by the observation that the "long" lines of the higher chromosphere are generally weakened in sun-spot spectra, while the "short" lines of the lower chromosphere are generally widened or strengthened. The arc spectrum of scandium was shown to consist of two distinct sets of lines which similarly present a differential behaviour in the spectra of the sun, sun-spots, and chromosphere. In the field of stellar spectra, Prof. Fowler proved that the chief substance concerned in the production of the flutings characteristic of stars of the Antarian type is titanium oxide. The tail spectrum of comets was identified by him with the spectrum of carbon monoxide at extremely low pressures—0·01 mm. or less; and during this research a new high-pressure (100 mm.) spectrum of the same carbon compound was discovered. Investigations of spark spectra, and particularly of Sir Norman Lockyer's class of "enhanced lines," led to the discovery of a new ultra-violet series ascribed to "proto-helium," and also to a series of close doublets having the spark-line of magnesium, $\lambda 4481$, as its leader. The bearing of these series upon theories of the constitution of the atom was discussed in the Bakerian Lecture delivered by Prof. Fowler before the Royal Society last year (NATURE, April 9, 1914, vol. xciii, p. 145).

PROF. CARL THEODOR LIEBERMANN, who died on December 28 of last year, at the age of seventy-two, left behind, in his numerous published researches, the record of a remarkably active scientific career. Carl Liebermann was born in Berlin in 1842, and spent the greater part of his life in his native town, first as assistant to Prof. v. Baeyer, and later as professor of chemistry in the Technical College of Charlottenburg, It was in Baeyer's laboratory in 1868 that young Liebermann, with his colleague, Carl Graebe, made the famous discovery of the synthesis of alizarin from anthracene, which, like modern synthetic indigo, revolutionised the colour industry of the time, and brought to a sudden end the cultivation of the natural product. It would be impossible in the course of a short notice to attempt to enumerate the variety of problems in organic chemistry to which Liebermann devoted his long life. Following up his first investigation, he made a comprehensive study of the various hydroxy-derivatives of anthraquinone and the corresponding derivatives of naphthalene (naphthazarin), from which he was led to formulate a theory of coloured compounds and mordants. He included in his researches the study of many natural and artificial dyestuffs, such as brasilin, rhamnetin, quercetin, chrysarobin, cochineal, coerulignone, and a variety of phenol colouring matters, the structure of which he was able in many cases to ascertain. In later years he turned his attention to the alkaloids, especially the numerous constituents of the coca-leaf, which he isolated and studied. Among these constituents he examined cocaine, for which he devised a method of synthesis, cinnamylcocaine, the truxillines, which he also synthesised, and also ascertained the structure of the interesting pair of truxillic acids with which they are combined; benzoylecgonine; tropa-cocaine and hygrine. The latter he also found in Peruvian cusco-leaves, together with cuscohygrine. Prof. Liebermann received the honorary degree of D.Sc. of the University of Leeds in 1906, and was also an honorary fellow of the Chemical Society.

WHEN Columbus discovered and landed on Jamaica during his second voyage, in 1494, he found it populated by Arawak Indians, who, after some hesitation, followed by bribing, received the white men in a friendly spirit. The subsequent settlement of the island by the Spaniards, and the impressment of the natives for work in the gold-mines of Haiti, as well as for agricultural labour in their own island, soon led, however, to their extermination, and by 1558 the whole Arawak nation appears to have been completely wiped out. To recover traces and relics of this lost race has been the self-imposed task of Mr. G. C. Longley, of Pelham Manor, New York, who for the last half-dozen years has passed the winter in the island exploring the old kitchen-middens. The result is a collection of some 1500 celts, fragments of pottery, grinding-stones, stone-pendants, etc., all of which have been presented by the collector to the American Museum of Natural History. They form the subject of an illustrated article by Mr. Longley in the *American Museum Journal* for December, 1914.

A NOVEL kind of nesting-box made of bark in the shape of a slug, so as to be almost invisible when affixed to the trunk or arm of a tree, is described and illustrated in the *Selborne Magazine* for February.

A WELL-MERITED protest against the treatment of horses with the home troops in the early part of their training in certain districts is formulated in the February issue of the *Animals' Friend*, where it is stated that horses taken out of good stables were tethered in the open during wet and cold weather—in some cases even without rugs. Many fine horses, as we can testify from personal knowledge, were utterly ruined, if not actually killed, by such treatment.

IN his annual fish-notes from Great Yarmouth, for 1914, Mr. A. H. Patterson, in the January number of the *Zoologist*, expresses the opinion that the fecundity of the herring is so great as to render it impossible for sea-birds, such as gannets and cormorants, even to reduce, let alone deplete, the shoals

that annually visit our coasts. The reduction in the numbers of cetaceans in recent years must also be taken into account, as well as the increasing capture of dog-fishes for food. Nothing can ever exhaust the shoals save the trawl-net, which in a few hours can destroy, in the shape of ova on the sea-bed, millions more potential herrings than those devoured in the adult state by birds in a twelvemonth.

THE most striking photographs in the January number of *Wild Life* are those of the head of a Guinea baboon and of a magnificent cluster of eggs of the large yellow underwing moth. In some instances a moth of that species will lay no fewer than two thousand of these beautifully sculptured eggs, which are at first white, but change to purple before hatching. Another good sample of photography is a badger just peering out from its "sett" beneath the trunk of a giant oak. The writer of the accompanying letterpress, or at all events the editor, should, however, have known that it is quite out of date to refer to the badger as *"Ursus" meles*. Indeed, the practice of introducing the scientific names of well-known animals in publications of this nature is altogether unnecessary.

THE Imperial Department of Agriculture for the West Indies has issued a useful pamphlet (No. 76) dealing with Indian corn (maize). The cultivation, husking, milling, etc., are described in detail, and the insect pests are fully treated with the aid of illustrations. Of these the corn-ear "worm," *Laphygma frugiperda*, is the most serious.

INDIAN Forest Bulletin, No. 26, gives an account of the resin industry in Kumaon, the preliminary experiments for which were carried out by Dehra Dun officers twenty-five years ago. The oleo-resin from the Chír pine (*Pinus longifolia*) is now successfully obtained by methods similar to those in use in the Landes district of France, and 43,000 maunds of crude resin were yielded in 1913-14.

THE buildings of the Forest Research Institute at Dehra Dun are described and illustrated in the December number of the *Indian Forester*. The buildings just completed consist of a main research institute in which the fine library is housed, a chemical laboratory with a separate distillery and separate gas-house, workshops for the economist and entomologist, an insectary, and a students' laboratory. The buildings are in red brick, uniform in style but unfortunately very far from beautiful.

THE Potamogetons of the Philippine Islands have been examined by Mr. A. W. Bennett, and his account appears in the same number of the *Philippine Journal of Science*. Only one new species is described. The almost world-wide range of some of the species of these aquatic plants is of interest, *P. angustifolius*, for instance, being found in Europe, North America, Cuba, Madagascar, India, China, and Luzon. *P. pusillus* is equally widespread. *P. javanicus* appears to be the only species found in the Philippines which extends to Australia.

IN 1901, amongst 2000 seedlings that were raised from the nuts of a certain black walnut (*Juglans Californica*) tree, growing at Santa Ana, in California, there were found twenty plants with peculiar foliage. The parent tree, which was normal, had large compound leaves, each composed of eleven to nineteen leaflets. The peculiar seedlings bore small leaves, each made up of three leaflets, or in rare cases reduced to a single leaflet. Mr. N. B. Pierce, of Santa Ana, writing in NATURE, September 10, 1914, p. 34, considered this sport to be a hybrid between the Californian walnut and the evergreen oak, *Quercus agrifolia*, which grows in the same region; and the occurrence of a supposed bigeneric cross created a sensation in California. The sport, while interesting, seems merely to be a case of arrested development, exactly similar to that of the simple-leaf ash well known in Europe, and figured in NATURE, January 7, 1915, p. 522. Prof. Babcock, of Berkeley University, has made an elaborate study of this sport, publishing the results in two profusely illustrated bulletins ("Studies in Juglans," i. and ii., Univ. of California, Pub. in Agri. Sciences, vol. ii., 1913, 1914), and comes to the conclusion that there is no evidence of hybridisation, and that the sport does not arise from visibly malformed flowers or fruits. He states that a normal tree has been found which annually produces a small percentage of the trifoliolate form. This is exactly the case with the simple-leaf ash, and the real cause of the arrested development which is present is as yet unexplained.

THE Monthly Meteorological Charts of the Atlantic and Indian Oceans for February, 1915, which have recently been issued by the Meteorological Office, give much detail of interest to the seaman, such as winds, currents, barometric pressure, temperature, and ice. The Atlantic chart mentions that the frequency of fog in February is similar to that recorded since October, and the maximum frequency in mid-Atlantic seldom exceeds 5 per cent., as against 40 per cent. in July. Steamers making the Transatlantic passage in February are not likely to be hindered by fog. Thick weather is, however, commonly experienced from December to February near the African land, due largely to dust blown seaward from the Sahara. Charts of mean salinity and surface temperature are given for the Atlantic and for the English Channel for October, 1914. The isohalines coupled with the sea surface isotherms will be of considerable scientific value with the extension of the period. The Indian Ocean chart has a copious note on submarine seismic disturbances. It mentions that some years ago the late Sir G. H. Darwin, member of the Meteorological Council, pointed out that probably the actual places of origin of earthquake shocks are usually situated under the sea in proximity to a coast. Numerous extracts are given from special meteorological logs kept on board ship, and in these the sensation is commonly described as though the vessel was grinding over a rocky bottom or reef.

IN his address to the physics section of the American Association for the Advancement of Science in

December last the chairman, Prof. A. D. Cole, of the Ohio State University, after reviewing the evidence for the existence of the electronic atom with a central nucleus, expressed the opinion that some such form of atom would soon receive general recognition. He does not, however, think that the details of any of the atomic models at present under discussion can be considered as more than tentative and provisional. The address is reproduced in *Science* for January 15, and gives a clear and readable account of the advances made during the past three years.

THE *résumé* of communications made to the French Physical Society at the meeting on January 15 includes a short account of the automatic apparatus devised by M. E. L. Dupuy for the study of the anomalies in the expansion of alloys with rise of temperature. The nature of these anomalies makes it desirable that a continuous record of the expansion should be obtained, and M. Dupuy has succeeded by means of his apparatus in obtaining records for a number of chrome-nickel steels which go far towards clearing the way for a complete explanation of their behaviour. The new apparatus requires a rod about 7 cm. long of the material to be tested, and a similar rod of silica. The two support a mirror which rotates about a horizontal axis as the lengths of the two rods become different during the expansion. A beam of light after reflection at this mirror falls on a second, which is rotated about a vertical axis as the current from a thermo-junction in contact with the specimen varies. The beam of light is received finally on a photographic plate, and a curve results the abscissæ of which are temperatures and ordinates expansions.

IN a paper entitled "Alchemy and the Devil," by Dr. J. B. Craven, Archdeacon of Orkney, read before the Alchemical Society on February 12, attention was directed to the close association which existed in the eyes both of the Church and the people between alchemy and magic, and the stern disapprobation with which such arts were viewed, as aiming at gaining the pleasures of wealth and the senses by demoniacal aid. The State joined in this denunciation, and in 1404 the practice of alchemy was made a felony in England. In 1689, however, this Act was repealed, doubtless owing to the saner and more scientific attitude towards nature and the investigation of her secrets then coming to the fore, and culminating in the foundation of the Royal Society. Whilst, in fact, alchemy and magical practices had little in common, many seekers after the Philosopher's Stone were inspired by evil motives—by greed and avarice. But others were true natural philosophers, and there was, Archdeacon Craven suggested, a still higher alchemy, which aimed, not at making material gold, but at the transmutation of the soul's dross into spiritual gold.

ATTENTION may be directed to a paper in which Mr. W. N. Haworth describes a "New Method of Alkylating Sugars" (Trans. Chem. Soc., 1915, vol. cvii., p. 8). This operation has been carried out previously by means of alkyl iodides and silver oxide, two expensive agents which have the advantage of avoiding complications, such as racemisation, the Walden inversion, and the interconversion of glucosides. It is now shown that similar results can be achieved in aqueous solutions and at about one-fifth of the cost by using alkyl sulphates and caustic soda as alkylating agents. In every case where comparison was possible, the optical rotatory power of the product was equal to that obtained by the earlier methods, and it is clear that the easier and cheaper preparation will greatly facilitate synthetic experiments in the sugar series.

THE January issue of the Chemical Society's Journal contains a redetermination of the atomic weight of tin by Mr. H. V. A. Briscoe, working in Prof. Baker's laboratory at South Kensington. It is remarkable that nearly all the previous determinations gave values approximating to 118, with the exception of five series of measurements by Bongartz and Classen, which gave the value 119·0, which has been generally used ever since. Nearly all the early measurements depended on the oxidation of tin to the dioxide or the converse reduction, but it is doubtful whether this oxide is a suitable substance for experiments on atomic weight. On the other hand, all the five methods of Bongartz and Classen depended on weighing tin in the form of an electrolytic deposit on platinum, and would be vitiated by the inclusion of mother-liquor in the deposit. The new measurements now described depend on finding the ratio, $SnCl_4 : Ag$. Fifteen analyses gave numbers ranging from 118·678 to 118·714, and eleven of these fell between 118·690 and 118·711. The atomic weight finally deduced is 118·70, and seems to be worthy of considerable confidence.

THE well-deserved popularity of the two-cycle hot-bulb, or semi-Diesel engine, is directing the attention of designers toward the perfecting of this simple type of prime-mover. Earlier examples of this type were rather uneconomical compared with the four-cycle engine, but this objection has been gradually reduced. In ease of starting, trustworthiness, etc., the hot-bulb semi-Diesel engine has undoubted advantages over some other forms. *Engineering* for February 12 has illustrated descriptions of an engine of this type made by Martin's Cultivator Company, Ltd., of Stamford. The engine illustrated gives 9 brake-horse-power at 475 revolutions per minute, and has a single cylinder 7 in. diameter by 8 in. stroke. Scavenging air is compressed in the crank-case. The engine is started by a blow-lamp, and will start in about three minutes from cold on crude oil, and in five minutes on paraffin. Regulating and governing are effected by varying the stroke of the fuel-pump. There are many points in the design of this engine which should make for trustworthiness in working and freedom from breakdown.

THE *Engineer* for February 12 contains an illustrated description of the construction of the new Mappin terraces at the Zoological Gardens in Regent's Park. The area covered by the terraces and hills takes the shape of a quadrant, and measures about

10,000 square yards. The hills are about 70 ft. high, and have an area of about 39,000 square feet; these are made in reinforced concrete about 3 in. thick. The lower terraces where the heavier animals are quartered have thicknesses varying from 5 to 7 in. No two square yards of surface are alike. The entire area was divided into squares of approximately 7 ft. side by radial and concentric lines. Contours along each of these lines were drawn, and these, together with a plaster model, enabled the scaffolding and centering to be erected. Timber being out of the question for the centering on account of the irregularity of the surface, a simple and effective substitute was found in wire netting having a fairly small mesh. By mixing the concrete fairly dry, very little escaped through the meshes. The whole is supported on reinforced concrete columns; very wide and shallow beams span the columns in both directions, and are embodied in the thickness of the slabs which form the surface of the terraces and hills. The work was completed in thirteen months.

MESSRS. JOHN BARTHOLOMEW AND CO., of the Geographical Institute, Edinburgh, have published a new and revised edition of their "Route Chart of the World," which is sold at 1*s*. on paper, and 1*s*. 6*d* on cloth.

THE Proceedings of the third International Congress of Tropical Agriculture, held at the Imperial Institute at the end of June last, have been published by Messrs. John Bale, Sons and Danielsson, Ltd., in one volume, at the price of 10*s*. net. An article describing the meetings of the congress was published in the issue of NATURE for July 9, 1914 (vol. xciii., p. 489). The volume has been edited by the honorary secretaries of the congress. It runs to 407 pages, and includes abstracts of the papers supplied by the authors, reports of the discussions, and the address of the president, Prof. W. R. Dunstan. More than 150 papers, coming from authorities in fifty different countries, were presented to the congress, and the principal problems connected with tropical agriculture were dealt with.

AMONG the forthcoming books of the *Oxford University Press* are the following:—In *Anthropology*:—Aboriginal Siberia: a Study in Social Anthropology, M. A. Czaplicka, illustrated; Contributions to the Ethnology of the Salish Tribes, J. A. Teit; Lower Umpqua Texts, L. J. Frachtenberg. In *Biology*:—Heredity and Environment, E. G. Conklin. In *Geography*:— Historical Geography of South Africa, Sir C. Lucas, part ii., from 1895 to the Present Day; Geography of Eastern Asia, D. Paton; The Voyages of the Norsemen to America, W. Hovgaard (Scandinavian Monographs, vol. i.). In *Medical Science*:—The Evolution of Modern Medicine, Sir W. Osler. In *Miscellaneous* publications:—Scientific Management, C. B. Thompson; Architectural Acoustics, W. C. Sabine.—The *Cambridge University Press* announces for early publication the following volumes in the "University of Chicago Science Series":—The Origin of the Earth, Prof. T. C. Chamberlin; The Isolation and Measurement of the Electron, Prof. R. A. Millikan; Finite Collineation Groups, Prof. H. F. Blichfeldt.—*Henry Holt and Co.* (*New York*) announce:—The Functions of the Nervous System and the Special Senses, R. P. Angier; General Zoology, Prof. E. G. Conklin; Economic Zoology and Entomology, Prof. V. L. Kellogg and R. W. Doane; Industrial and Commercial Geography for High Schools, Prof. J. R. Smith: College Text-book of Botany, Prof. D. S. Johnson.

OUR ASTRONOMICAL COLUMN.

A NEW COMET, 1915*a* (MELLISH).—A telegram from Prof. Strömgren, Copenhagen, received at the Royal Astronomical Society on February 12, announces the discovery of a small bright comet by Mr. J. E. Mellish, of Madison, Wisconsin, U.S.A., in the position R.A. 17h., declination 3° N., and moving slowly east. A further telegram received on February 16 announces that on February 14 the position was R.A. 17h. 7m., declination 2° 54′ N. The comet is thus in Ophiuchus, and rises about 2 a.m., so that it should be visible in a small telescope between that hour and daybreak.

THE ZODIACAL LIGHT.—Those who are in a position to make observations of the zodiacal light will find some very useful information in the notes on this subject published in the U.S. *Monthly Weather Review* (September, 1914), by Mr. Maxwell Hall. The author describes the chief points which should receive the observer's careful attention, and suggests the best seasons for studying the eastern and western branches. Naturally, low latitudes are best suited for the observation; the fact that no instruments are required, but simply a level terrace and wide expanse of sky should multiply the number of those who observe this interesting and beautiful phenomenon.

ASTRONOMY AND MATHEMATICS.—In an address as vice-president and chairman of Section A (Astronomy and Mathematics) of the American Association for the Advancement of Science, Dr. Frank Schlesinger took as his subject the object of astronomical and mathematical research (*Science*, January 22). The address takes the form of pointing out to the astronomer and mathematician the great need of mutual help, and the tendency of meetings of mathematical and astronomical societies to increase the separation between these two sciences. Dr. Schlesinger directs attention to numerous astronomical problems in the solution of which the help of the mathematician is needed, and takes as an example that which concerns spectroscopic binaries, which offers a rich field.

THE MADRID OBSERVATORY'S ANNUAL FOR 1915.—The Annual for 1915 issued by the Madrid Observatory under the editorship of Prof. Iniguez, is a volume of 703 pages. The first two hundred pages are devoted to tabular statements regarding the ephemerides of the sun and moon, followed by those of planets, satellites, and comets, and facts dealing with eclipses and occultations, together with some numerous useful tables. These are followed by several articles by different authors, among which may be mentioned a long article on time determination, and a preliminary account of the solar eclipse expedition of August last. A *résumé* of the observations of the sun made at the Madrid Observatory during 1913, including spots, faculæ, prominences, etc., is given, concluding with the meteorological observations made during the same year.

WHAT IS GRAVITATION?—"It is scarcely too much to say that the nature of gravitation remains as much

a mystery to-day as when the law was first formulated by Sir Isaac Newton." Thus writes Prof. Eddington in one of those excellent articles on "Some Problems of Astronomy," which appear monthly in the *Observatory* (February, p. 93). The article continues as follows:—"In the meantime, theories of matter, of æther, and of electricity have arisen, have held their vogue, and have been superseded by others; but gravitation stands apart from these changing views. No experiment has as yet shown any relation between it and the other phenomena of nature; the simple law, unconditional and universal, has been all-sufficient hitherto. We have grown accustomed to regarding gravitation as something outside the scope of ordinary physical theories. If a new model of the atom is put forward, we ask if it accounts for the Zeeman effect, for chemical affinity, for the dispersion of light, and a host of incidental phenomena; but it would be considered unfair to suggest that it ought to account for the one fundamental and universal property of matter—gravitation." Prof. Eddington then discusses suggestions that have been made concerning possible mechanisms for gravitation, and finally asks the question, "Does gravitation conform to the principle of relativity?" A decisive result of one of the tests, whether it be positive or negative, would, he states, be of remarkable importance, and "a positive result would mean that gravitation has been pulled down from its pedestal, and ceases to stand aloof from the other interrelated forces of nature."

EUGENICS AND WAR.

THE second Galton Lecture, in memory of Sir Francis Galton, born February 16, 1822, was delivered on Tuesday evening to the Eugenics Education Society by Prof. J. Arthur Thomson, of Aberdeen University, who spoke on eugenics and war. Certainties as to the effect of war on the natural inheritance of the race have not yet been established, but some probable risks are discernible. In ancient times, when fighting was the order of the day, a weaker clan may have been literally extirpated by a stronger, as black rat by brown rat; but nation does not exterminate nation nowadays. In ancient times a battle may have been an effective sifting out of the weaker, less nimble, more cowardly combatants; but it is not so now. For the elimination is either fortuitous or in the wrong direction. The finest bodies of men are chosen for the most hazardous tasks, often involving terrible mortality, and the conspicuously brave are particularly apt to be cut off. In modern warfare the sifting tends to be dysgenic.

In the second place, there is in the making and maintenance of the army, in a nation with voluntary military service, a selection of the more chivalrous, the more virile, the more courageous, the more patriotic, and among these there is a mortality high above that of non-combatants, which means some degree of impoverishment of the race. If the number of combatants was small in comparison with that of the non-combatants, the degree of impoverishment might be slight, but if we have in our British population about 6,250,000 men between eighteen and forty-five, and if we have, as we may well have, a fighting force of three millions, the disproportionate mortality among the combatants is likely to be serious. The eugenic safeguard is in the sound nucleus of "fit" and brave men who remain to keep things going, and in the women (though they again are differentially affected in Belgium and Serbia), but it looks as if this war meant for Britain a disproportionate elimination of those whom we can least afford to lose. Darwin's sentence, in reference to the past, is probably true of the present: "The bravest men, who were always willing to come to the front in war, and who freely risked their lives for others, would on an average perish in larger numbers than other men."

In the third place, there can be little doubt that the economies and retrenchments after a great war tend to handicap most severely the more highly individuated members of the community. The highly skilled, whose work is not absolutely necessary, will be pinched most; and they are the salt of the race. On the whole, the tendency of modern warfare is dysgenic.

The second subject of discussion was the Darwinian concept of the struggle for existence, in regard to which there is widespread misunderstanding. As Darwin said, the term is used "in a large and metaphorical sense," to include all forms of the clash that occurs when organisms assert themselves in any fashion against environing limitations and difficulties. The reactions may be competitive or non-competitive, self-regarding or other-regarding, with teeth and claws, or with wits and kindness. It is not doubted that one way in which animals answer back to their difficulties and limitations is to intensify internecine competition; it is maintained, however, that another way, common among the finer forms of life, is to increase parental care or to experiment in co-operation. An extraordinarily large proportion of the time and energy of living creatures is devoted to activities which are not to the advantage of the individual, and it is an inadequately appreciated part of nature's strategy that the types that survive are not only those that sharpen weapons and thicken armour, but also those in which the individual has been more or less subordinated to the welfare of the race. The improbability of war being the saving grace of human history grows upon us.

The third point in the lecture was that since war, *biologically regarded,* is, in spite of all its nobility, heroism, and skill, a reversion to the most primitive and crude form of the struggle for existence, it involves a serious risk of slipping down the rungs of the ladder of evolution. What sowings of dragons' teeth there must be in the terrible struggle of this war; is it weak to be afraid lest by and by the crop that springs from them may include something worse than armed men?

The discussion then turned to the eugenic position in regard to some practical questions. It is possible that the losses of the war, taken along with the falling birth-rate, may move public sentiment to a stronger disapproval of selfish forms of celibacy and to a stronger encouragement of chivalrous marriages. There is patriotism in dying for our country, perhaps also in marrying for her. In regard to the marriage of recruits, more than eugenic considerations have to be borne in mind, but where adequate provision is secured for the possible widows and children, there seems no reason to place obstacles in the way of the marriage of recruits of suitable age and good record. It is for eugenists to scan critically all proposals hurriedly projected to meet crises of war strain, such as putting children at the disposal of the farmer—a doubly dangerous suggestion. To be resisted also is the natural desire to economise in the higher super-necessaries, such as various forms of art, for this means crippling super-men. One of the results of the war is likely to be a freshened enthusiasm for all-round physical fitness, and it must be granted that all improvements of nurture are eugenic as long as it is clearly recognised that veneering does not make bad wood sound. The British temperament has an inherent dislike of coercion, and schemes of compul-

sory military training are to be looked on with grave suspicion. There is the risk of insidious Prussianising. For the undeniable privilege of being part of civilised Europe and for the undeniable distinction of having been willing—on this occasion—to do the right thing at all costs, we shall have to pay a long price, and it is to be feared that part of this price will be the shelving of eugenic endeavours and our connivance thereat. It may be, however, that facts will give the lie to our fears, and that the impoverishment of the possible parent-stock of the future will be in some measure counteracted by an enrichment of our social heritage—perhaps even by a nearer approach than we have ever known to *positive* peace.

STANDARDISING APPARATUS AND METHODS.

SEVERAL circulars recently received from the Bureau of Standards of the Department of Commerce, Washington, well illustrate the untiring industry to be found in the American public offices. Circular No. 9 deals with the standardising of glass volumetric apparatus such as flasks, burettes, pipettes, pyknometers, and measuring cylinders. The bureau aims at encouraging excellence of quality in such apparatus by co-operating with the makers on one hand, and on the other with the users. To this end the circular describes specifications for the various classes of instruments, and the bureau admits for standardising that apparatus only which conforms to the specifications. It is pointed out in the circular that certain of the demands, such as those regarding the quality of the glass and the process of annealing before calibration, are largely dependent for their fulfilment on the integrity and good faith of the manufacturer. Users can therefore help to secure a high degree of excellence by supporting conscientious makers and giving consideration in the first place to quality, and only secondly to the matter of cost. The circular supplies information on such points as the best design of apparatus, the material, the methods of marking the graduations, the units of capacity employed, and the limits of error allowable. There are also directions for the manipulation of the apparatus during testing; and for those who wish to calibrate their own burettes and pipettes a brief description of the method to be employed is given.

Circulars Nos. 36, 48, and 222 deal respectively with industrial gas calorimetry, standard methods of gas testing, and flame standards in photometry. These are technical subjects, and it would be impossible in any moderate space to discuss or criticise the very numerous points raised in these circulars. It may suffice to refer to the last-named, and to state that the variation of the light of flame standards of light as determined by atmospheric conditions and as observed by different observers, or computed by different empirical formulæ, are discussed at length. It is often questioned whether the illuminating power of gas, for example, is more fairly determined by comparison with a flame standard which itself is affected by atmospheric conditions (moisture, CO_2, pressure), or whether a standard which is independent of these conditions, such as an electric filament lamp run under strictly defined conditions, would not be more correct. As the luminosity of the gas flame itself also is affected by atmospheric conditions, though not identically to the same extent as the flame standards of light, the practice in England is to determine the quality of the gas by reference to a flame standard, and to ignore atmospheric conditions. With an invariable standard of light gas of the same quality would appear to differ more according to the weather conditions than it does with a flame standard, and for this reason if very elaborate corrections are to be avoided the use of the variable standard is considered in this country more appropriate than that of an invariable standard.

Three technologic papers issued by the Bureau are devoted to analytical researches, and deal with the determination of ammonia in illuminating gas, the iodine number of linseed and petroleum oils, and the analysis of printing inks. The first of these, by J. D. Edwards, is of more interest in the United States, where the amount of ammonia in illuminating gas is still subject to control than in the country where no ammonia limits are now in force. It deals with the choice of indicators, effect of carbon dioxide on the titration, errors due to solubility of heads, and to incomplete washing, and the choice of absorption apparatus. Paper No. 37, by W. H. Smith and J. B. Tuttle, deals with the iodine number of linseed and petroleum oils. The main point established is that for the iodine solution used (iodine bromide in glacial acetic acid), and probably for other solutions in common use, the conditions of the experiment must be more rigorously fixed than is now usual. Thus 0·1 gram of oil with 25 c.c. of iodine solution gives a lower iodine absorption figure than when the weight of oil and volume of solution are doubled. For mineral oils the absorption increases with excess of iodine, and there is in this case no tendency to reach a constant value. Paper No. 39, on the analysis of printing inks, by the same authors, gives details of the procedure of analysis adopted at the Bureau of Standards for the separation of oil and pigment, the analysis of each separately, and concludes with remarks on the relation of aniline dyes to paper, and on the accuracy obtainable in the analysis.

GASEOUS EXPLOSIONS.[1]

THE investigation of gaseous explosions is of interest to chemists, physicists, and engineers. The chemist studies the laws of combination and dissociation; the physicist deals with modes and rates of inflammation, variation of specific heat, maximum temperatures attained, and laws of radiation and cooling; while the engineer considers both chemical and physical effects as bearing on the practical operation and thermo-dynamics of the internal combustion engine. He also interests himself in the analogous phenomena of inflammable dust explosions as found in coal-mine and flour-mill accidents. The matters of interest are obviously numerous and complicated, and it is accordingly necessary to limit their consideration to a few points. The points selected will be dealt with as they bear more particularly on the engineering problems of the internal combustion engine. In 1907 the British Association, at its Leicester meeting, appointed a committee of investigation. This committee has been at work ever since, and much light has been thrown by the experiments of its members upon the facts connected with gaseous explosions as occurring in closed vessels and within engine cylinders having moving pistons. It is now proposed to describe some of the work of the committee, dealing first with the phenomena of rising temperature, and secondly with that of cooling after explosion.

When a mixture of coal gas and air is ignited within a strong closed vessel, it is found that the pressure rises rapidly, attains a maximum, and falls relatively slowly. To this rapid pressure rise is due the term gaseous explosion. Such explosions are

[1] Abstract of discourse delivered at the Royal Institution on Friday, January 29, by Dr. Dugald Clerk, F.R.S.

obtained with mixtures of all inflammable gases or vapours with air or oxygen, and very similar phenomena occur with like mixtures of inflammable dust. The rise and fall of pressure is studied by means of sensitive indicator devices, which produce tracings on a rotating drum.

The pressure rise is caused by the formation of flame at the ignition point—in this case an electric spark—and the spread of this flame throughout the vessel increases the temperature of the gaseous contents, and thus increases the pressure, as in a closed vessel the volume remains constant. The rate of pressure rise is thus, broadly, the measure of the rate of the travel of the flame through the mass; and, if it be assumed that maximum pressure is attained when the whole vessel is filled with flame, then it is possible to determine the flame velocity by these measurements.

In these experiments the flame velocity for the weak mixture is about 2 ft. per sec., and for the strong mixture 13 ft. per sec. These velocities are attained in closed-vessel experiments without a moving piston. In actual engine cylinders, where the charge has been introduced at a high speed through an inlet valve, the flame velocity is much higher, and it varies with different types of engine from about 20 to 100 ft. per sec. The cause of this variation for similar mixtures has been the subject of investigation by Clerk and Hopkinson, and it has been definitely proved that the higher flame velocity found in working engine cylinders is due to the residual turbulence of the mixture after compression caused by the high rate of flow into the cylinder through the inlet valve. In some engines the gases forming the charge flow through the inlet valve at a rate as high as 160 ft. per sec. Without this increase of flame velocity in the engine cylinder it would have been impossible to run high-speed engines, such as petrol engines, in an economical manner. At the lower flame velocity of the closed vessel the exhaust valve will be open before the pressure had time to rise. The effect of turbulence within the cylinder is very marked in other respects. The rate of loss of heat from a heated platinum wire to the mass of air in the combustion space of an engine is much greater for any given point of the stroke when the engine is running fast than when it is running slow, and if the charge be trapped, so as to allow several compressions and expansions before measuring the heat loss, the turbulence has so died down that the conductivity diminishes.

Another point of interest in gaseous explosions is found in the fact, predicted by Clerk many years ago, but proved by Hopkinson, that the flame entirely fills the vessel before maximum pressure is attained, that is, the combustion, even in an explosive mixture of gas and air, is relatively slow as the chemical combination approaches completion.

Another point proved by Hopkinson's experiments in a large closed vessel is that at whatever point in the vessel the ignition be started, that point is the point of maximum temperature during the subsequent pressure rise, and at that point the temperature rises about 500° above the temperature of combustion, due to adiabatic compression of the hot gas.

The investigations of Profs. Callendar, Dalby, and Coker by means of platinum resistance thermometers and platinum alloy thermal couples has proved the temperatures attained in ordinary engines to vary from about 1800° C. to 2500° C. The new methods of direct thermometric measurement of the temperature flame have amply proved, however, the general correctness of the older method of deducing mean temperature by pressure change.

The investigations of Callendar, Hopkinson, and David (Prof. Hopkinson's pupil) on radiation are of great importance, and prove that this source of heat loss is only second in magnitude to heat loss by convection and conduction. All the radiation experiments clearly show the existence of an unexpected transparency of flame to its own radiations. The radiation work throws much light upon heat distribution in the rapidly succeeding explosions used in internal-combustion engines.

It was long ago observed by Hirn, Bunsen, and others that the rise of temperature in gaseous explosions could not be calculated from the then assumed specific heat of the constituent gases and the known calorific value of the inflammable gas. The deficit of temperature was found to be about 50 per cent., and many attempts were made to explain this deficit, Hirn advocating the theory of heat loss on the rising line and Bunsen supporting the idea of a limit to temperature due to dissociation. Later, the French observers, Mallard and Le Chatelier, maintained that at least part of the deficit could be accounted for on the assumption of increase of specific heat of the gases. Investigations of the members of the Committee have dealt, not only with the points which have been here discussed, but with all these questions—heat loss on the rising line, specific heat of the constituent gases, heat loss on the falling line, and dissociation of the combining gases.

Specific heat work has been in progress by Clerk, by Callendar and his pupil, Swann, and much of this work has not yet been published. Dissociation has been discussed by Dr. J. A. Harker, Prof. Smithells, and Dr. Bone, and both internal energy and dissociation have been discussed by Hopkinson. Ignition temperatures of gases have been dealt with by Prof. Harold Dixon, and Dr. Watson has studied the nature of the exhaust gases from the petrol engine. Many experiments, too, have been made on the law of cooling and heating of gases under compression in cylinders by Hopkinson, Dalby, Callendar, and Clerk.

As a result of this work, the conclusion has been arrived at that, so far as explosions in internal-combustion engines are concerned, dissociation has but little to do with the limit reached. This limit is partly due to increased specific heat at high temperatures, to heat loss to the walls, and to radiation from the explosion. Varying specific heat and increasing radiation account for most of the deficit. Allowing for all these things, however, it appears now to be established that combustion is not quite complete even at maximum temperature, and Watson's experiments on the spectrum of an explosion flame appear to support this view.

All these matters are still under examination, and it is hoped that in the near future a much more complete knowledge may be gained than at present exists. Much is known in a qualitative way, and some quantitative knowledge has been attained, but much still remains to be done in the way of quantitative determinations of matters at first apparently so simple as specific heat.

CLIMATE AND TREES.

IN an article on "Woods and Trees of Ireland," in the *Co. Louth Archaeological Journal* for 1914, Prof. Augustine Henry states that in Ireland, as in Scandinavia, the climate prevailing in neolithic times was drier and warmer than that of to-day. Many facts are adduced in support of this improvement, which in Scandinavia amounted to an increase of 4° F. in the average annual temperature. The occurrence of this optimum climatic period is confirmed by the

fact that two species of elm in England are unable now to produce fertile seed.

The English elm produces good seeds freely in the warm valley of the Tagus at Aranjuez in Spain, but not in Madrid on the cold plateau 500 feet higher. In England it invariably reproduces itself by root-suckers. The Cornish elm produces ripe fruit in Brittany. Certain forms of Alchemilla are unable now to produce good pollen, yet form seed parthenogenetically. In the Faroe Isles thirty-six species of plants scarcely ever ripen their seeds; and five species never flower. The question of what plants in Ireland are now in too northerly or too cold a climate requires study in the field.

Much has been written on the Lusitanian flora of Ireland, involving the question how the Arbutus is confined as a native tree to Kerry and Cork, not being indigenous elsewhere in the British Isles. Its nearest station on the continent is near Paimpol in Brittany, where, on the abrupt and rocky slope of the cliff of Trieux, for about one and a half miles, this species is very abundant in a wood mainly composed of oak and mountain ash. It is interesting to note that the Cornish elm (*Ulmus stricta*), indigenous only in our islands in Cornwall and Devon, is similarly met with in Brittany. The English elm (*Ulmus campestris*) is probably also a Lusitanian species, occurring elsewhere than in southern England only in Spain as a wild tree. It appears to have entered England by the Severn valley, crossing over the Cotswolds into the Thames valley, and southwards as far as the Isle of Wight.

Prof. Henry, in addition to giving much historical matter concerning the ancient forests of Ireland, shows how the primitive woods and their remains can be easily recognised by the occurrence in them of a peculiar fauna and flora, which is absent in plantations and in arable and pasture lands. A list is given of these sylvicole animals and plants.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GLASGOW.—The following additional examiners have been appointed:—Surgery, Sir Charles B. Ball, Bart.; medicine, Sir Thomas Oliver; physiology, Prof. E. P. Cathcart; geology, Dr. John Horne; zoology, Mr. H. H. Brindley; engineering, Prof. J. B. Henderson; mining, Prof. W. H. McMillan.

Forty-three members of the teaching staff, professors, lecturers, and assistants, are engaged in military service at the present time, and nearly five hundred commissions in the Army and Navy have been granted to students and junior graduates of the University. One, who afterwards died of wounds, received the Victoria Cross.

LONDON.—The Senate has conferred the titles of Professor and Reader in the University upon the following:—*Professors*:—Dr. A. L. Bowley (London School of Economics), statistics; Mr. L. R. Dicksee (London School of Economics), accounting and business organisation; Mr. J. E. S. Frazer (St. Mary's Hospital Medical School), anatomy; Dr. T. M. Lowry (Guy's Hospital Medical School), chemistry; Mr. J. H. Morgan (University College and the London School of Economics), constitutional law; Dr. W. J. R. Simpson (King's College), hygiene and public health; Mr. J. H. Thomas (University College), sculpture; and Mr. G. Wallas (London School of Economics), political science. *Readers*:—Dr. R. W. Chambers (University College), English language and literature; Mr. H. Crompton (Bedford College), chemistry; Dr. J. S. Edkins (Bedford College), physiology; Mr. W. J. Goudie (University College), theory and practice of heat engines; Mr. Major Greenwood (Lister Institute), medical statistics; Dr. R. G. Hebb (Westminster Hospital Medical School), morbid anatomy; Dr. R. T. Leiper (London School of Tropical Medicine), helminthology; Dr. H. R. Le Sueur (St. Thomas's Hospital Medical School), chemistry; Dr. F. S. Locke (King's College), physiology; Miss Sara Melhuish (Bedford College), education; Dr. F. G. Pope (East London College), chemistry; Dr. H. E. Roaf (St. Mary's Hospital Medical School), physiology; Dr. O. Rosenheim (King's College), biochemistry; Mr. J. Henderson Smith (Lister Institute), bacteriology; Dr. J. F. Spencer (Bedford College), physical chemistry; Dr. H. M. Turnbull (London Hospital Medical College), morbid anatomy.

MANCHESTER.—The movement started last year for the establishment of a Radium Institution in Manchester met with a generous response from the public. Thanks to the assistance of public men and the Press, the committee that was appointed to carry out the scheme was able to collect a sum of about 30,000*l.* The radium department was established at the Royal Infirmary, and began work on January 1 in a number of rooms that had been equipped at a cost of 1000*l.*, and started with about 800 milligrams of radium metal. The contract for the radium, which cost about 21,000*l.*, was fortunately given to an American firm, and its delivery was not therefore interfered with by the outbreak of the war. In order to ensure the maximum efficiency, the Radium Committee, acting on the advice of Sir E. Rutherford, Sir Wm. Milligan, and other experts, took control of the equipment of the laboratories; and the standardisation of the radium was done in the physical laboratories of the University of Manchester. The committee has also drawn up a scheme for the distribution of radium either in the solid form as applicators, or as emanation tubes from the liquid form, to the other hospitals in Manchester and the district. Dr. Arthur Burrows is the radiologist at the infirmary responsible for the administration, Mr. H. Lupton is the physicist in charge, and Sir E. Rutherford acts as consulting physicist to the department.

OXFORD.—The Committee for Rural Economy reports that during the past academic year forty-eight individual students worked in the department. The soil survey of the district round Oxford has been continued, and a new research on the nitrogen in peat has been started. The new buildings, erected at a cost of nearly 6000*l.*, were completed and ready for occupation in October last. Several papers have issued from the school during the year, including six by Prof. Somerville (Sibthorpian professor), a joint paper by Prof. Somerville and Mr. Harper, and others by Messrs. Harper, Morison, Doyne, Sothers, and Jones. Prof. Somerville continues to edit the *Quarterly Journal of Forestry*.

The annual report of the Delegates for Forestry shows that the number of the students in the department at the beginning of the year 1914 was thirty-eight. This number by the end of the year, in consequence of the war, had declined to fourteen. A visit was paid, under the personal direction of the professor of forestry, Sir W. Schlich, to the Forêt de Lyons, in northern France, and weekly excursions were undertaken to Bagley Wood, where, by permission of St. John's College, a forest nursery and experimental plantations have been established. Here periodical measurements are taken of many species of forest trees. Advice was sought and given in respect of twelve estates aggregating 9322 acres, and other

work of an advisory nature was carried out. Valuable research has been performed by Mr. E. A. Speyer, who has now accepted a forestry appointment in Ceylon, and by Mr. W. E. Hiley. The finances of the Forestry School are assisted by an annual grant of 250*l.* from the Board of Agriculture and Fisheries.

THE authorities of the Royal Technical College, Glasgow, may well be proud of the part which members, students, and past-students of the college are taking in the King's service in connection with the war. A list, confessedly incomplete, which has been issued, gives the names of 1023 officers, non-commissioned officers, and men, together with their rank, regiment, or ship, and the last year in college, all of whom have been thus connected with the college, and the names of forty-seven other men serving about whom particulars are as yet unknown.

A COPY of the calendar for the session 1914–15 of the University College of North Wales has been received. The new calendar follows on the same lines as those of previous issues. We notice that during 1913–14 the extension work in agriculture carried out by the college was placed, as regards organisation, on a new footing. In three of the North Wales counties served by the college, advantage was taken of the offer of Government help through the Farm Institute Fund to increase very greatly the sum annually devoted to agricultural instruction and to place the work in the hands of county organisers, appointed by the college, but working under the directions of the county agricultural committees. Special lecturers in horticulture, poultry-keeping, and dairy work are also provided by the college for county work.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 11.—Sir William Crookes, president, in the chair.—Dr. D. H. **Scott**: *Lepidostrobus kentuckiensis*, nomen nov., formerly *Lepidostrobus Fischeri*, Scott and Jeffrey.—A correction. The name *Lepidostrobus Fischeri* having been anticipated by Renault in 1890, it is necessary to give a new name to the Kentucky cone described by Scott and Jeffrey (*Phil. Trans.*, Ser. B., vol. ccv., 1914, p. 354). The fossil is now named *Lepidostrobus kentuckiensis*.—T. **Lewis** and M. A. **Rothschild**: The excitatory process in the dog's heart. Part ii.—The ventricles. (1) The excitation wave appears at the pericardial surface of the dog's heart at times which show no great variation relative to each other; but the distribution of the time values over the surface with such variations as they show is very fairly constant from heart to heart. (2) The time at which the excitation wave appears at the surface is controlled by the length of the Purkinje tract to the endocardium beneath the region tested, and by the thickness of the ventricular muscle in the same region. (3) The excitation wave is not propagated by simple spread from base to apex or apex to base through bands of muscle fibres, as has commonly been held hitherto. (4) The capacity of striated cardiac tissue to conduct appears to be related to the size of the cells composing it and to its load of contained glycogen. (5) The auriculo-ventricular bundle and its branches constitute a system of fibres specially endowed in regard to their arrangement and physiological properties to give quick distribution of the excitation wave throughout all parts of the ventricle.—A. J. **Walton**: The variation in the growth of mammalian tissue *in vitro* according to the age of the animal. Previous work has shown that plasma of animals varies considerably in its value as a medium for the cultivation of tissue. The present experiments were carried out with a view of determining whether these differences were due to the age of the animal from which the plasma was obtained. The tissues and plasma of rabbits were alone used, and the majority of animals were of a known age. Tissues of young and old animals were used and were grown in pure plasma from the same animals. In all cases it was found that the young tissues grew better than the old, but the plasma of the young animal was not nearly so satisfactory a medium as that of the old animals. Hence the best results were obtained when young tissues were grown in the plasma of old animals and the worst results when old tissues were grown in young plasma.

Geological Society, February 3.—Dr. A. Smith Woodward, president, in the chair.—Prof. T. McKenny **Hughes**: The gravels of East Anglia. The author discusses the sources from which the subangular gravels that cover such large areas in East Anglia can have been derived. He points out that their great variety of fracture, colour, etc., proves that they cannot have come directly from the Chalk, or from Boulder Clay derived directly from the Chalk, or from the Lower London Tertiaries, none of which contain subangular gravels but only beds of pebbles, and those mostly of small size. The character of the flints in the gravels indicates that they have been derived from surface-soils which have been winnowed and shifted by soil-creep, rain, and streams, until arrested on the terraces and flats of the valleys. The dry land of Miocene age was the first over which the flints of our gravel-beds could have received that subaerial treatment which they all seem to have undergone.—E. **Anderson** and E. G. **Radley**: The pitchstones of Mull and their genesis. The pitchstones here discussed occur with extraordinary frequency, intruded into the Tertiary plateau-lavas of the eastern portion of the Ross of Mull, as well as in less number in other parts of the island. They fall into two main divisions, distinguished by the absence or by the presence of porphyritic felspars. The petrological characters of these pitchstones, and their more crystalline margins, are such that they seem to warrant the grouping of the rocks under a new type-name, and the name leidleite has been chosen. The porphyritic pitchstones occur as flat or gently-inclined sheets; they also are associated with a more crystalline phase, and have been grouped under the type-name inninmorite.

Zoological Society, February 9.—Mr. R. H. Burne, vice-president, in the chair.—E. G. **Boulenger**: An Aglyphodont Colubrid snake (*Xenodon merremii*), with a vertically movable maxillary bone. The vertical mobility of the maxillary bone in snakes had previously been regarded as essentially characteristic of the Viperidæ. Observations on the snake in question, which was recently received by the society from Mr. W. A. Smithers, showed that the mobility of its maxillary bones was so great that the fangs could be not merely erected, but were capable of being thrust forward and sideways, the mechanism being as perfect as in any of the vipers. Mr. Boulenger pointed out that the discovery of a solid-toothed Colubrid with vertically movable maxillæ went a long way towards settling the so often discussed problem of the derivation of the viperine maxillary bone. The author traced the probable evolution of the bone, expressing the opinion that the Viperidæ were descended from the Opisthoglyph Colubrids, and that the old view, recently revived, that they were of Proteroglyph

ancestry, must be abandoned once and for all.—Dr. W. **Nicoll**: A new species of liver-fluke from the kestrel.

Mathematical Society, February 11.—Prof. A. E. H. Love, vice-president, in the chair.—G. H. **Hardy** and J. E. **Littlewood**: (i) The zeros of the Riemann zeta-function. (ii) An assertion of Tchebychef.—G. B. **Jeffery**: The steady motion of a solid of revolution in a viscous fluid.—S. T. **Shovelton**: Relations amongst Bernoulli's and Euler's numbers.—W. P. **Milne**: Apolar generation of the quartic curve.

CALCUTTA.

Asiatic Society of Bengal, January 6.—Maude L. **Cleghorn**: A note on the floral mechanism of *Typhonium trilobatum*. Describes the trap-mechanism of the spathe, by means of which beetles are ingeniously captured at night to ensure cross-pollination. The trap-mechanism of this plant resembles that of the Cuckoo-pint (*Arum maculatum*) in the entrance and exit of the trap being above and at the same opening, but differs from it in the deliberate opening and closing of the passage leading down into the trap. Its floral mechanism does not seem to be so perfect as that of the common Kachu (*Colocasia antiquorum*), but it appears to be an advance on that of the Cuckoo-pint.—F. H. **Gravely**: The evolution and distribution of Indian Spiders belonging to the sub-family Aricularinæ. The Ischnocoleæ found in the Indian Peninsula and Ceylon form a very compact group, probably related to those of other parts of the world through their most primitive species only. It is concluded that the Poecilotherieæ have originated from the Ischnocoleæ as a result of their adaptation to a new environment in the Indian Peninsula or Ceylon, to which they are still confined.

DUBLIN.

Royal Dublin Society, January 26.—Prof. H. H. Dixon in the chair.—Prof. W. **Brown**: The subsidence or damping of torsional oscillations in iron wires is much less than in nickel wires, and is greater in an alternating magnetic field than in a direct field, whilst the reverse is the case with soft nickel wires. With iron wires when the longitudinal load on the wire is sufficiently increased, the damping curves obtained in the direct and alternating magnetic field are identical. Results are also given for iron wires alloyed with silicon, chromium, and nickel, as well as for two non-magnetic wires.—Prof. H. H. **Dixon** and W. R. G. **Atkins**: Osmotic pressures in plants. V.—Seasonal variations in the concentration of the cell sap of some deciduous and evergreen trees. A series of cryoscopic and conductivity measurements made on the sap pressed from plant organs after treatment with liquid air showed that the greater part of the osmotic pressure is due to dissolved carbohydrates. The concentration of electrolytes in leaves increases with age. A similar increase was not found in the roots of *Ilex aquifolium*. The concentration of carbohydrates fluctuates greatly, and causes large variations in the osmotic pressure. In the leaves of *Syringa vulgaris* it was found that the osmotic pressure rose from the opening of the buds and reached its maximum in August. The leaves of both Ilex and Hedera showed higher osmotic pressures in winter than in summer. The osmotic pressure of the tissues of the roots of Ilex attained its maximum in September.

PARIS.

Academy of Sciences, February 8.—M. Ed. Perrier in the chair.—A. **Lacroix**: The existence of grained nepheline rocks in the volcanic archipelago of Kerguelen.—G. **Bigourdan**: Application of the angular comparator to the determination of astronomical refraction and its constant. Details of the proposed method for using the instrument described in a recent paper to measure atmospheric refraction.—Armand **Gautier**: The influence of fluorine on plant growth. In certain rare cases the presence of fluorides in the soil inhibits growth, but in general it has a stimulating effect on growth, flowering, and the formation of seeds.—Ed. **Delorme**: Wounds of the external genital organs.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the second quarter of 1914. Observations were made on seventy-one days, and the results are given in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—E. **Goursat**: A class of integral invariants.—Et. **Delassus**: The theory of unilateral finite linkages.—Léon **Bloch**: The theory of absorption of light in metals and in insulators.—F. **Bodroux**: The preparation of esters. Mixtures of alcohol, water, and formic acid give formates on slow distillation, but formic acid has very slight catalytic power in ester formation from other acids. The mixture of sulphuric and hydrobromic acids obtained by decolorising a mixture of bromine and water with sulphur dioxide is recommended as a catalyst, and details are given of its use in the preparation of propyl and *iso*butyl bromides.—L. **Grimbert** and O. **Bailly**: A method for distinguishing the glycerophosphoric mono-esters and on the constitution of crystallised sodium glycerophosphate.—A. **Sartory** and L. **Spillmann**: The bacteriology of gaseous gangrene. In agreement with the results of Weinberg, Doyen, and Yamanouchi, the authors find present in all cases *Bacillus perfringens* in the gangrene pus. Other organisms are present, but this bacillus appears to be the most important as regards pus formation.—P. **Mazé**: The determination of the rare mineral elements necessary to the development of maize. Boron, aluminium, fluorine, and iodine are necessary for the growth of maize.—Em. **Bourquelot**, M. **Bridel**, and A. **Aubry**: The biochemical synthesis of the β-monoglucoside of ordinary propylene glycol with the aid of emulsin.

ROMAN BIRDS AND AMERICAN POETS.

The Birds of the Latin Poets. By Prof. E. W. Martin. Pp. 260. (California: Stanford University, 1914.) Price 1.00 dollar.

THIS book is a monument of patient industry redolent rather of the midnight oil than of the woods and fields. It is mainly an anthology of quotations from Latin, American, and English poets. As a serious contribution to our knowledge of birds, whether European or American, it is not of great value, and naturalists will find it disappointing. But scholars will find it useful as a dictionary or concordance of Latin birds, and to American nature-poets it will prove a treasury of their own bird-lore. The preface should be read first, to prepare the reader for its defects, which to our mind are serious. "My single year in Europe," says the author, "occupied largely with the technique of our craft, left scant time for woods, meadows, and riverside. Besides, this is the task of years for a finished expert in the birds of Europe."

Not having the latter qualifications, Prof. Martin is driven to illustrating the birds of Virgil and Ovid by those of America—which is unsatisfactory, to say the least. The species are hopelessly confused, and we are seldom helped to identify them.

"Naturally, in bringing together American and Roman birds, I have attempted no close scientific paralleling of species; I have rather tried to group the birds which have roused similar reactions in the feelings of their poetic observers. Hence Roman nightingales have suggested American mocking-birds and even whip-poor-wills, while larks have been answered by bobolinks and starlings by meadowlarks."

In the lengthy bibliography at the end of the book several British ornithologists are mentioned, but we miss the names of Yarrell and Howard Saunders, and apparently Dresser's monumental "Birds of Europe" has not been used at all.

We must now make some more detailed criticisms. On p. 43 Wordsworth's line, "The tremulous sob of the complaining owl," is quoted under Bubo, the eagle-owl; whereas he is certainly referring to the brown or tawny owl. Nor are we told that he afterwards changed this line into "The sportive outcry of the mocking owl." On p. 68 Tennyson's "many-wintered crow" is the rook, as his next line shows. Why did not Prof. Martin quote it? "Presso gutture," so far from meaning "with clear deep note," means the falsetto love-note of the rook in spring (p. 75). Under Haliæetos (p. 109) no attempt is made to distinguish the sea-eagle from the osprey. The Nisus and Scylla myth is probably simply typical of any hawk that strikes down its prey in the air. Kingsley's magnificent hexameter would have been worth including: "As when an osprey aloft, dark-eye-browed, royally crested."

On p. 118 we are told that "the swallow is an enemy of bees, which they feed (*sic*) to their young." This is true, but some comment is needed. Was Tennyson right when he changed "bee" into "fly" in the well-known line, "The swallow stopt as he hunted the fly"? There is a beautiful swallow legend on p. 121, which we are glad to see. In the note on p. 240 the house-martin's name, *Hirundo urbica,* is applied to the swallow. In spite of his apology in the preface, we find it difficult to forgive Prof. Martin for illustrating our queen of song-birds with the whip-poor-will and mocking-bird. Moreover, it is the reed-warbler, and not the sedge-warbler, which is called the "mock-nightingale" in England (p. 242). But the note on Ruscinia contains much valuable matter, especially Prof. Pierantoni's remarks about the Italian nightingale and the poplar-tree, which is an interesting confirmation of Georgic iv., 511. After quoting four words from Coleridge on p. 131, Prof. Martin hurries on to something inferior and less relevant. Surely this beautiful passage was worth quoting in full:—

'Tis the merry nightingale
That crowds and hurries and precipitates
With thick fast warble his delicious notes,
As he were fearful that an April night
Would be too short for him to utter forth
His love-chant, and disburthen his full soul
Of all its music.

There are several quotations from Tennyson, but we miss his "mellow ouzel fluting in the elm"; and his exquisite line on the ring-dove or wood-pigeon is applied to the turtle-dove. Again, his line, "The fire-crowned king of the wrens," is applied to the common wren; and under the same heading (Regulus) we meet with Gilbert White's wood-wren, which is not a wren at all. Milvus is paralleled with not only kite, but also with hawk, falcon, buzzard, and even eagle. On p. 153 we are told that "the note of the bee-eater is like that of wren and swallow." On p. 197 the same quotation from the "Anthologia Latina" appears, with the remark, "The wren's song is like that of the bee-eater and swallow." What this means we must leave our readers to determine.

Strix is illustrated by "the bat and owl inhabit these." We are not sure that Lowell himself would have recognised this illuminating excerpt from his works. Ulula is said to be "the sceech-owl (*sic*) or possibly the barn-owl." We in Eng-

land do not know the difference. Here are three consecutive quotations illustrating "The Spring Migration and Spring Song":—

And new-come birds each morning sing.
(LOWELL.)
Two feathered guests from Alabama, two together.
(WHITMAN.)
And warmed the pinions of the early bird.
(THOREAU.)

We will leave our readers to make their own comments. There are a vast number of quotations like these, which seem to be stirred in at random. We believe Prof. Martin's countrymen have a prejudice against Greek, but in our opinion his book would have gained enormously in interest and value if he had included some Greek quotations, or at least translations of them. For instance, Homer's passage on the nightingale is even finer than Virgil's. (See Odyssey xix., 518.)

But "a detailed study of the birds in the English poets is, perhaps, our most immediate need" (Preface, p. 1). Prof. Martin may be glad to see our own Laureate at his best in "Nightingales":—

Alone, aloud in the raptured ear of men
We pour our dark nocturnal secret; and then,
As night is withdrawn,
From these sweet-springing meads and bursting boughs of May,
Dream, while the innumerable choir of day
Welcome the dawn.

We gladly acknowledge that Prof. Martin has done a great deal of hard spadework which will serve as a foundation for future writers. He has written a modest, honest, and very painstaking book, displaying a German thoroughness which we should like to have seen turned to better account. Many of his American quotations are extremely pretty, and it is a pity that his gold should suffer from contact with so much dross. Work of this kind should be done, as he confesses in his preface, "preferably by a native, on the ground; and it may well be the task of some future Thoreau or Burroughs."

T. F. ROYDS.

FACTORY ECONOMICS.

The Modern Factory, Safety, Sanitation, and Welfare. By Dr. G. M. Price. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd, 1914.) Price 17s. net.

DR. PRICE has been for some years the Director of the Joint Board of Sanitary Control in the mantle, costume, and blouse industries in the United States, a new experiment in the sanitary control of an industry by organised employers, organised workers, and representatives of the public. He was also director of the investigations of the New York State Factory Commission in 1912 and 1913, and his previous experience as a sanitary inspector and as practitioner in a crowded section of the East End of New York entitles him to speak with authority on the close relation between factory conditions and industrial health. His book is one which should especially commend itself to employers, his clear style and practical knowledge enabling him to dispense with the technical terms which so frequently deter business men from profiting by scientific studies of health conditions.

The chapter on the rise, growth, and influence of the factory is as good as any history of all industries in all countries in all times contained in thirty-eight pages can possibly be. The coincidence of a great increase of population in England with an alleged increase in occupational mortality, both due to the same cause, does not receive either here or anywhere else the attention it deserves.

The rest of the volume has the freshness and originality which only practical knowledge can give. In a short notice it is only possible to direct attention to the wealth of detailed examination of means of improving factory conditions, and to give a few quotations bearing on questions of pressing importance in the United Kingdom.

With reference to underground bakeries and other employment in cellars, Dr. Price concludes: "Cellars cannot be kept clean as other parts of the house, for they are semi-dark, contain most of the plumbing pipes and fixtures, and are, as a rule, the dumping-ground of the whole house. Cellars are also the natural habitation of insects, rodents, etc., and are also in proximity to breeding-places of flies, which are attracted to the food-stuffs" (p. 50).

The desirability of paying attention to beauty in architecture is urged, but rather from the point of view of the community living in the neighbourhood than of the worker. It must be remembered that money spent on front gardens and outsides of factories does not necessarily guarantee even good surroundings for the workers inside.

Fifty-seven pages with twenty-two illustrations are devoted to the causes and prevention of factory fires. The chapter on factory accidents and safety contains 103 pages and eighty-one illustrations. The estimates quoted of accidents in the United States (pp. 133–4) will not bear cross-examination and would be better omitted. The chapter itself is of the highest value. Attention should be paid to the section on accidents due to the physical unfitness of workers: "Not only should there be a routine physical examination of every worker in every establishment before employment, but there should be a periodical examination not less than once in three months, by competent medical men,

of every employee in the establishment, to determine his physical condition and his fitness for his special work" (p. 150).

The subject of light and illumination in factories receives careful treatment: "In Holland the law requires a minimum intensity of 10 bougie-meters (1 foot-candle) to be maintained, and in some special industries, such as sewing, embroidery, knitting, printing, etc., an intensity of 15 bougie-meters ($1\frac{1}{2}$ foot-candles) is required" (p. 240).

Employers welfare work is considered, and incidentally "scientific management" is brought under review: "The chief opposition to scientific management in factories comes from the workers themselves, from their representatives, and from those social workers who dispassionately judge this new efficiency movement in industrial production" (p. 303). The example of an English manufacturing firm in employing a dentist to attend to the teeth of their workers is recommended for imitation.

The chapter on "Air Ventilation in Factories" includes forty-five pages and twenty-one illustrations; that on "Industrial Tests and Dusty Trades," an equal number of pages and thirty-seven illustrations. The illustrations in the chapter on "Industrial Poisons, Gases, and Fumes," by showing the intense discomfort of the necessary preventive measures, enable the reader to realise to a small extent the terrible dangers to which the workers in certain industries are exposed.

CACAO AND COCO-NUTS.

(1) *Cocoa.* By Dr. C. J. J. van Hall. Pp. xvi+515. (London: Macmillan and Co., Ltd., 1914.) Price 14*s.* net.

(2) *The Coco-Nut.* By Prof. E. B. Copeland. Pp. xiv+212. (London: Macmillan and Co., Ltd., 1914.) Price 10*s.* net.

THESE two volumes form notable additions to the literature of economic botany, and will be welcomed alike by planters and departmental officials. (1) For some years past the cacao planter has been tolerably well provided with useful handbooks, and an extensive and important literature has arisen in regard to special aspects of his industry. Dr. van Hall's task, therefore, has been undertaken with considerable initial advantage, but with a special opportunity of sifting the evidence now available and affording an authoritative summing-up. Few are better qualified for this task than the author, and the present volume unquestionably affords the best available discussion of the principles underlying the successful cultivation of cacao. The arrangement of the book follows established lines. Chapters on the history, chemistry, and botany of *Theobroma Cacao* are succeeded by a discussion of methods of cultivation, fermentation, and preparation for the market, and treatment of pests and diseases; there is, moreover, an admirable account of the varying methods of cultivation and preparation adopted under the varying conditions of the great cacao-growing countries. Throughout the book the usual English rendering, "cocoa," is adopted in preference to "cacao."

Among the most valuable chapters are those dealing with the botanical characteristics of the tree and its cultivation as a crop. The correct understanding of the morphology and physiology of the plant is of the greatest practical importance, and much of the author's convincing treatment of the problems of cacao cultivation rests upon his appreciation of this fact. Planters will turn with interest to the discussion of the perennial questions of "shade" and manures, while the account of the progress made in Java with experimental grafting and budding of selected varieties will be welcomed by West Indians, who were the first to recognise the possibilities of this practice. It would seem, however, that at present Dr. van Hall does not fully share the optimism expressed in certain circles in regard to the *practical* possibilities of this line of work. The author will gain the confidence of planters and others by his respect for the experience of sound, practical men and avoidance of dogmatic assertion: "It is a golden rule that cultural methods must always be entirely dependent on local conditions." The book is well printed and the numerous illustrations are excellent.

(2) Prof. Copeland's well-illustrated book is one of the best accounts of the science and practice of coco-nut culture that has yet appeared. As professor of plant physiology in the College of Agriculture of the University of the Philippines, the author has for some years past been occupied with researches into the physiology of the coco-nut palm, and the present volume is substantially a discussion of the practical aspects of coco-nut growing in the light of the results of his investigations. As main topics the author deals with the physiology of the palm, climate and soil, diseases, selection of seed, field culture, and coco-nut products. His own practical experience has been the basis for his treatment of planting practice, and, in consequence, the book is chiefly concerned with coco-nut planting as carried out in the Philippines. Special value attaches to the chapters on climate, soil, and culture, since, as might be expected, they have been written with full regard to the physiology of the plant, a subject dealt with all too briefly in an excellent and

suggestive section. The importance of selection of seed to meet the varying needs of the different markets for coco-nut products is insisted on in a very interesting chapter.

A pleasing omission from the book is the oft-encountered estimate of "cost of establishing a plantation," and the author explains the absence of statistics of coco-nut production on the grounds of their untrustworthiness. On the other hand, it should have been found possible to include, in the brief chapter on "Coco-nut Products," a reference to the now important trade in "desiccated coco-nut." It is interesting to note that the author follows Cook in regarding the American tropics as the home of the coco-nut palm; that he finds no evidence that salt is necessary for the full development of the plant; and that he discounts the view that sea-shores are the only proper localities for a plantation. S. E. CHANDLER.

MAN AND THE UNIVERSE.

(1) *The Concept of Sin.* By Dr. F. R. Tennant. Pp. iv+281. (Cambridge University Press, 1912.) Price 4*s.* 6*d.* net.

(2) *God and the Universe: a Physical Basis for Religion and Ethics.* By Prof. G. W. de Tunzelmann. Pp. 256. (London: S.P.C.K., 1912.) Price 4*s.*

(3) *The Principia or the First Principles of Natural Things, to which are added the Minor Principia and Summary to the Principia.* By Emanuel Swedenborg. Translated from the Latin by J. R. Rendell and I. Tansley, with an introduction by Isaiah Tansley, and a foreword by Sir William F. Barrett. Vol. i., pp. cv+545; vol. ii., pp. xxi+699. (London: The Swedenborg Society, 1912.)

(4) *Outlines of the History of Psychology.* By Prof. Max Dessoir. Authorised translation by Donald Fisher. Pp. xxix+278. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1912.) Price 7*s.* net.

(1) IN Dr. Tennant's lucid and fair-minded discussion of the meaning of sin particular points might indeed be criticised. But the query in one's mind is rather the general one as to the value of the concept—why has there been a "decay of the sense of sin"? This is dealt with in an appendix, but quite other reasons than those there recognised must, one feels, be faced.

There are two views of the world; as a slough to be crossed or a marsh to be drained. On the first indeed we shall assign ethical value to results "only in so far as these are exponents of the goodness of the will whence they spring." On the second, such things as suffering and ignorance are evil, not merely as "exponents," or in a "quasi-æsthetic" sense (indeed a Kipling may find a pleasing symmetry in the "widow in sleepy Chester" compensated by an expiatory heap of skulls in Cathay). The present war may be due rather to a collective fallacy than to sin; if its miseries would in that case have no interest for ethics—well, so much the worse for ethics. Just as the deadliest false witness is borne in good faith, so man's cruellest inhumanity to man has been done with approving conscience. Conversely Huck Finn, one supposes, sinned in aiding the runaway Jim, as did the Precentor in failing to enlighten the Little Minister's mother.

From this point of view, again, we shall ask first and last, What is feasible, what is modifiable? Now a man's standard of right is indefinitely alterable, but the degree of his conformity to it, his native conscientiousness, may, like his native retentiveness or intelligence, be fixed. So with the race; the standard changes while the deviation of individuals—the moral scatter—remains fairly constant. And in moulding the race of the future we cannot (apart from eugenics) assume the possibility of influence more direct than through the social environment. Further, the goodwill cannot be only formal if we are to avoid the circularities of the will to believe. And just as the "paradox of hedonism" has a psychological as well as a logical meaning, so the constant query "How shall I acquire merit?" though it need not produce the Pharisee, is yet far from that objectivity which is the mark perhaps of genius and surely of the idealist and love. To the mother the child is not an "exponent" of the parental instinct, but an end. Finally, even if life *is* an examination we are only candidates. To divide the sheep from the goats may be God's business; that it cannot be ours is indeed emphasised by Dr. Tennant. He warns us, too, that he writes for theological students rather than social reformers. But that is just it; we are all social reformers.

(2) Dr. Tunzelmann attempts to provide a "physical" demonstration of the existence of God. The mechanical view, or "model," of the universe has had to be supplemented by the energy model, and this, in its turn, fails to explain the initial distribution of energy that it presupposes. There remains only the mind model. That mind does affect the distribution of energy is "proved" by practically assuming interactionism. But even interactionism only refers to the relation of mind and brain, so that the argument would seem at best to suggest that the material universe is, or was, the cortex of Universal Mind. And mind does not will or know its own nervous correlates. Dr. Tunzelmann's argumentation is strangely un-

equal; often strikingly acute it is often as notably weak, *e.g.*, his identification of life and mind. Convincing as a refutation of crude materialism, the book is scarcely so in its more ambitious aims.

(3) Swedenborg's "Principia" suggests again the distinction between the examiner and discoverer points of view. As a candidate Swedenborg would deserve high marks; "nothing can dim the glory of this magnificent dash into the unknown," and it is easy to recognise in him anticipations of modern physical theories. But, alas! we want views which will not merely be consistent with future results, but will bring these nearer. There remains, no doubt, the purely historical interest, but the history of ideas is peculiar inasmuch as what was helpful in the past is preserved in the present, while the errors, though inevitable at the time, were not merely unsatisfactory as "models," but as mental habits had to be painfully unlearnt. Hence to the student of a science its history is apt to be confusing rather than helpful; and this difficulty one cannot but feel in the case of (4) Prof. Dessoir's history, even though the history of psychology is itself psychology, and excellently as the task is done. The translation reads well, but surely "moment" in the sense of "factor" is still somewhat German English?

C. S.

OUR BOOKSHELF.

Artificial Waterways of the World. By A. B. Hepburn. Pp. xi+171. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 5*s.* 6*d.* net.

THIS book, dealing principally with American waterways, also contains a short account of the principal canals of the world, and is well worth the attention of those interested in internal navigation.

The object of the author is stated to be to place before the public the salient facts as to internal artificial navigation in relation to commercial development. The author considers that the use of canals is to supplement and complement, and not to attempt to rival railways.

Canals have not now the same importance in the transport of materials and the development of the resources of England that they have in America, with its enormous area of inland country situated a long distance from the seacoast. In Great Britain there are no fewer than eight first-class ports situated within comparatively short distances from the interior, and there is no large manufacturing town more than eighty miles from the sea-coast.

An interesting account is given of the original construction and subsequent improvements of the Erie Canal, the principal artificial waterway in the United States. This canal connects the country around Lake Erie with the seaport at New York. It was opened for traffic in 1825, and has, from time to time, been enlarged and improved, and is now capable of taking barges 150 ft. long and carrying 240 tons. It is State owned and now toll free. For a quarter of a century it was the greatest transportation line in the country, giving settlers in the west country an outlet for their products. With its connections it is 433 miles in length, and second only to the Great Canal of China among the artificial waterways of the world. Its importance has, however, been considerably diminished, the tonnage carried by this canal being now only about one-twentieth of that carried by the railways.

The British Journal Photographic Almanac, 1915. Edited by G. E. Brown. Pp. 1068. (London: Henry Greenwood and Co., Ltd.) Paper, 1*s.* net; cloth, 2*s.* net.

THIS volume is the fifty-fourth issue of the photographer's most useful companion, and will be found to be up to the usual standard of accuracy and completeness.

Two notable articles of great interest to amateur workers are those of "Modern Methods of Enlarging," by the editor, and "Photography with the Microscope," by Dr. Duncan J. Reid. Both of these deal with the subjects in clear and precise style, and are well illustrated by carefully selected diagrams. The *résumé* of the year's practical work and the section on novelties in apparatus bring the reader right up to date as regards methods and apparatus. The volume embodies as usual the many formulæ and tables needed in the practical man's work and such useful information as particulars of the photographic societies in the British Empire, etc. By no means unimportant is the well-arranged mass of advertisements of the numerous photographic firms in which the announcements of apparatus and materials are of great interest to the practical worker. Complete indices to text and goods advertised make the mass of valuable information included in these 1068 pages readily available.

Heaton's Annual. The Commercial Handbook of Canada and Boards of Trade Register, 1915. Edited by E. Heaton and J. B. Robinson. Pp. 516. (Toronto: Heaton's Agency; London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd.) Price 5*s.*

THE eleventh annual issue of this useful work of reference will be welcomed by all who have commercial or other dealings with Canada. The detailed information is brought together in a form which makes it easily available, and it will prove of assistance to teachers of commercial geography as well as business men. This year, for the first time, an economic bibliography of the Dominion and Provincial Government reports has been added. The general information includes valuable notes on agriculture, technical education, fisheries, mining, and temperature and rainfall among other matters likely to appeal to students of science.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Measurements of Medieval English Femora.

As it was I who suggested to Dr. Lee the illustration of her mathematical work by a consideration of Dr. Parsons's recent paper on the English thigh bone in the *Journal of Anatomy*, and as I am further responsible for emphasising the extraordinary proportion of the sexes reached by him (owing, as I believe, to his fallacious method of sexing), I may, perhaps, be permitted to reply to his letter in NATURE of February 11.

In the first place, I should like to make a general defence of the action of the Biometric School in venturing to deal with what are too often supposed to be purely anatomical matters; I cannot forget that my criticism of another distinguished anatomist some years ago met with the reply, published in your columns, that he had no intention of discussing the matter with one whom he stated had no anatomical training. In a letter to Dr. Lee, Dr. Parsons emphasises the distinction between the man with anatomical knowledge and the person who approaches these problems with scientific training, but is wanting, so he assumes, in observational experience. Nearly twenty-five years ago, when I first entered from the mathematico-statistical side upon the study of craniometry and osteometry, I venture to think that there existed a very general Continental opinion that British work on these subjects was largely the product of dilettanti. The object of the Biometric School was to reverse that judgment, and to show foreigners, that we in England could provide not only measurements, but methods and results, which they would be compelled in self-defence to adopt, extend, and imitate. In the course of that quarter-century many thousands of crania, many hundreds of skeletons have passed through or remained in my Biometric Laboratory. We have had the most generous help of quite a number of highly trained anatomists, and have been compelled to study many anatomical memoirs. Is it likely that we should remain totally ignorant of the physical properties of the material we have had to deal with, or with the views of anatomists with regard to it? Indeed, one of our extreme difficulties has been the "pie-crust" character of many of the bones coming into our hands. Experience, however, has convinced me that sex has very little indeed to do with the destruction of either craniological or osteological material. That depends to some extent on age at death, but chiefly on the *immediate* physical environment during the period before exhumation of the individual skeletons. We are quite familiar with the distressing experience involved in boxloads of bone dust and bone fragments. But in the face of that experience I state that Dr. Parsons's sexing of the Rothwell femora which gives 64 per cent. males and 36 per cent. females is in error, and bears internal evidence of this error.

In the case of the Naqada skeletons which were among the first brought to my laboratory the wastage through the breaking up of material was excessive, the quantity of bone dust and fragments practically equalled the usable material; the centuries of desert exposure, and the long rough sea journey had produced a selection of bones some 6000 years old, which, if Dr. Parsons's views were correct, should have largely influenced the sex proportions. Yet on a sexing based on far surer ground than Dr. Parsons's, namely, on that of the crania and pelvic bones of the skeletons, we found 59 per cent. of the bones were *female* and only 41 per cent. of the bones *male*. Two series of long bones from London plague pits sexed *anatomically* gave only 56 per cent. males and 44 per cent. females, and the selective destruction in this material must have been very great. In this case the mathematical sexing, using the bicondylar width—which I shall show in a forthcoming memoir to be a more trustworthy sexual character than the femoral head—gave only 52 per cent. males and 48 per cent. females. Where we find—as we do find occasionally—a great disproportion in the sexes, and it is not due to archæological causes, *i.e.* battlefield interments, chief or warrior burials, monastic settlements, etc., it results, I believe, from the personal equation involved in much anatomical sexing. I have watched many an anatomist sexing; he may look at numerous points, but he has rarely given them relative *quantitative* weights; he is almost certain to be biassed by his pet sexual character in the living, the shape of the forehead, the bridge of the nose, the nape of the neck; from nasion to basion there is not a single feature of the skull which is not a pet sex-determinant to one man or another. And it is just the same in the far more difficult matter of long-bone sexing. It is the obliquity of the femur with one man, the muscularity with a second, the pilastric diameter with a third, while Dr. Parsons, following Dwight, pins his faith to the femoral head, and having reached results which give an immense male preponderance, explains it by restating the old axiom[1] that female bones cannot stand the wear and tear which male bones may be expected, owing to their stronger constitution, to survive. What if the female bones were by their smaller size likely to be subjected to a lower bending moment relative to their flexural rigidity? But Dr. Parsons's own material answers himself. His missing female bones are not the small but the *large* female bones, precisely those bones which were likely to be treated as male bones on his plan. If anyone with experience of frequency distributions will examine his distribution (on p. 256, *Journal of Anatomy and Physiology*, vol. xlviii.) they will find, not that the females are abruptly cut off on the *dwarf* side, but that females are abruptly cut off on the *giant* side, and males on the *dwarf* side. Why? Because in transferring Dwight's rule based on the mixed material of American dissecting rooms to an English medieval population, he has not only overlooked the complete difference of race and time, but a still more important point. *Dwight was measuring moist bones with the cartilage attached*—and, if Dr. Parsons meant to apply this rule, he should have subtracted 3 to 4 mm. from Dwight's limiting values before applying them to his own material!

Looking at Dr. Parsons's results on p. 256 I can but conclude that his sexing is based on a fallacy, and the dip he has created in the Rothwell femora between those with 45 and 47 mm. heads—the range of Dwight's supposed doubtful sex—is due to conscious or unconscious selection of his material; out of the great masses of bones available at Rothwell (which should have occupied in measurement of many characters and in their adequate reduction the whole time of a man for four or five years) Dr. Parsons has chosen a small series giving a remarkable dip at Dwight's limits, limits which I venture to suggest have here no application. These

[1] I should like as a layman to enter a vigorous protest against Dr. Parsons's, an anatomist's, opinion, that female bones disintegrate "for the same reason" as those of children!

and other points will be discussed in our memoir on the London femora now at press. I write at present at this length merely to indicate that in suggesting to Dr. Lee to illustrate her tables on Dr. Parsons's material, I had in view many observational points which Dr. Parsons, like not a few of our English critics, considers we have made no attempt to appreciate—being "mere mathematicians." KARL PEARSON.

Galton Laboratory, University of London.

A Remarkable Dry Fog in the East Indian Archipelago.

THE observations made on Ben Nevis upon the transparency of the air have shown very clearly that with increasing relative humidity the transparency is diminishing, a consequence of the increasing volume of the light-scattering particles, from which it may be concluded that the particles are of hygroscopic character.

The influence of humidity on the size of these particles was obvious in a very striking way in the dense dry fog that towards the end of the dry monsoon of 1914 spread out over the East Indian archipelago, causing much trouble to navigation.

A short description of this phenomenon is given below. The fog had a grey colour, and was most intense in the month of September, and especially in October, and disappeared when the rains fell. In its most typical form it appeared in Sumatra, in the neighbourhood of Ambon and the islands to the south-east.

In Sumatra it was observed to the north as far as Medan (Deli), the Karo plateau near the Toba lake and Tapanoeli, to the south as far as Benkoelen and the highlands of Kerintji. It was not observed in the open ocean outside the Mentawei Islands.

In the morning the sun was not visible before eight o'clock, when it appeared as a dim red disc. Objects in general were barely visible at 500 metres' distance, and on the thickest days invisible within half this distance; the mountains had disappeared entirely from view.

In Ambon the sea was sometimes invisible from the lighthouse, which is situated close to the shore, and 140 metres above the sea. Also in the straits between Sumatra and Borneo, and the west and east coast of Borneo, the fog was very thick, and though in somewhat less degree it was also observed in the northern part of the Strait of Makasser, on the north coast of New Guinea (in these regions, however, it was more or less mixed up with smoke from forest fires, which caused local intensification), on Sumatra's west coast north of Padang and Malakka Strait.

Though in the other parts of the archipelago the transparency of the air was greater, it was not quite clear, on account of the blue haze that is common to the dry season.

A similar phenomenon (described by Dr. van Bemmelen, *Meteorl. Zeitschr.*, August, 1905), perhaps still more intense, was observed in the very dry year 1902; it then extended to the southern part of the China Sea and to the south-east so far as the Tanimber Islands, the region of greatest intensity being about the same as in 1914. It was also reported from the abnormally dry years 1885, 1888, 1891, and 1896. In Karimata Strait it is a common phenomenon.

Now it is very remarkable that the southern boundary of the fog coincides rather closely with a well-defined line, that separates the region of practically no rainfall from that of greater humidity where light rains begin to appear. In 1914 this line ran in the months of September and October over the south-east point of Sumatra, along Billiton and Borneo's south coast, through Makassar Strait, along North Celebes, and south-eastwards along the south coast of New Guinea, Ambon, and the region south-east of it lying as an oasis of light rainfall in the dry region.

From this it is evident that it is the hygroscopic particles that form the blue haze in the south-eastern part of the archipelago, which, entering into moister regions and increasing their radius, give rise to the appearance of the grey fog.

Physical laws fully account for the fact that the fog is a mere intensification of the haze, though the rather fast transition of the light blue haze to the much thicker grey fog gives the impression of a new phenomenon springing into existence.

So long as the particles are much smaller than the wave-length, the intensity of the scattered light in relation to that of the light falling upon it, may be represented by $I=\alpha r^6/R^2\lambda^4$, when r is the radius of the particle, R the distance from the observer, and λ the wave-length. When r is increasing, the ordinary reflection ultimately appears, and $I=\beta r^2/R^2\lambda^0$.

From the method of dimensions may be concluded (conf. Rayleigh, "Theory of Sound," II., p. 152), I being a simple ratio and α and β passing gradually and rather slowly into each other as r increases, that as the exponent (n) of λ is changing from 4 to 0 the exponent (m) of r changes from 6 to 2. Therefore, so long as n is large enough to produce a colouring of the haze, m will cause a very rapid increase of the intensity of the scattered light, which may account for the rather sudden change of the blue haze to the grey fog.

It is not in the first place the greater number of particles that account for the difference between the transparency of the air in the dry and wet season, but their hygroscopic character. On December 23, 1914, when the wet season had already set in, I counted with Aitken's apparatus at Batavia 50,000 particles in 1 cub. cm., the relative humidity being 84 per cent., and no trace of haze was to be seen. However, on the Ardjoeno (at 2500 metres' height) on October 29, towards the end of the dry season, their number was only 1800 in 1 cub. cm., and notwithstanding the humidity was only 40 per cent., the surroundings were enveloped in an intense blue haze. Especially these very hygroscopic particles, when entering moister regions, will be susceptible to a strong increase of volume, and therefore will be the principal producers of the fog.

When we put the question where those highly hygroscopic particles come from that are responsible for the phenomenon described above, it may be remarked that for the greater part they do not form during the short journey of the trade wind over the archipelago. This takes only a few days, whereas the fog appears after many months of excessive drought. Two causes may be mentioned to which they owe their existence, viz., burning processes in Australia, which are also most frequent after long-prolonged droughts; and, secondly, which I take for the greater influence, the formation from the components of the air, ozone, nitrogen, etc., during the slow descending movement in the Australian anticyclone, in which the air probably takes several months to reach the layers near the surface of the earth. C. BRAAK.

Batavia, January, 1915.

A Penalty on Research.

IF Sir Wm. Ramsay was refused a rebate of the duty on alcohol I could scarcely expect better treatment. Nevertheless, I should like to add to his protest, and complaint After a correspondence lasting

several weeks and some courtesy showed me by the local authorities I received the bluntest refusal to my request for a small supply of duty-free alcohol at my private laboratory in Cambridge, and this in spite of the fact that owing to an accident I am permanently prevented from leaving my house and availing myself of the duty-free alcohol at the biochemical laboratory of the University. H. ONSLOW.

11 St. James's Square, S.W., February 19.

MANY who, like myself, are privately engaged in biological research, will feel grateful to Sir William Ramsay for having directed attention to the difficulties which are unreasonably put in their way in regard to the supply of alcohol. May I take this opportunity of adding that, for those not connected with some university or museum, the only methylated spirit obtainable is adulterated to make it undrinkable, which also makes it absolutely useless for the operations of the biologist, who is thus driven to incur great expense in the purchase of alcohol. Some time ago I applied to the excise officers here for a licence to be supplied with methylated spirit for use in research work, and I offered to enter into any bond and to comply with any regulations they liked to impose to ensure its safe custody and honest use. After a correspondence extending over nearly three months, this licence was refused. I hope that Sir William Ramsay's letter may receive attention in the proper quarters, and that reasonable facilities may be given for the supply of both alcohol and methylated spirit for the purposes of research.

ARNOLD T. WATSON.

Sheffield, February 22.

Cement for Polarimeter Tubes.

I SHALL be much obliged if any reader of NATURE will suggest a cement suitable for fastening the end discs to polarimeter tubes. The cement I should like to hear of should be capable of withstanding the action of organic liquids at temperatures between 200°–300°. Fusion of the discs to the tubes would, of course, be best, but would be almost certain to introduce strain. There is no great difficulty in working without cement up to about 200°, but beyond the temperature at which rubber melts—and is, therefore, unsuitable for washers—the problem of keeping the liquid in its tube is by no means a simple one. Possibly someone engaged in work making similar demands may be able to assist me. T. S. PATTERSON.

University of Glasgow, February 20.

The Prices of Chemicals.

"J. J.'s" complaint against chemical dealers for unduly raising prices in consequence of the war seems to have been unjustifiable in the case he mentioned, but it would apply in some other cases. A few weeks ago I wrote to several dealers for some racemic acid; one firm, who had a stock of only half an ounce, let me have it at the pre-war price, whilst another, with a larger stock, charged me just double. S. P.

THE MANUFACTURE OF DYESTUFFS.

THE GOVERNMENT'S MODIFIED SCHEME.

THE discussion on the various aspects of the problem of producing in this country an adequate supply of dyestuffs proceeds without intermission. The question has for some time assumed a national aspect and has been the subject of Parliamentary debate or question on at least three occasions. It has also been debated at meetings of the Chambers of Commerce in the chief industrial centres, and people most directly interested have had many opportunities of expressing their opinions at meetings of their various organisations, or at gatherings specially convened for the purpose.

To a great extent the discussions have centred round the adequacy and equity of the commercial proposals involved in the official scheme now before the public. These have received much more general acceptance than those put forward in the first scheme, and it appears probable that the committee has now received promises of support to an amount representing a substantial proportion of the initial capital proposed for the new company.

The members of the committee themselves admit that it is an easy matter to criticise the scheme adversely, and it is obviously impossible to devise a solution of the problem satisfactory to all minds.

If the matter is to be viewed as an ordinary commercial proposition, if questions of free trade or protection are to be taken into account, or if early dividends are to be assured, then any scheme which might be put forward could be shown to be unworthy of support. But whilst criticism on these lines has been plentiful, there has latterly been a rally of support by those taking broader views—a support which has probably been largely induced by a sense of national need, and has certainly been greatly developed by the action of the Government in offering to endow the research work which is essential to the extent of 100,000*l*. This action has engendered a feeling of confidence that the Government will take any further steps which the future may show to be vital to the success of the British dye manufacturing industry.

It is to be hoped that the committee in charge of the scheme will shortly be able to announce the results of its inquiries and that these will show that the great textile trade of the country has responded adequately. In the meantime, the arrangements for carrying out the necessary preliminary chemical work should be proceeded with.

A Mobilisation of Chemists.

Speaking in Bradford on February 8, the present writer advocated immediate action by the Government or the Board of Trade Advisory Committee in the direction of utilising the services of British chemists. There is on one hand a large amount of chemical work to be done before the industry can be greatly developed, and on the other, there is a great number of well-staffed and well-equipped laboratories in our universities and technical colleges which might render great service to the industry. To avoid wasteful duplication of work and to co-ordinate the results, it is essential that some organised scheme and allotment of work should be arranged, and it is suggested that a conference of those concerned

should be held at an early date to formulate such a scheme. Even if to-morrow the whole of the available chemical force set to work on some organised plan, it would not be any too soon to get the necessary information together for the use of the existing works and the new works when they are started.

The urgency of this action is further shown by a resolution passed by an important meeting held in Manchester on February 16, which was presided over by Sir Chas. Macara. The resolution, which was carried unanimously, stated: "That in the opinion of this meeting the Government would do well to organise immediately the present chemical talent in the country with a view to chemical research being undertaken for, and on behalf of, all manufacturers interested, and that the services of these experts should be available for all desirous of availing themselves thereof."

The adoption of such a plan for bringing the educational institutions more closely into touch with the industries would in all probability mark the beginning of a new era in which both would benefit. The more intimate association of professors of chemistry with chemical industry would introduce into the works that higher ideal and broader scientific spirit upon which successful research and development depend, whilst the schools would benefit by the great incentive of practical reality.

The Parliamentary Debate.

Since the above was written, the important debate in the House of Commons on Monday, February 22, has advanced the matter another stage. The criticisms offered by various speakers raised few novel points, and the general tone of the debate was, on the whole, favourable to the Government scheme. Several speakers, including Sir Philip Magnus, expressed the opinion that the grant of 100,000*l.* for research work was totally inadequate. Mr. A. Chamberlain and others emphasised the great difficulties the undertaking would have to face on the conclusion of the war, and many speakers acknowledged that the question of the manufacture of dyes was of such a special character as to warrant quite exceptional treatment.

Mr. Runciman, speaking on behalf of the Government, made the interesting announcement that upwards of 400,000*l.* has already been subscribed towards the capital of the new company, and further stated that the signing of the five years' agreement was not an essential condition of subscribing capital, but that priority of supply would be given to those who had given the undertaking. His concluding remarks may be quoted: "I am surprised that anyone should suggest that we have not adequate chemical knowledge in this country. We have sufficient first-class men, but we lack an adequate number of second-class chemists, which we shall not produce if they are only paid 3*l.* a week.

"Even if this were only an emergency scheme the million pounds promised by the Government would be well spent. A single month of unemployment in the textile trade would mop up more than that of our national money. It is the disadvantage of all practical schemes that they are full of compromises, but no step has been taken without a practical reason."

WALTER M. GARDNER.

ON COLOUR SENSITISED PLATES.[1]

II.—THEIR APPLICATIONS. PANCHROMATIC PLATES. TESTING DYES, ETC.

The commercial "ortho-" or "iso-chromatic" plates, which are specially sensitised for green, besides their obvious uses for scientific purposes in which red sensitiveness is not necessary, are of especial use in the photography of coloured objects where an improved result, as compared with an ordinary plate, is desired, rather than a full correction. As the unassisted eye is not a very keen critic of the relative brightnesses of different colours, especially when they are not in juxtaposition, such an improvement is often all that is necessary. The deficient sensitiveness to red causes a pure red to be represented as if it were black. But almost all colours in nature and most artificial colours are not pure, and so far as a red contained any green or white, that is so far as it reflected any other light whatever in addition to the pure red, except pure blue, then the rendering of the red would be improved. But this fact as to most natural colours being mixed is also a disadvantage, for all coloured objects, so far as they reflect any red, will suffer because of the want of red sensitiveness of these plates.

Plates are made specially sensitised to red and called red and yellow sensitive, and practically all that has been said with regard to green sensitised plates, both now and in the previous article, applies to these, only that the deficiency here is green instead of red.

By the use of more than one sensitiser, plates may be sensitised to both green and red, and the early panchromatic plates were of this type. They had three maxima of sensitiveness, one in the blue due to the plate (that is, the silver bromide) not specially sensitised, and one in the green and one in the red due to the two sensitisers. Such plates may be regarded as being as much of an improvement on "orthochromatic" plates as these are on ordinary plates, but the sensitiveness is uneven, and they consequently suffer as already described. By the careful selection and combination of sensitisers this unevenness has been very largely overcome in the panchromatic plates of the present day. Excessive blue sensitiveness of course remains, but this is easily obviated by a pure yellow filter.

The three illustrations (Fig. 2, *a*, *b*, *c*) show the effects of various colours by the use of ordinary, orthochromatic, and panchromatic plates, respectively. The colour filter used with the orthochromatic plate might with advantage have been

[1] Continued from p. 677.

rather darker. The "L" near the middle is deep blue, the word "mark" is white, and the ground they are on is yellow. The book covers are red. It will be noticed how the panchromatic plate gives the yellows better than the orthochromatic plate,

(*a*) Ordinary Plate.

(*b*) Isochromatic Plate and Yellow (×4) screen.

(*c*) Panchromatic Plate and Yellow (K 3) Screen.

FIG. 2.

and gives the reds, which the orthochromatic plate renders in the "Gazetteer" and "Atlas" as if the red paper was of the same colour as the black printing ink. Other effects will be clear without further description.

Panchromatic plates have been made commercially for fifteen years or more, but the plates of the last few years are very superior to their predecessors. Some makers issue more than one kind, the variation so far as colour sensitiveness is concerned being chiefly as to the extent of the red sensitiveness. Some are sensitive only to about the red lithium line or the C line in the solar spectrum. Others are sensitive to beyond the A line or the red potassium lines, and plates can be supplied that are sensitive considerably further into the infra-red. For the correct representation of coloured objects infra-red, and even the extreme red, sensitiveness is only harmful, just as ultra-violet sensitiveness is, because these radiations are dark to the eye. It is well to choose a plate for this purpose that is not sensitised to the extreme red, and it is necessary to use a colour filter that cuts off the ultra-violet (some of the older yellow filters did not do this) and reduces the intensity of the blue so that it does not produce an undue effect. With a modern panchromatic plate a suitable filter will require the exposure to be increased perhaps only five times, as compared with the exposure necessary for a white object without the filter. This does not mean that such a plate and filter will give a sensitiveness curve that will exactly coincide with the luminosity curve of the solar spectrum, but it is a very near approach to it, so near that for general purposes it is more important to see that the present degree of perfection is maintained, rather than that it is increased, though of course we hope for still better results in due time.

There are many uses to which colour sensitised plates and colour filters may be put besides the correct representation of colour luminosities in the photography of objects, spectrum photography, and in connection with three-colour reproduction processes. Given black and white and any single colour, it is possible to photograph the three so that the colour is represented as if it were *either* black or white. Take the simple case of a drawing or manuscript in black ink on white paper with alterations in red ink. The red alterations can be made to appear as black as the black ink by using blue (or blue and green) light only, that is, a light which has no red in it. An ordinary plate, which is sensitive only to blue, will give this result. But the red alterations can be made to appear as white, and therefore to disappear, by using red light only, that is, a plate sensitised to red in conjunction with a red colour filter. Engineers' drawings in blue, as when copied by the ferroprussiate process, give poor contrast on ordinary plates because the active light is chiefly blue, but with a red sensitised plate and red (or yellow) filter the blue becomes practically black. Similarly it is often possible in photography to eliminate stains on documents, or to find an inscription that has faded into invisibility. In this latter case it may be well to use extreme measures, as including as much ultra-violet as possible in one experiment, and the

extreme red in another, if the colour character of the detail being searched for is unknown.

By modifying such extreme measures as just described, it is obviously possible by photography to intensify or diminish the apparent effect of any colour, and so, as for example in stained physiological sections, to improve on the original, or from one original to get two (or more) photographs that represent the section in, as it were, two (or more) different conditions as to staining.

The photographer has also by such means a very large measure of control over the effect of mist. The writer has shown that light is scattered by particles of a diameter equal to half a wave-length of the scattered light. By passing a brilliant pencil of light through a flask of filtered distilled water the path of the pencil may be scarcely visible (the "Tyndall effect"). But by photographing the arrangement on an ordinary plate, that is, using blue and ultra-violet light, the path of the light will probably be shown very conspicuously indeed, the particles that escaped removal by filtration being not large enough to scatter light of greater wave-length than the ultra-violet and the extreme blue. When the particles of the mist or turbidity are graduated in size, as they generally are, and are not coarse like the dust that may be stirred up from a dry road, then the longer the wave-length of the light used the less does the mistiness show in the photograph. When the air is misty, by the use of a yellow filter distant objects may be photographed more clearly than they can be seen, and by using only infra-red light Prof. Wood has obtained photographs in which the sun shines, though there was only a grey cloudiness visible.

Though the colour sensitising of plates is now as much the manufacturer's business as the preparation of emulsions and the coating of the plates therewith, the experimentalist may wish to try the effect of a dye for himself. The solution must be very weak indeed, say one of the dye to from 10,000 to 50,000 times its weight of water. Ammonia is often advantageous to the extent of one per cent. of the whole. The best formula is simply a matter of experiment. The following, for example, is a varation recently published by Messrs. Michaud and Tristan (*Brit. Jnl. of Phot.*, lxii., 56) for sensitising for the red and infra-red:—

Alcohol 50 per cent., 200 c.c.
Ammonia, 4 c.c.
Alizarin blue S, 0·04 gram.
Silver nitrate 10 per cent. solution, 5 drops.

The same dye is efficient without the silver salt and the alcohol, but presumably these are advantageous. In general, after the plate has been in the dye solution for two or three minutes, it is washed for a few minutes and then dried. Plates so treated vary very much as to the time that they will remain in good condition. For example, plates bathed in the solution quoted above must be used within a few hours, but in other cases they may last for months.

It is much less risky to make colour filters than to bathe plates, as most dye solutions will be absorbed by a clean gelatine film. But colour filters are now made by several firms, and the Wratten department of Kodak catalogues standardised colour filters of nearly a hundred different transmissions.

CHAPMAN JONES.

PROF. G. F. J. ARTHUR AUWERS.

THE brief paragraph in our issue of last week, announcing the death of Prof. Auwers, must have been read with the deep regret that follows the loss of one who long occupied a commanding position in the world of science, and whose place it will be difficult to fill. For more than fifty years he had illuminated the science of astronomy, and by providing much of the material by which it is hoped to attack successfully the problem of the structure of the sidereal universe, he linked together the astronomical thoughts and methods of the past with the philosophical problems that engross and captivate the attention of astronomers of to-day.

In the history of astronomy of position, by which is understood the accumulation and arrangement of facts depending on a star's place in the sky, three names stand out prominently. Bradley, in whose valuable series of observations, long waiting for an interpreter, lay hidden the secret of stellar proper motion; Bessel, who made these measures available to the astronomers of his day; and Auwers, whose early appreciation of the necessity of the highest accuracy gave to these observations an increased value by his long and patient examination, laying the foundation of that system of thorough uniformity which has welded meridian observations into a more consistent whole, facilitating the combination of star catalogued places on a common basis, by the removal of systematic errors or discrepancies. Auwers taught the necessity for a higher standard of accuracy, and it is not too much to say that in the department of reduction and discussion of observations he long stood without a rival. His *forte* lay in the control and management of large masses of work, in the unhurried, careful supervision of every stage, bringing an acute and trained judgment to bear equally on all parts of the investigation.

If his reputation rests especially on his re-reduction of Bradley, it must be remembered that he encouraged and assisted other large undertakings. He took a prominent part in the re-observation of the Durchmusterung zones, a work of many years' international co-operation successfully carried out under the auspices of the Astronomische Gesellschaft. He was among the first to investigate the proper motion of faint stars, and he foreshadowed some of the conclusions that have been established by the most modern and thorough of inquiries. The determination of solar parallax by the method of the transit of Venus is a somewhat discredited problem now, but forty

years ago it occupied a very conspicuous position, and Auwers's work on the German share in the complete investigation exhibits at least all that could be derived from the process. Of still earlier date, and of unquestioned excellence and success, were his discussions of the variable proper motion of Sirius and Procyon. How brilliantly his location of the position of the unsuspected satellites was justified, is well known.

It would be impossible to do justice in a short notice to talents so varied and to an industry so active as Auwers exhibited throughout a long career, but it may be permitted to say that, notwithstanding the bitter estrangement that separates us from German thought and German ambitions, every English astronomer would be willing to lay a tribute of respect on the grave of Arthur Auwers. W. E. P.

NOTES.

SIR ANTHONY A. BOWLBY has been chosen Bradshaw lecturer of the Royal College of Surgeons of England for the ensuing year.

IT is announced in *Science* that Prof. R. H. Richards, professor emeritus in the Massachusetts Institute of Technology, has been awarded the gold medal of the Mining and Metallurgical Society of America in recognition of his services in the advancement of the art of ore dressing.

AT the meeting of the Royal Geographical Society on Monday, February 22, Dr. Page, the American Ambassador, presented to Dr. Scott Keltie, secretary of the Royal Geographical Society, the Cullum gold medal for long and eminent service to geography, awarded by the American Geographical Society.

THE gold medal of the Institution of Mining and Metallurgy—the "blue ribbon" of the profession—has been awarded to a distinguished Canadian, Dr. Willet G. Miller, provincial geologist of Ontario, in recognition of the eminent services rendered to mining by his admirable work as an economic geologist.

THE officers of the Royal Astronomical Society elected at the annual meeting on February 12 were as follows:—*President,* Prof. R. A. Sampson; *Vice-Presidents,* Dr. J. W. L. Glaisher, Major E. H. Hills, Dr. W. H. Maw, and Prof. H. H. Turner; *Treasurer,* Mr. E. B. Knobel; *Secretaries,* Prof. A. S. Eddington and Prof. A. Fowler; *Foreign Secretary,* Prof. Arthur Schuster.

PRINCE B. GALITZIN has been elected an honorary fellow of the Physical Society. The following is the list of officers of the society elected for the ensuing year:—*President,* Sir J. J. Thomson. *Secretaries,* Dr. S. W. J. Smith (Royal College of Science, S.W.), and Dr. W. Eccles (University College, Gower Street, W.C.). *Foreign Secretary,* Dr. R. T. Glazebrook. *Treasurer,* W. Duddell. *Librarian,* Dr. S. W. J. Smith.

AT the annual general meeting of the Geological Society, held on February 19, the following officers were elected:—*President,* Dr. A. Smith Woodward; *Vice-Presidents,* Dr. H H. Bemrose, Mr. Clement Reid, Dr. A. Strahan, and the Rev. H. H. Winwood; *Secretaries,* Dr. H. H. Thomas and Dr. H. Lapworth; *Foreign Secretary,* Sir Archibald Geikie, O.M., K.C.B.; *Treasurer,* Mr. B. McNeill. The president's address delivered at the meeting dealt with the evolution of the fishes in geological time.

THE virtual German monopoly in the manufacture of dye-wares is a matter of national concern in other countries as well as in Britain. It is announced that arrangements have been made by the Benzol Products Company of Philadelphia to commence dye manufacturing on a large scale in about six months' time. A new company, styled the "Russian Society of Chemical Industry," has also been formed in Moscow to manufacture dyes for the sixty large consumers in that district.

ON Tuesday next, March 2, Prof. W. J. Pope will begin a course of two lectures at the Royal Institution on colour photography (scientific applications): (1) "Photographic Appreciation of Colour in Monochrome"; (2) "Photography in Natural Colours"; and on Thursday, March 4, Sir Herbert Warren will begin a course of two lectures on poetry and war. The Friday evening discourse on March 5 will be delivered by Prof. E. B. Poulton on mimicry and butterflies, and on March 12 by Sir Rickman J. Godlee on back to Lister.

NEWS has been received of the arrival at Khartum of Dr. C. Christy, who has been engaged during the past three years on a zoological mission in the Belgian Congo undertaken officially on behalf of the museum at Tervueren. We hear that he has made very large collections of the animals of the Ituri forest and other regions of the Congo traversed by him, though it is difficult to say what is to become of the specimens under the conditions existing in Brussels. Dr. Christy was fortunate in shooting two okapi, thus joining the very small band (not more than three or four) of white men who have shot an okapi. Nearly all the specimens now in Europe were killed by natives. Dr. Christy's bag also included several specimens of Meinertzhagen's great black forest pig and many of the dwarf Ituri buffalo.

Science announces the following deaths of men known in the scientific world:—Dr. Anthony Woodward, at one time assistant in the department of geology and for thirty-seven years librarian of the American Museum of Natural History, New York City; M. Alfred Tournier, formerly professor of viticulture at the University of California and later connected with the U.S. Department of Agriculture, who was killed on December 12 in the war; Dr. C. F. Brackett, professor emeritus of physics in Princeton University, in his eighty-second year; Dr. B. Sharp, formerly corresponding secretary of the Philadelphia Academy of Natural Sciences and professor of invertebrate zoology there and in the University of Pennsylvania, aged fifty-six years.

WE regret to announce that among the victims of the war must be numbered M. Joseph Déchelette,

the eminent French archæologist, who was killed in action on the Aisne on October 4 last, at the age of fifty-three. His most important work was the "Manuel d'archéologie préhistorique celtique et gallo-romaine," which, unhappily, after the issue of two volumes, remains unfinished. He also, in collaboration with M. E. Brassart, published "Les peintures murales du Moyen âge et de la Renaissance en Forez." He was also the author of works on "L'oppidum de Bibracte," "Les fouilles du mont Beuvray," and "Vases céramiques ornés de la Gaule Romaine," for which he was awarded the medal of the Académie des Inscriptions et Belles-Lettres, and was appointed Chevalier of the Legion d'honneur. The death of this indefatigable archæologist, who was Conservateur of the Musée de Roanne, is a serious loss to French archæology.

ALTHOUGH much of the activity of research laboratories has been curtailed by the war owing to the patriotic action of the younger workers joining one of the Services, there remain a number of men and women carrying on research. In the subject of chemistry special difficulties have arisen because practically all very pure chemicals have hitherto been made in Germany. No very large stock of chemicals of this description is held by dealers, but researches either completed or abandoned have left a considerable amount in public and private laboratories in this country. In an attempt to render these stocks available to workers, the chemical department of the Imperial College, South Kensington, has started a bureau of exchange. Circulars have been sent to most of the university and college laboratories in the kingdom asking for lists of chemicals which are not in immediate use. Many lists have already been sent, and workers who are in urgent need of fine chemicals have been put into communication with those who have some to dispose of. It is hoped that any chemist who has not received the circular will communicate with the bureau giving a list of the materials he has available and also his requirements. As a rule, chemicals have been sold at cost price, but the financial arrangements are left entirely to the buyer and seller.

THE Medical Committee of the British Science Guild has done a good work by its resolution condemning a notorious anti-vivisection advertisement. The object of the advertisement was to prevent our soldiers from being protected against typhoid fever. If it be asked why any one of the many anti-vivisection societies should behave in this way, we can only say with Dr. Watts that "Satan finds some mischief still for idle hands to do." Anti-vivisection since August has been more or less short of work. Few of us are wanting to hear Pasteur called a charlatan; few of us are wanting anti-vivisection lectures and shops. Everybody is sure, who is capable of clear thinking, that our men of science are neither cruel nor stupid. But anti-vivisection cannot rest. It must find something to attack, something to abuse. Happily, by mere vulgar abuse, it does itself more harm than good; and we may well believe that quiet, level-headed, charitable folk are mostly by this time sick of the very name of anti-vivisection. We hope that it will be many years before anti-vivisection emerges out of the public disgrace which it has brought upon itself. The resolution of the British Science Guild is fairly outspoken, though it might justly have used stronger language. We hope that it will be very widely circulated; half a million copies, distributed through the country, would be none too many

THE second Indian Science Congress was held, under the auspices of the Asiatic Society of Bengal, in Madras, from January 14 to 18 last. There was a large and representative attendance of delegates from all parts of India, and the Hon. Surg.-Gen. Bannerman, I.M.S., who is president, delivered an address. According to the *Pioneer Mail*, the president insisted on the importance of a knowledge of biology to medical, sanitary, and scientific men working in the tropics. In the course of an appeal to wealthy Indians to endow medical research so that their poor but capable fellow-countrymen might have something to look forward to as a reward for scientific toil, Surgeon-General Bannerman said:—"There are plenty of subjects for research which ought to be endowed, chairs in our medical schools and universities that ought to be established all over India. Indian universities are at present mere skeletons. Will no one here take up the rôle of beggar and try to extract a few lakhs of rupees from the hoards of his wealthy and aristocratic friends?" Continuing, he said India wants to have, not only more chairs and lectureships, but also research scholarships or fellowships, established fellowships, available for a student and research worker, so that he may live in reasonable comfort and be able to devote his whole energy to work, without anxiety for those depending on him. In Madras a beginning has been made in this direction, owing to the enlightened liberality of the Raja of Pithapuram, who has presented 50,000 rupees for the expenses of an inquiry into diabetes, the fell disease which has carried off so many of the best brain workers in this part of India.

THE authorities of the Sheffield Public Museums are to be congratulated on the attention they are devoting to the collection and classification of documents and other records relating to local history. The systematic collecting of such records, as we learn from the report for the period from March, 1912, to March, 1914, was commenced at the High Hazels Museum in 1901, and afterwards extended to the establishment in Weston Park. The gift to the Public Library of the "Jackson Collection," rich in documents relating to Sheffield, has largely added to the value and interest of the series, which is now very extensive.

"PIGMY" stone implements form the subject of an article, with two plates, by Mr. C. Hartley in *Spolia Zeylanica* for December last (vol. x., pt. 36). Such implements occur locally in many parts of the world, including the British Islands, but they are nowhere more common than in Ceylon, where they occur in great profusion at Bandarawela. At least ten distinct types of these implements are recognised by the author, but axe-heads, together with saws, spear-

heads, and punches, are totally wanting. The question whether the pigmy and the ordinary Neolithic types of implements were manufactured and used simultaneously by a single race is, for the present, left without a definite answer.

IN *Man* for January Mr. Edge Partington supplies a graceful obituary notice of Mr. Norman Hardy, one of the best of our anthropological artists, who died about a year ago. His work began with illustrations for Dr. Beddoes's "Races of Mankind." He travelled widely in Australia and the Pacific, and some of his best drawings appeared in "The Savage South Seas" and "Women of all Nations." In 1907 he went to the Kasai with the expedition led by Mr. E. Torday, and his last work was the tracing of the wall paintings in the tombs of the Kings at Thebes. He was for many years an active member of the Royal Anthropological Institute, where the simplicity and kindliness of his nature, as well as his skill as an artist, won him the regard of many friends.

IN the proventriculus of the flea there is a valvular arrangement of chitinised spine-like epithelial cells which normally prevents the regurgitation of blood from the stomach during the act of sucking. A. W. Bacot and C. J. Martin have shown that in the plague-infected flea this mechanism is upset by a copious growth of plague bacilli which gets entangled among the spines, thus allowing the regurgitation of infected blood and the infection of a new host. In the fourth Plague Supplement of the *Journal of Hygiene* (January), this mode of transmission of plague by the flea is further elucidated by Bacot as the result of a study of serial longitudinal sections of infected fleas. Bacot also shows that in cool weather fleas are able to survive and to carry *B. pestis* for periods up to forty-seven days in the absence of any host, and afterwards to infect mice. He also shows that under experimental conditions bugs can transmit plague from mouse to mouse. Active healthy mice, however, eat the bugs, and an ingenious arrangement is described whereby the bugs are given shelter in saw cuts in the walls of wooden tubes in which the mice reside. Blood in the bug's stomach does not form so favourable a medium for the growth of the plague bacillus as in that of the flea, and it would therefore appear that the bug is not likely to be an active carrier of the infection under natural conditions.

THE June number of *Peru To-day* contains an article entitled "The Conquest of Verruga," by Mr. C. H. T. Townsend, entomologist to the Peruvian Government. The author gives a brief summary of the results of his investigations upon Verruga Peruana, a disease which causes great ravages and much mortality in the Andes, and he claims to have solved the problem of the etiology of the disease and to have proved conclusively that it is transmitted by a tiny fly, a species of Phlebotomus, to which he has given the name *P. verrucarum*. The fly is crepuscular and nocturnal in its habits, remaining hidden by day in caves or in crevices in rocks and in the walls of human habitations. Protection against the fly, and consequently against the disease, can be obtained by sleeping under muslin-nets, by applying ointments to the exposed parts of the body just before dark, and by the use in bedrooms of electric fans arranged in such a way as to direct strong currents of air towards the open windows through which the flies come in. The flies appear to breed in the canyons in which there is sufficient moisture to support a luxurious vegetation, but not in the dry canyons without vegetation; the life-history of the fly has not yet, however, been observed. The author believes that small rock-lizards constitute a reservoir for the disease, and that the flies, which feed naturally on the blood of these reptiles, transmit the virus from them to human beings.

ONE of the most difficult problems with which the museum curator has to deal is to find a satisfactory method of presenting fishes for public exhibition. Stuffed specimens are an abomination; spirit specimens, however cunningly painted, are worse; and the ordinary type of cast is altogether wanting in sharpness and definition, owing to the external layer of plaster being disintegrated by the mucus from the skin during the process of setting. For the latter defect Messrs. Gill and Fletcher, of the Hancock Museum, Newcastle-on-Tyne, claim, in the February number of the *Museums Journal*, to have found an effectual remedy, and, judging from the figure of one ready for painting, their casts certainly seem to be a great improvement on the old-fashioned type. A continuation of the article is to follow.

"AN Appreciation of Theodore Nicholas Gill," illustrated by a portrait in academical robes, is the title of an article communicated by Prof. A. Lucas to the January number of the *American Museum Journal*. Dr. Gill, who died in September last, is regarded by the author as having possessed an extraordinary grasp of various branches of zoology, and this despite a natural indolence, which led him to forgo personal investigation, and to rely largely on the work of others as a basis for his own generalisations. Among the latter "were the recognition of the claim of the elasmobranchs to a position of the 'highest' rank, and of the purely artificial nature of the groups Carinatæ and Ratitæ among birds." As regards the latter item, his views, which are undoubtedly correct, were diametrically opposite to those of the late Prof. Alfred Newton.

MR. S. TABER discusses the earthquakes of the Charleston district in the Bulletin of the American Seismological Society of America (vol. iv., 1914, pp. 108–60). The earthquake-series of 1886 was preceded by a prolonged interval of repose, only eight shocks being recorded during the previous two centuries. Since August, 1886, the decline of the after-shocks in frequency has been gradual though fluctuating, 318 being reported from 1886 to 1897, and 77 from 1898 to 1913. The shocks are most frequent in September and rarest in April. Mr. Taber considers the relations between earthquake-frequency and various meteorological and astronomical factors. He finds that shocks are most frequent after long-continued periods of local rainfall, when the pressure of the underground water is relatively greatest on the north-

west side of the originating fault, and when the barometric gradient is directed to the south-east. On the other hand, he can discern no relations between earthquake-frequency and changes in barometric pressure or the tides of the neighbouring coast or sunspot maxima or lunar periodicities.

DR. E. WARREN gives, in the Annals of the Natal Museum for September, 1914 (vol. iii., pt. 1), a full and well-illustrated description of a remarkable plumularian hydroid zoophyte discovered on living oysters in 1911 on the coast of Pondoland, of which a preliminary notice has already appeared. Although nearly allied to those species of Plumularia with hydrothecæ arising from the main stem, it differs by the presence of pinnules on some of the pinnæ, thereby approaching Schizotricha, in which nearly all the pinnæ are thus furnished. It is therefore provisionally included in that genus, as *S. simplex*. Its main claim to interest is, however, connected with its reproduction, which is of a unique type. Instead of the egg being furnished with a yolk-supply sufficient to maintain the young until capable of foraging for itself, as in the great majority of invertebrates, "the egg remains quite small and is never provided with a perceptible quantity of yolk, but segments, and development takes place, in a kind of maternal placental tissue which supplies the embryo with food during the whole development." In another article in the same issue Mr. H. C. Burnup reviews the minute pyramidal striated S. African land-snails of the genus Ennea, with descriptions of new species and races.

THE recently received number of the *Philippine Journal of Science* (vol. ix., sec. c., No. 4, August, 1914) contains two papers by Mr. E. D. Merrill, in which no fewer than ninety-three new species of Philippine plants are described. Forty-three were collected by Wenzel in the island of Leyte, whose collections have already added very largely to a more complete knowledge of the rich flora of the archipelago. The other new species come from various islands, and are included in Mr. Merrill's tenth and concluding instalment of new or note-worthy Philippine plants.

STEPS are being taken to secure the trade in senna in British hands. The plant from which the finest quality of senna is obtained grows in the Sudan, where the leaves and pods are collected and dried by natives, and sold to collecting agents for export. At one time this trade was entirely British, and the produce was sold through London, but afterwards it passed into German hands. The Imperial Institute has been in communication with the chief British importers and with the Egyptian Government, and the export of senna from Egypt has now been prohibited except to the United Kingdom and France. British firms are making arrangements direct with the native growers, which should not only restore the trade to this country, but lower the price and secure the purity of the supply.

MR. W. G. REED, of the Department of Geography of the University of California, presented a paper, "Climatic Provinces of the Western United States," to the Cordilleran Section of the Geological Society of America, and this paper has been printed in the Bulletin of the American Geographical Society (vol. xlvii., No. 1). After discussing various classifications, such as those of Supan and Herbertson, Mr. Reed advances a new classification based upon considerations of rainfall, temperature, and relief. The area from the coast to the Rockies is divided into four main regions, a northern and southern coast strip divided at 40° N., and a northern and southern "rain-shadow" strip divided about 43° N. The coast strips are subdivided mainly for topographical reasons into smaller divisions. The main divisions are, on the whole, just, since the whole rain-shadow area is characterised by a relative raininess in the month of May, which is lacking along the coast strip, but it seems probable that Mr. Reed has not made sufficient allowance for two facts regarding the coast strip. In Washington the month of maximum raininess is November, and the further south one goes the later in the season does this maximum occur, and at the same time the relative raininess shows considerable increase. Probably these facts would have commanded attention had Mr. Reed made rainfall graphs in a generalised form for his subdivisions instead of taking single places as types.

IN the *Philosophical Magazine* for January Mr. A. E. Young obtains formulæ for the effect of stiffness and stretching on the form of a suspended wire or tape. The importance of these investigations largely depends on their application to the steel tapes and other substitutes for the old chain in modern surveying.

IN a paper communicated to the Proceedings of the Cambridge Philosophical Society (xviii., 2), Dr. Norbert Wiener proves in a short note that the shortest curve dividing a given area in a given ratio consists of a circular arc or a number of such arcs, each terminated on the boundary of the area. The paper was originally intended to be a joint article by the author and Dr. Szász, and to contain a proof that the shortest curve dividing any scalene triangle in a given ratio is a circular arc with the most acute apex as centre. Owing to the war this has not been possible, but the results are so self-evident to an average English mathematician that no advantage would have been gained by a further discussion in print. The simplest plan is to replace the author's words, "dividing an area in a given ratio" by "cutting off a segment of given area from a given closed figure." The proof that the portion of the curve joining any two points on it is an arc of a circle is found in most text-books, and the reader should have no difficulty now in seeing, further, that the arc in question must meet the boundary at right angles (unless it passes through a re-entrant angle), whence the property which Dr. Szász intended to prove follows immediately.

THE December number of *Terrestrial Magnetism and Atmospheric Electricity* contains the results of the determinations of the deviation of the compass made on the magnetic survey ship *Carnegie* during her voyages from Brazil to St. Helena in 1913, and from

Norway to Iceland and thence to New York in 1914. The published charts of the South Atlantic all show the westerly deviation too small by a degree, or in one or two cases nearly two degrees, in the region 30° S., 24° W. Between Norway and Iceland the charts show deviations to the west 2° or 3° too small, between Greenland and Labrador they are 1·5° to 2° too high, and the British chart is nearly 3° too low at 55° N., 52° W. Along the east coast of America there are no serious errors in the charts as at present issued, although the U.S. chart is the least accurate of the three available.

SCIENTIFIC PAPER No. 231, issued by the Bureau of Standards, is devoted to a determination of the specific heat of copper over the temperature range 10° to 50° C., by Mr. D. R. Harper, of the bureau. The specimen of copper consisted of 50 metres of very pure annealed wire of 2·5 millimetres diameter wound into a compact coil 10 cm. diameter and 10 cm. long, with thin sheets of mica to maintain the insulation. The coil was suspended by silk threads in a vacuum vessel, and heated by an electric current sent through it. The current and potential difference at two points near the ends of the wire were determined by a potentiometer method. The standardisation of the wire as a resistance thermometer was carried out by the bridge method with the help of two standard platinum resistance thermometers. During the determination of specific heat the copper wire served as test specimen, as calorimeter, and as thermometer. The final result for the specific heat is $0{\cdot}0917+0{\cdot}000048(t-25)$ calories per gram degree.

A COPY of a "Biographical Sketch of James Smithson" has been received from the Smithsonian Institution at Washington. It is an abridgment of a chapter on James Smithson by the late Dr. S. P. Langley in "The Smithsonian Institution, 1846–1896: the History of its first Half Century." The founder of the institution was born in 1765. He graduated at Pembroke College, Oxford, in 1786. At a time when the study of physical science was almost unknown in the University, he appears to have conceived already that devotion to scientific research which characterised all his future life. He was admitted as a fellow of the Royal Society in 1787, his recommendation being signed, among other men of science, by Cavendish, who became an intimate friend. Arago, too, was added to his friends later, and he was a correspondent of Black, Banks, and Thomson. Smithson died at Genoa in 1829. His will provided that in the event of the death of his beneficiaries, his property should pass to the United States of America "to found at Washington, under the name of the Smithsonian Institution, an establishment for the increase and diffusion of knowledge among men." Thus his dearest wish that "my name shall live in the memory of man when the titles of the Northumberlands and the Percys are extinct and forgotten" seems likely to be accomplished.

AN electric tramway—described in *Engineering* for February 19—has been constructed recently to connect Osaka, which is the foremost industrial and commercial centre of Japan, with the town of Nara. The line is 19 miles long, and the steepest gradient is 1 in 30. The cars, which accommodate 100 passengers, and weigh 32 tons when fully loaded, are mounted on two trucks equipped with 160 horse-power motors. It was desired to keep the line as straight as possible, and the route selected for this reason involved the construction of four tunnels, the most important of which is the Ikoma tunnel. In cross-sectional area, this tunnel is the largest in Japan, and its length, which is 11,088 ft., is only exceeded by that of the Sasago tunnel on the Imperial Japanese Government Railways. The tunnel penetrates the Ikomayama Mountains, which rise to a height of 1500 ft. above sea-level. No shafts were used in the construction; work was commenced from both ends simultaneously in July, 1911, and the tunnel was completely finished in April last.

THE publishers of the *Revue générale des Sciences pures et appliquées* (Librairie Armand Colin, 103 Boulevard Saint-Michel, Paris, 5e), have issued general indexes of the contents of the first twenty-five volumes (1890–1914) of our contemporary. There are two indexes; one is a subject index arranged under twenty headings according to the branch of science with which the articles are concerned, the other is an index arranged under authors' names. These excellent indexes will save readers much time and trouble when anxious to trace an article published several years ago. The price of the publication is 3·50 francs.

MESSRS. G. BELL AND SONS, LTD., announce the publication at monthly intervals of sets of "Test Papers in Mathematics" for use in secondary schools. The series will be begun in May, and the first three sets to be issued will be compiled respectively by Mr. G. W. Palmer, Prof. T. P. Nunn, and Mr. H. C. Beaven.

OUR ASTRONOMICAL COLUMN.

COMET NEWS.—A telegram from Prof. Strömgren, dated February 19, announces the discovery of an object by Miss Leavitt as Metcalf's periodical comet (1906 VI.). The discovery was made on February 9 at 12h. 33·7m. Harvard mean time, the position of the object being given as R.A. 8h. 30m. 37s., declination $-1°\ 38'\ 42''$. No idea of the brightness of the comet is given, but as perihelion was passed last June the object may be considered very faint.

With regard to Mellish's comet, a further telegram gives details of an observation made at the Tashkent Observatory, Russia. On February 15, at 17h. 31·0m. Tashkent mean time, the comet's position was R.A. 17h. 9m. 11s., declination $+2°\ 47'\ 43''$.

A numerous and interesting series of observations of Delavan's comet (1913*f*) is contained in the latest issue (November) of *L'Astronomie*. M. Quènisset contributes several photographs taken in August and September last illustrating the development of the tail. Of special interest perhaps are the observations of M. H. Law, of Hörsholm, Denmark. This observer made a number of estimations of the brightness of the comet, and found a distinct fluctuation in magnitude in a period of about three weeks. The magnitude of this change is illustrated in a table and

diagram which he publishes in his communication. He shows further that this fluctuation in brightness was closely associated with the direction of the comet's tail in relation to the sun.

MAGNITUDE ERROR IN PARALLAX DETERMINATIONS.—In the January number of the *Astrophysical Journal* Prof. Kapteyn describes a very ingenious device for avoiding systematic error depending on magnitude in the measurement of stellar photographs. If this error could be removed, Prof. Kapteyn does not see why it should not be possible—in the average of a sufficient number of observations or of a sufficient number of stars—to be able to reach almost any desired accuracy. The method of removing the error looks surprisingly simple, and seems to contain a complete solution of the problem. The idea is to obtain stellar photographs on which the stars of all different degrees of brightness are represented by perfectly equal images. To secure this two photographs of the same star region are required. The first photograph is taken when the plate is placed slightly within the principal focal plane of the telescope. On this plate it will be found that after development all the stars will be represented by circles of the same diameter but of different densities depending on the brightness of the stars. This negative is now replaced in the telescope exactly in its former position, the cones of light of the several stars falling on it as before. A second photograph—the main plate—is now taken *in focus*. It will be seen that the light of a bright or faint star before it can reach the main plate will have to pass through a dense or faint film screen respectively. In this way the images are brought nearer to equality. At present only one test has been made, and that not under the best conditions, but the results are certainly very promising.

RADIOMETRIC MEASUREMENTS OF 110 STARS.—A comparison of stellar radiometers and radiometric measurements on 110 stars is the title of a paper by Mr. W. W. Coblentz, which appears in the Journal of the Washington Academy of Sciences for January 19 (vol. v., No. 2). This paper, as stated, is only a brief summary of one to appear in the Bulletin of the Bureau of Standards. Reference is first made to experiments which show that there is little difference in the radiation sensitivity of stellar thermo-couples constructed of bismuth-platinum and thermo-couples of bismuth-bismuth plus tin alloy, which have a 50 per cent. higher thermo-electric power. A stellar thermocouple was found more sensitive than a bolometer, and greater improvements are expected in the former than in the latter. Measurements were made of the bright and dark bands of Jupiter, the rings of Saturn, a planetary nebula, and 105 stars. Quantitative measures were made on stars down to 5·3 magnitude, and high-grade qualitative measures on stars down to 6·7 magnitude. Red stars were found to emit from two to three times as much total radiation as blue stars of the same photometric magnitude. Measurements were also made of the transmission of the radiations from stars and planets through an absorption cell of water. Of the total radiation emitted blue stars had about twice as much radiation as yellow stars, and about three times that of red stars in the visible region of the spectrum. The object of the investigation was primarily to form some estimate of the sensitivity required to be able to observe the spectral energy curves of stars, and the author was led to conclude that by using a 7-ft. mirror and increasing the sensitivity of his present radiometer twenty times the required sensitivity could not only be reached but was possible.

DETERMINATION OF TIME.—Under the title "Determinación de la Hora por Alturas absolutas, correspondientes é iguales de distintas Estrellas," Sr. Carlos Puente, of the Astronomical Observatory of Madrid, has published a very full account of the best-known methods of determining time by means of altitude observations of the sun and stars. The work consists of four chapters, of which the first deals briefly with the general principles of astronomical time, with its continuous record and methods of transmission. The other chapters discuss in detail the theory and practice of time determination, first by the observation of absolute altitudes based largely on a method developed by Prof. Donner, of Helsingfors, next by equal altitudes of the same object on both sides of the meridian, and thirdly by the observation of two stars at the same altitude. Each method is illustrated by practical examples, and the accuracy of the results is estimated. At the end of the work a number of useful numerical tables are given.

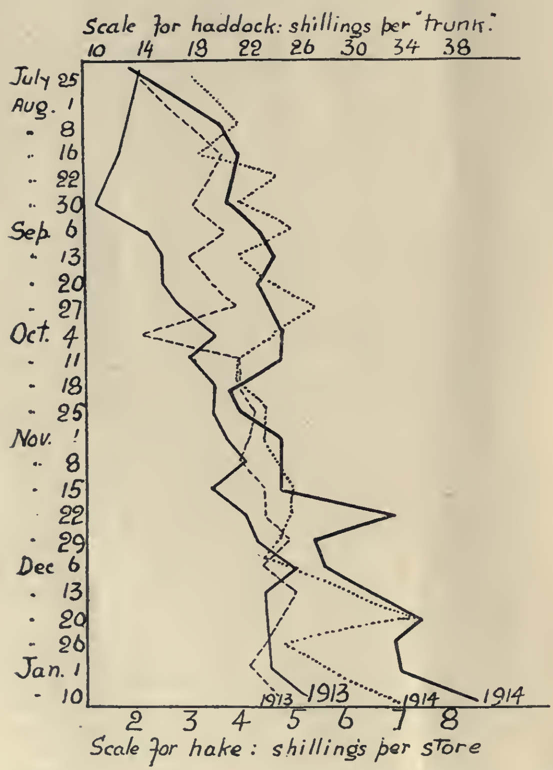
THE SEA FISHERIES AND THE WAR.

AFTER some six months of the war we can attempt to make estimates of its effects upon British industries, and anticipations of the future, with some degree of confidence. This is fairly easy with respect to the fisheries: the industry is being closely studied, and, unlike most, it is the object of both scientific and statistical investigation. The situation at present is one of extraordinary interest, even from a strictly scientific point of view. The enormous restrictions on fishery constitute (unhappily) an experiment on the grand scale, and since the scientific study of the industry has not altogether been allowed to drop interesting results should be forthcoming. The statistics of the next year or two will be of much value, in showing to what extent commercial exploitation of the North Sea depletes the natural resources of that fishing area. Amidst the distractions of the present time this question is not being neglected.

The industry itself has naturally suffered to a great extent. At the beginning of the war it was almost completely disorganised. About the beginning of August practically the entire Grimsby trawling fleet was laid up, and deep-sea fishing had almost been suspended; but at the beginning of October 500 Grimsby vessels had resumed fishing. Exports of both fresh and cured fish fell off to a great extent because of the loss of German trade. That country took more than 90 per cent. of the fresh fish exported from Britain, and about 43 per cent. of the pickled herrings. Russia took about the same proportion of our cured fish. This trade ceased, and at the beginning of August the stock of cured herrings held in Britain was estimated at 300,000 barrels, or about 37,500 tons in weight. How this part of the fishing industry has been affected since then it is still impossible to say. The quantities of fish landed also underwent a great decrease; in September, for instance, this decrease was about 38 per cent. of the quantity landed in the corresponding month of 1913. This falling-off has been due to several causes. A considerable number of trawlers were commissioned as mine-sweepers and patrol vessels—how many it is impossible to say. On August 18 the Navy List contained the names of 107 vessels, and two months later at least 200 of the total Grimsby fleet of 600 ships had been commissioned, or were waiting to be so. In itself this withdrawal of the best vessels, for defence purposes, led to a marked diminution of fishing; and since a large number of the best men were also taken there was a great shortage of officers, so that many

other vessels were laid up. Restrictions, by the Admiralty, on the movements of trawlers, also affected the industry, though as time went on it became evident that some of these restrictions were unnecessary. The positions of the mine fields became known, since it was seen that these had been placed (with characteristic ingenuity) near places from which merchant vessels making for English and Scottish ports took final bearings. The mine danger did not, it appears, frighten the skippers of trawlers very greatly, and the Admiralty even threatened "disciplinary measures" on skippers neglecting their instructions and taking their ships into danger. In fact, the danger of mines was less than had been anticipated. At the end of September eight British steam fishing vessels had been destroyed by mines and twenty-four had been sunk or captured by the Germans. At the end of the year seven mine-sweepers had been lost with fifty-nine casualties, forty men being reported as killed or missing.

Fish became scarcer and dearer, though less so than had been anticipated. The chart below shows the mean wholesale prices[1] of two species of fish (haddock and hake) at Billingsgate Market during each week of the last five months of 1913 and 1914:—



The continuous thin line refers to haddock, and to the year 1913. The continuous thick line refers to the same fish sold in 1914. The broken line refers to hake of 1913; the dotted line to hake of 1914.

Haddocks are essentially North Sea fishes, the percentage taken from that area being about 61 per cent. Hake are southern fishes, and are taken mostly to the south-west of Ireland and towards the Bay of Biscay. There are always violent fluctuations in prices of fish due to the effect of gales on the supply, but apart from these the price rises towards the end of the year. The rise of price over that of 1913 is fairly considerable in the case of the North Sea fish, and much less so in the case of the southern species. But it is far less than anyone might have anticipated at the beginning of August. There was, in fact, a general tendency to keep prices as nearly normal as possible, and it was also seen that the public were certainly not prepared to pay highly exaggerated prices for fish.

The shortage of skippers and mates of fishing vessels is far from creditable to the country. It was pointed out in NATURE some time ago that there was great need for the education and technical training of deep-sea fishermen, and that facilities did not exist. The trawler section of the Royal Naval Reserve was established in 1911, and it was evident two or three years ago that both the Board of Trade and the Board of Education were alive to the necessity for the better technical instruction of deep-sea fishermen. The local machinery was, however, wanting, and the efforts that have been made since 1911 to provide this have been most unsatisfactory. Now the pinch has come. It is no secret that a much larger number of trawlers would be employed in defence operations if officers were obtainable.

The scientific investigation of the sea-fisheries has not been abandoned, but its most important side, the work at sea, has practically been discontinued. This has been unavoidable, and if the organisations in existence before the war can only be kept going a great recrudescence of activity may be expected when peace comes. It must be admitted that the probable defection of Germany from the international investigations will be a great loss. That country has made few original and fertile discoveries in fishery science[2]—it is to Norway that we are principally indebted. But Germany has characteristically carried on routine research in a very thorough manner, and we may miss this in the near future. May we hope that a result of the war will be the determination of Britain to make this research with the honesty and efficiency represented by the German publications. We are only now realising how very painstaking was the German scientific and industrial campaign in the interest of her developing sea fisheries. It was stated a few weeks ago in NATURE that meteorological science had been pressed into the service of warfare by Germany. That has, probably, also been the case with some of the purely scientific results obtained during the investigation of the deep-sea fisheries; and it is a manifestation of *kultur* that we might very well imitate in the future, in peaceful interests.

J. J.

[1] The figures are summarised from the weekly lists published by the *Fish Trades Gazette*.

[2] Perhaps Hensen's quantitative Plankton methods are the exception to this statement.

METEOROLOGICAL CHARTS FOR THE MEDITERRANEAN.

PROF. L. MARINI has contributed to the *Annali Idrografici* of the Hydrographic Institute at Genoa a brief descriptive account of the distribution of pressure and wind in the Mediterranean region, together with tables of averages and charts based upon them. The publication is intended primarily for the use of the seafaring man.

The tables of pressure contain normal values for the four seasons and the year for 174 places. The values are given in millimetres, but it is not stated in the tables or on the charts if the gravity correction has been applied nor to what period the values refer. The values are given to two places of decimals which implies a far greater degree of accuracy than would be possible with the instruments used at most of the places; to say nothing of the differences arising from the exposure of the instruments, the reduction to sea-

level, and the hours of observation. The hours are not given, nor the heights of the places above sea-level, nor the months included in the seasonal periods. All these things may be of no interest to the sailor who will be expected to test the charts by his experience, but they are vital to the utilisation of the author's work by other meteorologists either for research or for incorporation in charts for wider areas.

The tables of wind give (1) for sixty-six places the "mean direction" of the wind for each season and the year, computed probably from Lambert's or some similar formula; (2) for seventeen regions of the Mediterranean the frequency of light, moderate, and strong winds for sixteen points of the compass, and the number of calms, also for each season and the year. The regions are roughly about 200 miles square.

The charts have been drawn with a great deal of care and the delineation is clear and attractive. They are on a relatively large scale, and consequently are folded into the book, which makes it troublesome to consult them, but the reader will feel that his trouble is compensated by the ease of seeing rapidly the general features and the details of the meteorological distribution. It may be remarked, however, that charts of normal distribution intended for the seafaring man ought to be printed on good linen-backed paper if they are to be used and not folded and put away in a drawer until a new set is received. Indeed, it is doubtful if the ordinary navigating officer will consult meteorological charts regularly until they are made part and parcel of his everyday equipment by being printed on his navigating charts.

Prof. Marini's charts showing the wind roses for the seventeen regions referred to, are very interesting, bringing out most clearly the relatively stormy winter conditions of the western Mediterranean and the great preponderance of winds from nearly due east or due west between Sardinia and Gibraltar. No wind rose is given for any part of the Adriatic. E. G.

LORD KELVIN'S WORK ON GYROSTATICS.[1]

I.—*Gyrostatic Experiments in the Glasgow Classroom.*

WHEN I was a student, and afterwards when I was an assistant at Glasgow, Lord Kelvin lectured to his ordinary class twice a week, when he was not called away, and his subject was dynamics. About the middle of the session gyrostats made their appearance on the lecture-table, and we had wonderful gyrostatic experiments which filled us with delight, and gyrostatic questions in the weekly class-examinations which were equally productive of dismay. These gyrostatic questions, like many of our exercises in natural philosophy, were often of a numerical character. It is always a good thing to get down to numbers, and it is a most healthful mental discipline to be forced to "get the units right." Our equipment for the solution of these problems was of the slightest, for Lord Kelvin was himself so keenly absorbed in observing the behaviour of the apparatus, that he rather frequently forgot to give us the full dynamical explanation of the curious evolutions which we beheld. I could follow the process of composition of angular momenta, and could see that the axis of resultant angular momentum turned at that rate; but why should that also be the rate of turning of the axis of figure? That was my special difficulty, and it was only afterwards, when I got the idea of steady motion, and saw how the general equation is obtained and how it breaks down into the conditions for steady motion, that the matter became clear. Then I found, moreover, that in the general case there are two possible rates of turning. It is a good thing to stimulate the curiosity of a student to make him find out things for himself: it is also an excellent thing to anticipate his difficulties to some extent, lest he grow weary and faint by the toilsome dynamical way.

The lectures that we had were undoubtedly most interesting and suggestive, though they were not perhaps always directed to the more prosaic topics which formed the staple matter of the degree examination questions for ordinary students. The first experiment made was always that of the equilibrium of this nearly egg-shaped piece of wood, which, scientifically described, is a homogeneous prolate ellipsoid of revolution. Its surface may be imagined to be generated by the revolution of an ellipse about its longer axis. (The diagram, Fig. 1, shows a really egg-shaped solid.) I lay it on its side, and we see that in that position it is stable for fore and aft inclinations, "pitching" I may call the motion, and in indifferent equilibrium for port or starboard displacement, or rolling. This is, of course, all without spin.

If, however, I apply to the solid, as it lies on the tray before me, an impulsive couple with my fingers, so as to make it rotate about one of the minimum diameters (that is, of course, a diameter about which the moment of inertia is a maximum), the solid shows that when spin is applied the equilibrium is unstable.

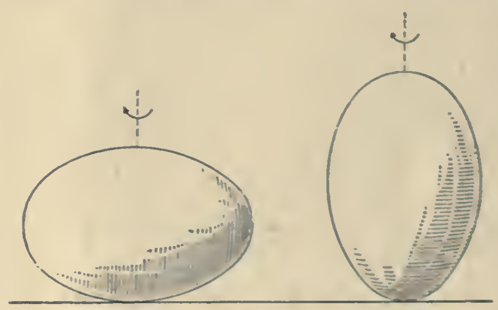


FIG. 1.

The ellipsoid at once sets itself on one end, and then rotates in stable equilibrium with the long axis nearly vertical. This is a very remarkable result. The centre of gravity has been raised, and the equilibrium is now stable. The spin has altered the conditions of equilibrium completely.

Of course, it was pointed out to us that all these phenomena are well shown by the ordinary spinning-top, spun by the unwinding from it of a string when the top has been skilfully thrown from the hand. Schoolboys are not encouraged now (indeed they are *dis*couraged by prefects and other important personages) to play with tops and marbles, and thus many phenomena of spin and collision which some of us used to observe are missed. The swaying round of the axis of a top when rising just after spin to the "sleeping" position, and the similar conical motion of the axis when the top is about to fall, give examples of precessional motion, of, in fact, the astronomical phenomenon called precession of the equinoxes.

Precession was illustrated by the interesting old model of a terrestrial globe which I have here (Fig. 2). You see that the globe is weighted so that a pin projecting from the north pole rolls round a ring, that is, a narrow cone fixed in the earth rolls in the inside of a cone fixed in space. These cones have their vertices at the earth's centre, the axis of the fixed cone is perpendicular to the ecliptic and its semi-angle is $23^\circ\ 27'$, that is, an angle equal to the obliquity of the

[1] Abridged from the Sixth Kelvin Lecture, delivered at the Institution of Electrical Engineers, on January 28, by Prof. A. Gray, F.R.S.

ecliptic. On this ring, which represents the ecliptic, you have the intersections with it of the earth's equator—that is, the equinoxes—and so, as the earth turns, the two intersections move along the ecliptic, the equinoxes precess. The earth, in fact, is a top on which we happen to live, the spin is one turn in 24 sidereal hours, and the conical motion is completed in a period of 26,000 years (Fig. 3). One of our problems was to calculate the diameter of this pin for the earth, or, as it was sometimes put, to find the diameter of the north or south pole! If I remember aright the diameter is about 21 inches.

These were our first gyrostatic experiments and illustrations. I must not omit to mention that the spinning of the ellipsoid was attempted also with each of two eggs, and that with one the experiment always succeeded, and with the other always failed. The reason of this failure and success was interesting; and although some students laughed at the experiment, it nevertheless arrested the attention of all. The contents of one egg were a viscid liquid, the contents of the other had been subjected to a process of coagulation by prolonged exposure to an elevated temperature. In other words, one egg, the one that would not spin on end, was raw, the other had been boiled hard. I now repeat this experiment, which is the scientific solution

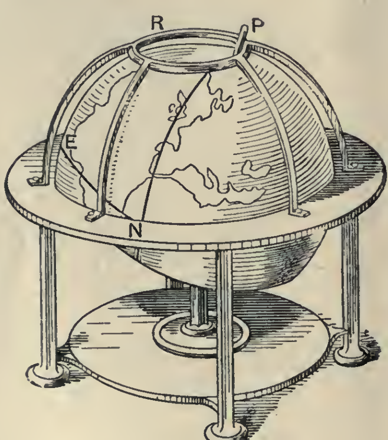

FIG. 2.

of the famous problem of Christopher Columbus, to make an egg stand on end.

It is very easy to show, on principles which I hope to explain later, why the solid prolate ellipsoid, the piece of wood, or the hard-boiled egg, sets itself on end when it is spun about one of the shortest diameters; it is not at all easy to show why the raw egg does not.

I shall now say something of Lord Kelvin's papers and work on gyrostatics, taking the various topics more or less in chronological order.

II.—*Dynamical Theory of Rotation of Plane of Polarised Light.*

The first paper in which Lord Kelvin dealt with what may be regarded as a gyrostatic problem is that published by him in the Proceedings of the Royal Society,[2] entitled "Dynamical Illustrations of the Magnetic and the Heliçoidal Rotatory Effects of Transparent Bodies in Polarised Light." He does not in that paper use the term "gyrostat" or "gyroscope," but the equations which are arrived at in the discussion of the dynamical illustrations referred to are in form essentially of the kind which he afterwards called gyrostatic.

The fundamental idea of this paper is one which he developed a good deal in later papers and, from time to time, in his lectures to his students. It is that the rotation of the plane of polarised light transmitted through a solution of sugar or tartaric acid, or across a plate of quartz cut at right angles to the axis of the crystal, is to be explained by a helical structure of the medium; while what appears at first sight to be the exactly similar rotation of that plane, by passage of the light through a piece of heavy glass along the lines of force of a magnetic field, is due to rotational motion already existing in the medium and compounded with the motion produced by the wave of light.

Think (as I heard him once say) of a transparent elastic medium full of little helical hollows of the order of 1/40,000 in. in dimensions, having all their axes turned the same way, so that to an observer looking along them the helices are all right-handed or all left-handed, or at least are preponderatingly in one direction or the other. Such a medium would have the property of transmitting, in the direction of the axes of the helices, waves of torsional displacement at different speeds according as the torsion is right-handed or left-handed.

On the other hand, let us think of a transparent elastic medium in which are embedded in a homogene-

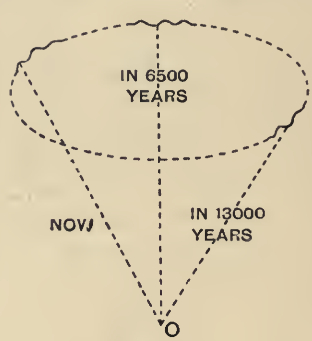

FIG. 3.

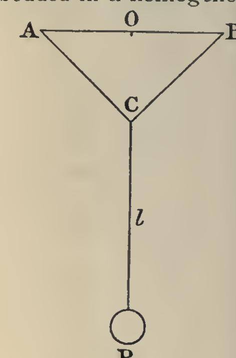

FIG. 4.

ous manner innumerable particles describing circular orbits, all of which, or a majority of which, face the same way, and are traversed by the particles in the same direction round. Now let a wave of turning motion of the medium be propagated in one direction or the other, parallel to the axes of the circles. A wave-motion of a certain rapidity in one direction round, say that of the motion of the particles in the circular orbits, will call for the same centreward force, applied to the particles by the medium, as a motion of greater rapidity applied in the contrary direction round. Thus oppositely directed circular motions will, for the same displacements of the medium, have different rapidities of turning (in planes perpendicular to the direction of propagation of the wave); the corresponding waves will travel at different rates, and one will gain on the other.

The illustration proposed was a double pendulum. A cord (see Fig. 4) is attached at the two ends of a horizontal rod A B, and to the middle point of this cord is fastened a simple pendulum, of length l as indicated. The distance of the bob from the rod is l', that is $l+OC$. The rod is made to turn with uniform angular speed ω about a vertical axis through its middle point O. The cords are supposed to be of negligible mass and quite flexible, and the bob is a massive particle.

[2] Proceedings of the Royal Society, vol. viii, p. 150, 1856.

If ω were zero we should have a pendulum the period of which is $2\pi\sqrt{l/g}$ for vibrations in the plane of the paper supposed vertical, and $2\pi\sqrt{l'/g}$ for vibrations at right angles to that plane; and the motion of the bob in the most general form would be compounded of two such oscillatory motions.

When the motion, with ω not zero, is referred to two rectangular horizontal axes of x and y through O, which revolve with the rod, the equations of motion of the bob are

$$\ddot{x}-2\omega\dot{y}+\left(\frac{g}{l}-\omega^2\right)x=0,$$

$$\ddot{y}+2\omega\dot{x}+\left(\frac{g}{l'}-\omega^2\right)y=0,$$

where x, y are the co-ordinates of the bob and $\dot{x}$, $\dot{y}$ their time rates of change, and $\ddot{x}$, $\ddot{y}$ are the accelerations corresponding.

The second terms on the left-hand sides of these equations, $-2\omega\dot{x}$, $2\omega\dot{y}$, are in form what were called afterwards by Lord Kelvin gyrostatic terms, and the conditions for the existence of real periods of oscillatory motion in the general case, depending, as the reality of these periods does, on the value of ω, gives us an idea of what he termed in that connection "gyrostatic domination."

In an Appendix to this lecture (see *Journal*, I.E.E.) will be found a synopsis of the solution of this interesting case of motion with some modifications of notation and mode of presentment. The reader may refer also to the original paper.[3]. It is reprinted as Appendix F of Lord Kelvin's "Baltimore Lectures."

The main results may be expressed as follows:—

(1) If a long straight rod, which is unequally elastic in two rectangular directions, or is of unequal diameters in these directions, if of uniform elastic quality (a rod of elliptic section, for example), be rotated rapidly about its axis, and vibrations be maintained in a fixed transverse direction at one end, waves of rectilinear vibration, the direction of which slowly turns round as the wave advances, will be propagated along the rod.

(2) Let the transverse elasticity of the medium (which, to fix the ideas, may be taken, as has already been suggested, as a long straight rod, along which waves of transverse displacement are propagated in the direction of its length) vary with the direction of the transverse, so that it has maximum and minimum values in axial planes at right angles to one another. If this rod be slightly and uniformly twisted about its axis, these planes become heliçoidal or screw surfaces. Think now of a line in space parallel to the axis of the rod. This line will intersect either of these surfaces at points the successive distances apart of which are all equal to the step s of the screw. If the rod be turned about its axis as a whole, each point of intersection will move along the line at a speed v which depends on the rate of turning.

Let a rectilinear vibration be kept applied at any cross-section, say one end, and let the rod be rotated about its axis in the proper direction, and at such a rate that the speed v just specified is equal to the velocity of propagation of the wave produced by the applied vibration. The result will be that a series of waves of rectilinear vibration will run along the rod, without any turning of the plane of vibration in space. In order that the rotation may be rapid, it is necessary that the wave-length, a say, should be many times the step s of the screw.

According to our notation the period of vibration is $2\pi/\mu$, and therefore the velocity of propagation of the waves is $a\mu/2\pi$. But if s be the step of the screw, and ω denote as before the angular speed of rotation, the value of v is $\omega s/2\pi$. Hence we must have $\omega s=a\mu$ or $\omega=a\mu/s$.

The effects of the twist and rotation thus exactly balance one another. The latter (see Appendix) gives a rotation of amount $\frac{1}{4}\pi\lambda^4/\omega^3\mu$ in a wave-length, or a complete turn in $8\mu\omega^3/\lambda^4$ wave-lengths. Hence the effect of a single turn of twist in a length s is equivalent to that of rotation in $8\mu\omega^3/\lambda^4$ wave-lengths.

The dynamical illustration is thus applicable to all the cases of turning of the plane of polarisation of light. There is one point of difference, however, which renders a rotational medium more truly representative of the magneto-optic turning, and is decisive as between a rotational and a structural explanation of the different phenomena. A beam of plane polarised light which has traversed a piece of heavy glass in a magnetic field will, if it be reflected and sent back through the medium, have the turning of the plane doubled by the backward passage, while backward passage through quartz or a sugar solution annuls the turning produced by the forward passage. These facts point, as Lord Kelvin repeatedly urged in his teaching, to a rotational explanation of the magneto-optic effect and to a structural explanation for the other.

III.—*Precessional Motion of a Liquid.*

About twenty years later gyrostatic problems attracted Lord Kelvin's attention in a very special way. From 1875 onward for several years he was much occupied with many things; for instance, he transacted much business connected with submarine cable instruments, eclipsing lights for lighthouses, and compasses and sounding machines. I was one of his assistants, and remember how busy we all were. For the two years from 1875 to 1877 there are set down in the list of his papers four on the subject of gyrostatic action, but of these only two were ever printed, the first and the last. The former was entitled "Vibrations and Waves in a Stretched Uniform Chain of Symmetrical Gyrostats,"[4] the latter "On the Precessional Motion of a Liquid."[5] I shall first give some account of the latter paper, because it contained descriptions and illustrations of gyrostats and gyrostatic action, and shall then return to the former.

The circumstances in which this paper was written were interesting. In 1875 Lord Kelvin (then Sir William Thomson) visited America as one of the judges of Group 25 (Scientific Instruments) of the Centennial Exhibition at Philadelphia. He then met and conferred on scientific questions with some of the most eminent natural philosophers of the United States.

A conversation with Simon Newcomb, in Joseph Henry's drawing-room in the Smithsonian Institution at Washington, led him to doubt the legitimacy of some of his own conclusions regarding the effect of elastic yielding of the crust on the precession and nutation of a liquid earth contained within a solid shell. These conclusions were stated in his paper on the rigidity of the earth,[6] and in §§ 847–8 of the first edition of Thomson and Tait's "Natural Philosophy." For example, he had decided that the yielding of the crust of an internally liquid earth, under the differential attractions of the sun and moon, would produce an effect on the precession so great as to be altogether incompatible with the excellent agreement

3 *Loc. cit.* above.

4 Proceedings of the London Mathematical Society, vol. vi., p. 190, 1875; Math. and Phys. Papers. vol. iv., p. 533.

5 British Association Report, 1876, Transactions of Sections, p. 1.

6 Philosophical Transactions of the Royal Society, vol. cliii., p. 573, 1863.

between theory (on the hypothesis of a solid earth) and observation, as regards precession and nutation.

Newcomb appears to have suggested that viscosity might possibly render precession and nutation the same as if the earth were rigid throughout. As a direct cause viscosity is inadmissible, but indirectly it is effective, for it at once occurred to Lord Kelvin that a very real cause of agreement between an internally liquid earth and a solid earth as regards precession at least, was probably to be found in the rigidity induced in the interior liquid by its rotation. Thus his attention was directed to the quasi-rigidity of a liquid induced by rotational (or vortex) motion, a subject which, as he told Section A of the British Association after his return from America, occupied his thoughts for weeks almost to the exclusion of all other scientific subjects.

He soon found that if the ellipticity is not too small the shell would not have more precession than the liquid, and that the compound rotating mass would have sensibly the same precessional motion as if it were a single rigid body. He came to the conclusion, however, that the lunar semi-annual and lunar fortnightly nutations would be greatly affected by interior liquidity of the earth.

At the Glasgow meeting of the British Association in 1876 Lord Kelvin was president of Section A, and began his presidential address by quoting the Anacreontic couplet :—

"Θέλω λέγειν Ἀτρείδας,
Θέλω δὲ Κάδμον ᾄδειν"

which begins the complaint of the poet that no matter what hero he wished to sing, his lyre refused to respond to any theme but that of love. Try as Lord Kelvin liked to speak of the scientific men, and scientific inventions that he saw in America, of American education, or the more recent advances of physical science, his thoughts ever came back to the subject of the internal rigidity of the earth and the difficult questions therewith connected. So to this topic he decided to devote the major part of his address. This he did with great effect, clearing away what was doubtful from his former arguments, emphasising and enforcing them as they remained, and reiterating with undiminished confidence his old conclusions.

To illustrate the precession of a rotating liquid he showed later in Section A what he called a liquid gyrostat, and also for comparison various solid gyrostats which had for several years been used for the dynamical illustrations of the natural philosophy class. I have these very gyrostats here on the table, and will use them for a repetition of some of the old historical experiments of the Glasgow class-room.

IV.—*Solid and Liquid Gyrostats. Gyrostatic Experiments.*

The construction of a solid gyrostat is shown in the diagrams before you, which were made, partly by myself, nearly forty years ago (Fig. 5). The instrument consists of a massive flywheel surrounded by a case of brass. The wheel is a disc of thick brass carrying a massive rim, so that the moment of inertia is made as great as possible. One diagram of this slide, as you see, shows a section of the wheel and case, the other a side view of the wheel.

The case is a cylindrical box surrounding the flywheel, with extensions enclosing the axle, for which they are provided with bearings at the ends. Round the case, as nearly as may be in the central plane of the flywheel, is a projecting rim, the edge of which is not quite circular, but rather polygonal with curved sides, and the points of meeting of the sides rounded off. The rim serves to support the gyrostat, as it stands on this glass plate, in some of its evolutions.

The bearings are cups in which the rounded points of hardened steel of the axle run. This is not a good arrangement if the gyrostat is to be subjected to shocks, or to be roughly handled in any way. Oiling also is required, after every second spin at least. In our new gyrostats we use ball bearings designed to resist considerable shocks and stresses without derangement. With these, in some experiments, we have gone up to speeds of about 25,000 r.p.m., and have found the flywheel to be still rotating rapidly after the lapse of forty-five minutes. Also the wheel may be run for several hours with only one oiling.

It will be convenient to show here some of the experiments usually performed in the ordinary class of natural philosophy in Lord Kelvin's time. The multiplicity of subjects put down to be treated in the dynamical part of the course precluded, as I have hinted, any detailed explanations of these experiments. They were carried out, in fact, with the avowed and excellent purpose of exciting curiosity in the minds of the students, and a desire to find out why gyrostats behave in a manner at first sight so anomalous. Interest was certainly aroused in a few, but I fear that the majority despaired of penetrating such mysteries, and sought external help for the mastering of the more hackneyed topics of the degree examinations.

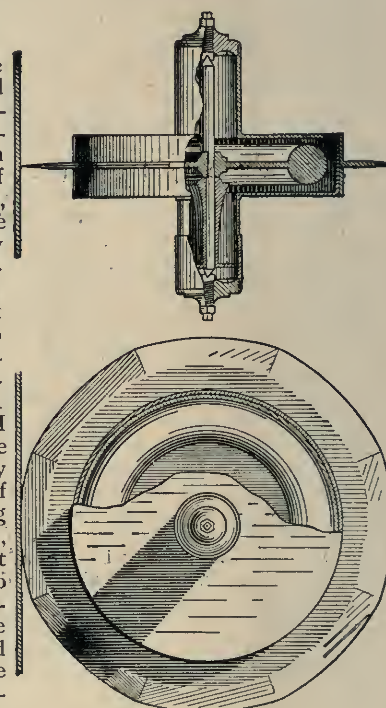

FIG. 5.

The process of spinning excited more interest than any other part of the experiment, for the ordinary elementary student cares more for a little bit of sensation than about the scientific result to be proved. A long cord was laid out on the floor, then the free end passed one and a half, or two and a half, times round the axle of the gyrostat, which was held by the operator, with its axis vertical, in a suitable socket on a table fixed to the floor. An attendant holding the free end ran away with it, slowly at first, then faster and faster, down a long passage and through a large adjoining room, while friction was applied to the cord as it entered the gyrostat case.

For the runner was substituted later a large wheel with grooved rim on which the cord was wound as it was drawn through the gyrostat. I estimate that speeds of about 100 turns per sec. or less may have been obtained in this way. Now, of course, one spins by an electric motor, as I shall presently describe.

I will make one or two of the experiments with the original gyrostats, but it will save time if I repeat the others with some of the new and improved gyrostats invented by Dr. J. G. Gray, whom I am fortunate in having to assist me on the present occasion.

[The usual experiments, illustrating precessional motion of a gyrostat with the axis horizontal, while under the influence of a couple due to the gyrostat overhanging, or to a weight hung on one end of the case surrounding the axle (Fig. 6) were performed.]

This behaviour of the gyrostat is often considered paradoxical, and must, I suppose, be regarded as difficult to explain in a popular manner. At any rate, the popular explanations are as a rule extremely unsatisfactory. Yet in this particular case of horizontality of the axis the matter is simple enough, I think. Let me illustrate by means of this pedestal top (Fig. 7). The curved arrowhead shows the direction of rotation, the projecting arrow the axis of spin, the arrow pointing down can be turned so as to show the direction of the axis of any applied couple. First observe that when I try to retard the precessional motion the axis descends, if I try to accelerate the precession the axis rises. This experiment shows that the horizontality of the axis depends

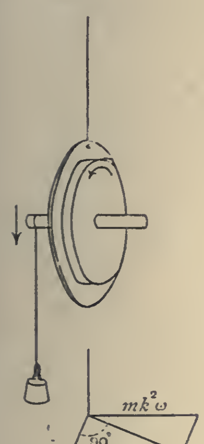

FIG. 6.

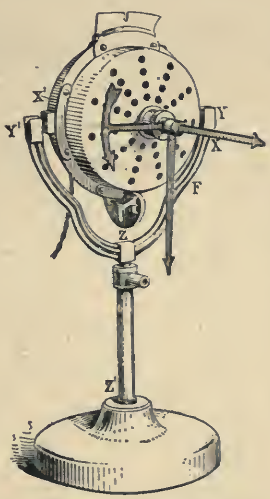

FIG. 7.—Motor-Gyrostat in "Fork and Pedestal" Mounting.

on the freedom of the gyrostat to precess at a certain definite rate. This rate, as we shall see presently, depends on the couple applied by the weight of the gyrostat acting downward in one vertical line, and the pull of the string acting upward in another line nearly vertical, and on the angular momentum of the flywheel.

Look at the thing in this way. The axis of rotation round which the flywheel has angular momentum is turning as you see towards the horizontal axis A of the couple, with angular speed, Ω say. Now, and this is the point not recognised as a rule, this motion itself creates a rate of production of angular momentum about the axis A of the couple. For when an axis with which is associated a directed quantity, L say, is turning towards a fixed direction at right angles to it with angular speed Ω, there is a time-rate of production of the quantity associated with the latter direction measured by the product $L\Omega$.

Now the flywheel is revolving with angular speed ω, so that if its moment of inertia is mk^2, it has angular momentum $mk^2\omega$ about the axis R; but with angular speed Ω the axis R is turning towards the instantaneous position of the axis A, a fixed direction to which R is at the moment perpendicular, and, in consequence of this turning, a rate of production of angular momentum $mk^2\omega.\Omega$ exists about A.

Now for the steady motion of the gyrostat, that is, steady turning in azimuth without rising or falling of the axis, it is only necessary that this rate should be equal to the moment of the couple about A, G let us say. Thus we get $mk^2\omega\,\Omega = G$, which gives $\Omega = G/mk^2\omega$.

If I hurry the precession by giving a little impulse, and then leave the gyrostat to itself, the hurried motion, if it continued afterwards in the horizontal plane, would result in a more rapid generation of angular momentum about A than there is moment of couple to account for, and the gyrostat would begin to turn about A, in the direction to cause the angular momentum to be produced at the proper rate, that is the axis would begin to rise. In the same way an impulse towards delaying the precession would cause the axis to begin to descend. In each case the result would be a succession of alternate rises and descents; but the subject of vibrations about steady motion will be found treated in the Appendix, § (5) [see *Journal*, I.E.E.].

Here it is important to remark that there are two possible precessional motions for the same spin and the same inclination of the axis of spin to the vertical, which are given in the theory as the roots of a certain quadratic equation (see Appendix). One is great, the other small. The former to the first approximation does not depend on applied forces, the other does. Lord Kelvin called the former "adynamic," the other "precessional." But in strictness both involve the forces, and they appear as the roots of a certain equation. One of these is at once approximately realised when the wheel is spun fast, the gyrostat set on the plate at rest, and left to itself. The motion is one of small oscillation about the steady motion, which is characterised by slow precession, given very nearly, but not quite exactly, by the same formula as before. The other motion of the axis in the same cone is one of much greater precessional angular speed. The popular expositions which I have seen of gyrostatic steady motion as a rule ignore this second possible motion. It can be realised by proper means.

In strictness we must regard this second precessional motion as characteristic also of the gyrostat when its axis is horizontal, but in that case the precessional angular speed is infinite, and only the slow motion is realisable.

The rule, often stated, that hurrying a gyrostat in its precession causes tilting up of the axis, and delaying the precession causes tilting downward, is true only of the slower more usual precession. For the faster precession exactly the reverse rule holds good. This fact does not seem to be generally known, as the rule is generally stated absolutely.

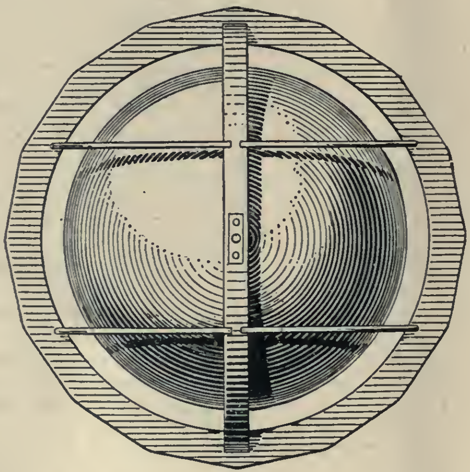
It is important to notice that if the centre of gravity of the gyrostat is above the point of support, supposed on the line of the axis, the two precessional motions are in the same direction; if, on the other hand, the centre of gravity be below the point of support, the precessional motions are in opposite directions. The faster motion changes sign in passing through an infinite value, when the axis is horizontal.

By the effect of hurrying or retarding the precession was sometimes explained in our lectures the rising and falling of a top spinning on a rounded peg in contact with a rough floor along which the top can move. At first the spin is fast and the slipping is such as to produce a hurrying friction couple which causes the erection of the top. After the spin has

fallen off the slipping is the other way and a couple which produces the reverse effect results, and the top falls.

[Experiments were here made with a gyrostat on gimbals, and with a gyrostat mounted on a trapeze hung by the crossed cords of a bifilar suspension. See "Gyrostats and Gyrostatic Action," NATURE, April 10, 1913, to illustrate the stabilising by spin of a gyrostat with two freedoms, both unstable without spin.]

As I have already stated, Lord Kelvin illustrated, by what he called a "liquid gyrostat," the fact that an oblate spheroidal shell filled with water behaves as regards precession as if its contents were solid. Here is the gyrostat with which the experiment was made (Fig. 8). It resembles the ordinary gyrostat, but the case is not completely enclosed, and the spheroidal globe containing water takes the place of the flywheel: these are the only points of difference. I spin the globe in the ordinary way, and you see that in all respects the liquid gyrostat imitates the behaviour of the solid one.



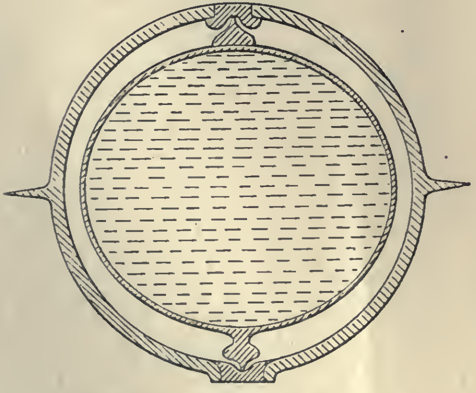


FIG. 8.—Liquid Gyrostat (Oblate).

This spheroid has an oblateness of about 5 per cent.; that is, the difference in length of the polar and equatorial diameters is about 5 per cent. of the length of either. Here, however, is another liquid gyrostat which has about 5 per cent. of prolateness (Fig. 9). I attempt to spin it, and you see that as soon as it is removed from the spinning apparatus its spin has entirely disappeared. In consequence of instability of the motion, the energy of rotation has been entirely transformed into heat, by turbulent motion of the water, into which the rotational motion breaks down. Permanent steady rotation of the liquid globe is impossible.

Oblateness, however, is not absolutely essential for steady rotational motion of a liquid round the axis of figure in a spheroidal case turning with the liquid. It was shown by Sir George Greenhill in 1880 (three years after the meeting of the British Association at Glasgow) that steady motion is possible in a prolate

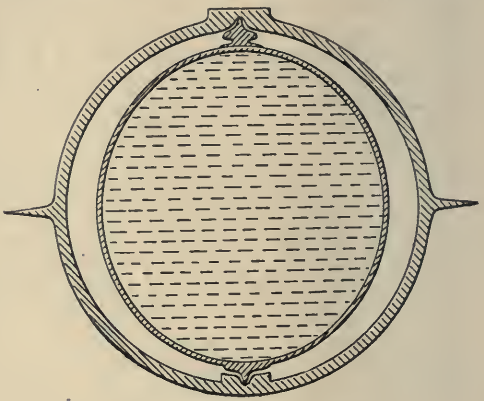

FIG. 9.—Liquid Gyrostat (Prolate).

spheroid, if it be sufficiently prolate. The axial diameter, in fact, must either be shorter than the equatorial diameter, or be more than three times as long.[7] As Sir George Greenhill points out, a modern elongated projectile if filled with a liquid would not rotate steadily about its axis of figure, and therefore would not have a definite trajectory as a rifle bullet has; it would turn broadside on to the direction of motion.

(To be continued.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BRISTOL.—The Society of Merchant Venturers, in whose Technical College the faculty of engineering is provided and maintained, has decided to offer ten scholarships, tenable in the faculty for three sessions, beginning with the session 1915–16, to the sons of officers in his Majesty's Service who have been killed in the war, and whose mothers or guardians are in needy circumstances.

CAMBRIDGE.—The adjudicators of the Smith's prizes and the Rayleigh prizes are of opinion that the following essays sent in by the candidates are of distinction:—H. Glauert, of Trinity College, on the elliptical form of a rotating fluid mass as disturbed by a satellite, and H. Jeffreys, of St. John's College, on (i) certain hypotheses as to the internal structure of the earth and moon, (ii) on a possible distribution of meteors, to whom the Smith's prizes have been awarded in alphabetical order. A Rayleigh prize has been awarded to J. Proudman, of Trinity College, for his papers on tidal motions.

MR. HERBERT A. L. Fisher, vice-chancellor of the University of Sheffield, has been elected a trustee of the British Museum, in succession to the Right Hon. Sir George O. Trevelyan, Bart., O.M., who has resigned on account of ill-health.

7 Proceedings of the Cambridge Philosophical Society, 1880 Encyclopædia Britannica," article, "Hydromechanics."

PROF. ARTHUR KEITH, conservator of the museum of the Royal College of Surgeons of England, will deliver, during the latter part of March, a course of five lectures upon the bearing of recent discoveries on our conception of the evolution and antiquity of man. The lectures will be given under the terms of the Macbride Foundation in Western Reserve University, Cleveland.

THE London County Council has arranged for a series of five public lectures to be given at the Horniman Museum, Forest Hill, on Wednesday evenings at 7.30 o'clock. The series commenced yesterday with a lecture on the Andamanese and other pigmies. The subjects of the remaining lectures will be: the Australian Aborigines; the Eskimo; the Papuans of New Guinea; and the Maori and other Polynesians. Each lecture is complete in itself, and there is no charge for admission.

A LECTURESHIP in ophthalmology has been established in Dublin by the bequest of Mr. R. J. Montgomery, who desired that it should be known as the Mary Louisa Prentice Montgomery lectureship, and that the appointment to it should rest each alternative five years with the Board of Trinity College, Dublin, and with the president, vice-president, and council of the Royal College of Surgeons in Ireland. Joint regulations for the lectureship have now been drawn up, and the first election will take place at the beginning of the next summer session.

THE distribution of prizes and certificates at the Sir John Cass Technical Institute and the opening of the new metallurgy laboratory for the mechanical testing of metals and alloys, presented to the institute by the Worshipful Company of Goldsmiths, by Sir Robert G. C. Mowbray, Bart., Prime Warden of the Worshipful Company of Goldsmiths, will be held on Wednesday, March 3, at 8 p.m. The chair will be taken by Sir Thomas H. Elliott, K.C.B., chairman of the governing body. There will be an exhibition of work by students of the department of arts and crafts and by members of the Arts and Crafts Society, as well as an exhibition of students' work and apparatus in the laboratories and workshops.

A NOTE in the *Daily Chronicle* of February 24 refers to the effect of the war upon the attendance of students in the twenty-two German universities. It appears that entered on their books are 52,504 students, against 59,600 this time last year. But of these 29,882 have been "permitted" to join the military forces of the Empire, including 300 women students in the army medical department. The actual attendance at lectures is given as 18,922 men and 3700 women. If the students of technical high schools with university status are added the grand total of 38,400 is reached, or about 75 per cent. of the entire number. The universities most depleted of students are those nearest the frontiers—Bonn and Heidelberg in the west, and Königsberg and Breslau in the east. It is stated in *Science* of February 12 that there are matriculated in the University of Berlin 7037 men and 898 women, as compared with 8200 men and 859 women last winter. These numbers show a marked contrast with those of our own universities; for at Oxford and Cambridge alone the number of undergraduates now in residence is about 2300, whereas at the like period last year it was 6700.

THE Council of the London (Royal Free Hospital) School of Medicine for Women is now arranging for a considerable extension of laboratory and teaching accommodation. This extension is necessitated both by the increasing number of women desirous of entering the medical profession and by the recognition of the fact that research work must be regarded as an integral part of education, and that no medical school can be considered as satisfactorily equipped without full facilities for the carrying out of scientific investigations. A site adjoining the present buildings of the school has been secured, and the extension will include additional accommodation for teaching and much improved facilities for research work. For this very necessary extension the sum of 25,000*l.* is necessary for building and equipment, and a further similar sum for endowment. By the kindness of the Duchess of Marlborough a meeting was held at Sunderland House on February 18 to promote the extension. The speakers were the Duchess of Marlborough (in the chair), Surgeon-General Sir Alfred Keogh, Dr. Mary Scharlieb, Dr. Florence Willey, Dr. Winifred Cullis, and Mr. Acland, M.P. The Duchess of Marlborough in her speech brought out the extreme urgency of the careful use of medical service during this present crisis and the great necessity for an increased service in the future, and particularly of medical women, who were needed as medical inspectors of school children and as workers in maternity and infant welfare centres, whilst there was also a very great need amongst women for practitioners of their own sex. Sir Alfred Keogh, Director-General of the Army Medical Service, paid an eloquent tribute to the work of the school, with which he had familiarised himself when, a few years ago, he had for the Board of Education to inspect practically every medical school in the country, saying that he yielded to none in his admiration of the school. He further made the gratifying announcement that as a result of the excellent work done by medical women in the war he had offered to two medical women who had organised a hospital unit in Paris, and later one at Boulogne, a hospital of 500 beds, or, if they could staff it, of 1000 beds here in England. The other speakers emphasised the necessity there would be for medical women after the war, when prophylactic measures would be of greater importance than before, and such work as ante-natal treatment and infant care would be of even greater significance when every child would be of added value.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 18.—Sir William Crookes, president, in the chair.—Prof. W. A. **Bone** and others: Gaseous combustion at high pressures. Mixtures of methane with less than its own volume of oxygen were exploded in steel bombs at initial pressures of between 8 and 32 atmospheres. The results were in harmony with the "hydroxylation" theory of hydrocarbon combustion put forward some years ago by Prof. Bone. Results of experiments upon an equimolecular mixture of ethane and oxygen have again confirmed the hydroxylation theory. Another section of the paper deals with an experimental determination of the relative affinities of methane, hydrogen and carbon monoxide for oxygen in flames. It is shown (1) that the affinity of methane is at least twenty times as great as that of hydrogen; (2) that when mixtures corresponding to $CH_4+O_2+xH_2$ are fired under high initial pressures, in which the partial pressures of methane and oxygen are kept constant and x only varied, the distribution of oxygen between the methane and hydrogen varies with x^2—which means that hydrogen is burnt *directly* to steam in flames as the result of the tri-molecular change $2H_2+O=2H_2O$, and not (as some have supposed) *indirectly* through hydrogen peroxide. The affinity of carbon monoxide

is shown to be comparable with that of hydrogen for oxygen in flames. The final section describes experiments in which the whole pressure curves, up to and far beyond the attainment of maximum pressure, were recorded when mixtures corresponding to (1) $2H_2+O_2+4N_2$, (2) $2CO+O_2+4N_2$, and (3) $CH_4+O_2+4N_2$ are exploded under initial pressure of about 50 atmospheres. The rates of attainment of maximum pressure in each case have no direct relation to the order of affinities of the various gases for oxygen.—Prof. W. M. **Hicks**: The orbits of a charged particle round an electric and magnetic nucleus. Two problems are discussed—the orbits of α-particles and the orbits of electrons round nuclei containing mass, a definite number, n, of positive electronic charges and a definite number, N, of co-axial magnetons—the motion being in their equatorial planes. It is found that combined systems (atoms) with α-particles may exist in which the α-particle revolves in permanent connection with the nucleus, provided the internal energy of the atom is greater than a certain critical value, and that states of "radio-active" instability occur in which, after a combination of long duration, the α-particle is shot off to infinity. The exact velocity of emission in any case depends on the values of the n, N, but it is of the order of magnitude of the velocity of emission of α-rays from radium. In the case of electronic orbits, in addition to the combined systems with internal energy less than from infinity, there can exist also permanent systems in which the internal energy is greater than that from infinity, although less than a certain critical amount, and in which again states of "radio-active" instability occur of the proper order of magnitude.—S. **Chapman**: The lunar diurnal magnetic variation and its change with lunar distance. Balfour, Stewart, and Schuster have developed a theory of the solar diurnal magnetic variations which attributes them to electric currents in the upper atmosphere, impelled by electromotive forces produced by the motion of the air across the earth's permanent magnetic field. The atmospheric conductivity is supposed to be wholly or partly due to solar influence and varies with the sun's hour angle. This theory apparently applies also to the lunar diurnal magnetic variations which possess a semi-diurnal component of constant phase, together with other components the epochs of which depend on the angular distance between the moon and sun; hence, when averaged over a lunation, all components save the former disappear. The suggested solar influence on the atmospheric conductivity is thus supported, and a semi-diurnal atmospheric oscillation—such as a lunar atmospheric tide—is suggested as the source of the magnetic variations. Before this theory was developed, Brown (Trevandrum Observations, 1863) had found that the amplitude of the 12-hour magnetic component at perigee was to that at apogee in the ratio of (lunar distance)$^{-3}$ at the two epochs—"as in the tidal theory," he briefly remarked; but Figee (Batavian Observations, 1903) disputed this conclusion. The present paper discusses the evidence, of this direct kind, for or against a tidal origin of these magnetic variations. Brown's and Figee's data are used, together with much newly computed material from other observatories. The total hypothesis is confirmed, although on account of the accidental errors affecting the minute quantities under discussion, the exact law of (distance)$^{-n}$, with $n=3$, is not beyond question, but if n is assumed necessarily integral, its value is certainly 3 and not 2 or 4.—Lt.-Col. J. W. **Gifford**: Some temperature refraction coefficients of optical glass. This is a supplement to a paper read in 1912 in which the refractive indices for 13 wave-lengths of 27 different glass meltings were given by the author. To this table are now added similar indices for six more Jena glass meltings, including those for the recent fluor crown. This is followed by a table of the temperature refraction coefficients for all the glass meltings dealt with, and attention is directed to the abnormal coefficients for fluor crown which is a minus quantity. An attempt is then made to determine, if only approximately, the influence of barometric changes on the refractive powers of optical glass which would seem to be, similarly, a minus quantity, amounting to something like six units in the sixth decimal place only.

Royal Meteorological Society, February 17.—Capt. H. G. Lyons, president, in the chair.—A. E. M. **Geddes**: Observations of the upper atmosphere at Aberdeen by means of pilot balloons. These observations were made at the Observatory, King's College, Aberdeen, during the years 1912 and 1913; and in every case two theodolites were used, thus securing an accurate determination of the flights to a level of 3000 metres. In clear weather the upward velocity of the balloon is shown to be fairly uniform, but to depend on more than the free lift. When clouds are present they influence considerably this velocity, the effect differing according to the nature of the cloud. The gradient wind velocities and directions have been calculated and compared with those actually found by observation.—V. G. **Anderson**: Influence of weather conditions upon the amounts of nitric acid and of nitrous acid in the rainfall at Melbourne, Australia. The author described the methods adopted and stated that the results of the daily determinations from November 1, 1912, to February 28, 1914, when correlated with the meteorological data for Melbourne and the isobaric charts for Australia, reveal the existence of a relation between weather conditions and the amounts of the nitrogen acids in the rainfall. The concentration of nitric acid reached a maximum in summer, a minimum in winter, and an intermediate position in autumn and spring. The concentration of nitrous acid reached a maximum in winter and a minimum in summer. Nine well-defined recurring types of rainstorms have been investigated, the amounts (pounds per 1000 acres) of oxidised nitrogen per day varying from 1·5 in the case of certain antarctic storms to 35·0 in the case of intense tropical storms.

Institution of Mining and Metallurgy, February 18.—Dr. F. H. Hatch, president, in the chair.—J. **Morrow Campbell**: Notes on some gold occurrences in Ashanti. Some 30 miles to the west of Kumasi are to be found igneous rocks intruding through the schist, some of which are granite, and non-auriferous. The non-granite dykes, on the other hand, are mostly auriferous, and the author has devoted special attention to three of these in his paper. All three are comparatively old, and show abundant internal evidence of the continuance of the crustal movements to which they owe their existence. These movements have produced fracturing, and have resulted in the formation of quartz veins traversing the igneous rock in all directions, and varying in width from more than a foot to mere partings. After describing in detail the composition and characteristics of these dykes, the author draws certain deductions. He points out that in Ashanti pyrites is abundant in quartz veins, and elsewhere, quite unassociated with gold, but that where arsenopyrite occurs gold so frequently accompanies it as to lead to the conclusion that their association cannot be fortuitous. He thinks it fair to conclude that the arsenopyrite caused the precipitation of the gold, and that the solution transporting the gold contained the latter in combination

with silica either as a silicate or as alkaline aurosilicate. The phenomena, he thinks, demand a single solution from which gold and silica may be precipitated simultaneously.—W. G. **Holford**: Some features in the mining problems of the eastern Witwatersrand area. This paper is a general review of the more intricate geological problems associated with mining in the particular area referred to, where conditions are somewhat different from those met with in the central Rand. For example, while it is found on the central Rand that the close proximity of the zones in which economic gold values are contained are in such close proximity as almost to constitute defined shoots, on the eastern rand the zones are less frequent and are of greater economic value in the synclinal portions of the areas. The author goes on to describe in detail the various features of mining practice in the district under consideration, dealing respectively with mining areas, shaft sinking, initial development, the mechanical equipment, and the labour problems encountered. Incidentally he makes a strong argument in favour of circular as against rectangular shafts.—W. B. **Middleton**: Prospecting tin land in Malaya. This is a practical paper concerning itself with the alluvial deposits which are the principal source of the tin production of the Malay Peninsula. The author gives full particulars of the various methods employed in treating, prospecting, and sampling the ground, including an elaborate description of the tools required, and as an appendix he furnishes a set of tables for calculations and conversions in connection with the work, which should prove of great utility.

CAMBRIDGE.

Philosophical Society, February 8.—Dr. Barnes, vice-president, in the chair.—Sir J. J. **Thomson**: Theory of the mobility of negative ions.—Dr. G. F. C. **Searle**: (1) The determination of the focal length of a thick mirror. (2) Experiment on the focal lines formed by refraction at a plane surface. (3) Calculation of the electrical resistance of a certain network of conductors.—C. T. R. **Wilson**: A method of measuring the thickness of thin plates. The method is a modification of that of Macé de Lépinay and Buisson in which μe, the product of refractive index and thickness, is obtained by measurements of the thin-plate fringes and $(\mu-1)e$ by observing the retardation produced by the plate when inserted in the path of a beam of light.—G. W. **White**: Investigation of the "wolf-note" in bowed stringed instruments. With all stringed instruments of the violin type a pitch can be found at which it is difficult and often impossible to obtain a pure steady tone. In the preliminary experiments to investigate this imperfect note photographs were obtained of the belly vibration of a 'cello by reflecting a beam of light from an optical lever to a moving photographic plate. A series of notes through the "wolf-note" played with a constant bow pressure was studied. At the "wolf-note" the vibration curve had an extremely big amplitude and showed that the unsteady nature of the tone was due to a "beating" of the instrument belly. The experiments proved conclusively that the "wolf-note" was caused by the impressed string pitch coinciding with the pitch of best resonance of the instrument.

MANCHESTER.

Literary and Philosophical Society, January 26.—Mr. F. Nicholson, president, in the chair. W. C. **Jenkins**: Manchester fogs of the last ten years. A comparison of the fogs in Manchester during 1904–1913 inclusive showed that the number of days affected by this phenomenon has increased during the latter years by at least 30 per cent. as compared with the earlier years of this period. By a rearrangement of the figures into seasonal effects the most striking feature is the increase of days classified as "gloomy" during the summer months, the number during the winter months of October to March remaining fairly constant. The number of days affected by "gloom" increased 100 per cent. during the period of the last four years as compared with the number so classified in the first four years of the period under consideration. These fog glooms are situated close to the earth's surface, as is shown by a comparison of sunshine records taken from the roof of the School of Technology and on the ground, the hours of sunshine measured on the ground being approximately 10 per cent. less than the amount recorded from the roof (100 feet higher).—Prof. W. W. Haldane **Gee**: Note on the monthly variation of sunshine. As a result of his examination of the Campbell-Stokes records, the author found that the average percentage of the possible sunshine usually reaches a maximum in May. A number of examples of this law were quoted. It was true for Glasgow, Douglas (I. of M.), Llandudno and Stonyhurst, 1880–1885; for St. Aubins (Jersey), 1880–1885; Blackpool, 1882–1885; Buxton, 1881–1885; Durham, 1880–1884; and for the Godlee Observatory (Manchester School of Technology), 1906–1910. The records for Stonyhurst for the thirty-three years from 1880–1912 also show the maximum in May. For 1910, Manchester (Oldham Road), Manchester (Whitworth Park), Buxton, Blackpool, and Llandudno also show the maximum in May. The author thought that the sunlight in May must have an important influence on vegetable growth.—W. C. **Jenkins**: Weather repetitions, with suggestions for long-distance forecast. Attention was directed to the repetitions in the weather for periods of twelve hours, twenty-four hours, seven days, and the lunar month, and also annual repetitions, making certain allowances—using particularly the records of rainfall. With the view of establishing these repetitions to a definite origin, the author showed the connection between numerous cyclonic paths and extra terrestrial phenomena, and assuming similar forces acting in temperate latitudes, he proceeded to demonstrate that cyclonic movements in the regions of this kingdom followed very much the variations expected under these conditions.

BOOKS RECEIVED.

Breeding of Farm Animals. By Prof. M. W. Harper. Pp. xvii+335. (New York: Orange Judd Co.; London: Kegan Paul and Co., Ltd.) 1.50 dollars.

Practical Physical Chemistry. By Prof. A. Findlay. Third edition. Pp. xvi+327. (London: Longmans and Co.) 4*s.* 6*d.* net.

A Summer on the Yenesei (1914). By M. D. Haviland. Pp. xi+328. (London: E. Arnold.) 10*s.* 6*d.* net.

Board of Education. Examinations in Science and Technology, 1914. Examination Papers and Reports of Examiners. Pp. 142. (London: H.M.S.O.; Wyman and Sons, Ltd.) 9*d.*

Alone in the Sleeping Sickness Country. By Dr. F. Oswald. Pp. xii+219. (London: Kegan Paul and Co., Ltd.) 8*s.* 6*d.* net.

Arabia Infelix, or, the Turks in Yamen. By G. W. Bury. Pp. x+213. (London: Macmillan and Co., Ltd.) 7*s.* 6*d.* net.

The Chemistry of Petroleum and its Substitutes. By Drs. C. K. Tinkler and F. Challenger. Pp. xvi+352. (London: Crosby Lockwood and Son.) 10*s.* 6*d.* net.

Journal Kept by David Douglas during his Travels in North America, 1823–1827, etc., with appendices containing a List of the Plants introduced by Douglas, and an account of his death in 1834. Pp. 364. (London: W. Wesley and Son.) 21*s.* net.

Summary Report of the Geological Survey, Department of Mines, for the Calendar Year 1913. Pp. 417. (Ottawa: J. de L. Tache.)

Icones of the Plants of Formosa, and Materials for a Flora of the Island. By B. Hayata. Vol. iv. Pp. vi+264+plates xxxv. (Taihoku: Government of Formosa.)

British Museum (Natural History). British Antarctic (*Terra Nova*) Expedition, 1910. Natural History Report. Zoology, vol. ii., No. 2, Oligochaeta. By H. A. Baylis. Pp. 13–18. Zoology, vol. ii., No. 3, Parasitic Worms, with a Note on a Free-living Nematode. By Dr. R. T. Leiper and Surgeon E. L. Atkinson. Pp. 19–60. (London: British Museum (Natural History); Longmans and Co.) 1*s.* and 1*s.* 6*d.* respectively.

The Chemistry of Colloids and some Technical Applications. By Dr. W. W. Taylor. Pp. viii+328. (London: E. Arnold.) 7*s.* 6*d.* net.

Forest Valuation. By Prof. H. H. Chapman. Pp. xvi+310. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd.) 8*s.* 6*d.* net.

X rays and Crystal Structure. By Prof. W. H. Bragg and W. L. Bragg. Pp. vii+228. (London: G. Bell and Sons, Ltd.) 7*s.* 6*d.* net.

DIARY OF SOCIETIES.

THURSDAY, FEBRUARY 25.

ROYAL SOCIETY, at 4.30.—The Effect of the Depth of Pulmonary Ventilation on the Oxygen in the Venous Blood of Man: Prof. L. Hill and J. F. Twort.—The Effect of Functional Activity upon the Metabolism, Blood Flow and Exudation in Organs: J. Barcroft and Toyojiro Kato.—The Osmotic Balance of Skeletal Muscle: Miss D. Jordan Lloyd and W. B. Hardy.—The Function of Chlorophyll: Dr. A. J. Ewart.—Contributions to the Study of the Bionomics and Reproductive Processes of the Foraminifera: E. Heron-Allen.—The Influence of the Hydrogen Concentration upon the Optimum Temperature of a Ferment: A. Compton.
ROYAL INSTITUTION, at 3.—Struggle of Nations: Dr. P. Chalmers Mitchell.
CHILD STUDY SOCIETY, at 6.—*Discussion:* The Care and Development of the Child—from Ante-Natal Period to Five Years of Age. Ante-Natal Period: Dr. G. Eric Pritchard; Infancy: Miss J. Halford; One to Five Years: Dr. D. Forsyth.
INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Electricity applied to Mining: C. P. Sparks.

FRIDAY, FEBRUARY 26.

ROYAL INSTITUTION, at 9.—Solar Eclipse of 1914: The Rev. A. L. Cortie.
PHYSICAL SOCIETY, at 5.—Magnetic "Character" Figures, Antarctic and International: Dr. C. Chree.—The Electrification of Surfaces as Affected by Heat: Dr. P. E. Shaw.—Electromagnetic Inertia and Atomic Weight: Prof. J. W. Nicholson.

SATURDAY, FEBRUARY 27,

ROYAL INSTITUTION, at 3.—Recent Researches on Atoms and Ions: Sir J. J. Thomson.
ESSEX FIELD CLUB (at the Essex Museum, Stratford), at 6.—Incisor-teeth of Rhinoceros: E. T. Newton.—Palæolithic Implements and Plant Seeds from the River Gravel at Hackney Wick in the Lea Valley: A. Wrigley.—The New Witches-Broom on the Crack Willow: Miller Christy.—East Anglian Gravels: W. H. Dalton.

MONDAY, MARCH 1.

SOCIETY OF CHEMICAL INDUSTRY, at 8.
ARISTOTELIAN SOCIETY, at 8.—The Æsthetic of Benedetto Croce: A. A. Cock.
VICTORIA INSTITUTE, at 4.30.—The Spectra of Stars and Nebulæ: Prof. A. Fowler.
ROYAL SOCIETY OF ARTS, at 8.—Motor Fuels: Prof. Vivian B. Lewes.
SOCIETY OF ENGINEERS, at 7.30.—Running Costs of Motor Vehicles: Lieut. R. W. A. Brewer.

TUESDAY, MARCH 2.

ROYAL INSTITUTION, at 3.—Photographic Appreciation of Colour in Monochrome: Prof. W. J. Pope.
ROYAL SOCIETY OF ARTS, at 4.30.—The Northern Territory of Australia: Past, Present, and Future: D. Lindsay.
RÖNTGEN SOCIETY, at 8.15.—The Chemistry of the Radio Elements: A. Fleck.

WEDNESDAY, MARCH 3.

SOCIETY OF PUBLIC ANALYSTS, at 8.—The Soluble Chlorides and Total Chlorine in some English Cokes; S. W. Bridge.—The Routine Detection and Estimation of Boric Acid in Butter: H. Hawley.—The Structure of Pepper—Some New Features: T. E. Wallis.—The Occurrence of Chlorine in Coal: A. de Waele.
INSTITUTION OF ELECTRICAL ENGINEERS (Students' Section), at 7.45.—The Application of Electrical Engineering to Warfare—Communications, Wireless, etc.: P. R. Coursey; The Laying and Firing of Mines: S. G. Killingback; Searchlights and Projectors: E. L. M. Emtage.
ROYAL SOCIETY OF ARTS, at 4.30.—Shakespeare's Profession: W. Poel.
ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, MARCH 4.

ROYAL SOCIETY, at 4.30.—*Probable Papers:* A Bolometric Method of Determining the Efficiency of Radiating Bodies: Prof. W. A. Bone, Prof. H. L. Callendar, and H. J. Yates.—The Simplification of the Arithmetical Processes of Involution and Evolution: E. Chappell.—The Elastic Properties of Steel at Moderately High Temperatures: F. E. Rowett.
ROYAL INSTITUTION, at 3.—Poetry and War: Sir Herbert Warren.
ROYAL GEOGRAPHICAL SOCIETY, at 5.—Suess's Classification of the Eurasian Mountains: Prof. J. W. Gregory.

FRIDAY, MARCH 5.

ROYAL INSTITUTION, at 9.—Mimicry and Butterflies: Prof. E. B. Poulton.
GEOLOGISTS' ASSOCIATION, at 8.—Geology of the Glasgow District: Prof. J. W. Gregory.

SATURDAY, MARCH 6.

ROYAL INSTITUTION, at 3.—Recent Researches on Atoms and Ions: Sir J. J. Thomson.
